and to the solution are added 2 grms. of dihydrogen potassium arseniate dissolved in water, and 20 c.m.³ of a mixture of sulphuric acid and water in equal volumes, and enough water to increase the total volume to 100 c.m.³, or a little more. A platinum spiral is introduced, a trap made of a straight two-bulb drying-tube cut off short is hung with the larger end downward in the neck of the flask, and the liquid is boiled until the level reaches the mark put upon the flask to indicate a volume of 35 c.m.³. Great care should be taken not to press the concentration beyond this point on account of the double danger of losing arsenious chloride and setting up reduction of the arseniate by the bromide. On the other hand, though 35 c.m.³ is the ideal volume to be attained, failure to concentrate below 40 c.m.³ introduces no appreciable error. The liquid remaining is cooled and nearly neutralised by sodium hydrate (ammonia is not equally good), neutralisation is completed by hydrogen potassium carbonate, an excess of 20 c.m.³ of the saturated solution of the latter is added, and the arsenious oxide in solution is titrated by standard iodine in the presence of starch.

With ordinary care the method is rapid, reliable and easily executed, and the error is small. In analyses requiring extreme accuracy, all but accidental errors may be eliminated from the results by applying the corrections indicated.

THE SEPARATION AND DETECTION OF Al, Cr, Fe, Co, Ni, Zn, Mn, Ba, Sr, Ca, Mg, K, Na, NH₄.*

By J. S. C. WELLS, Ph.D.

In the following course of analysis I have adopted the plan used in "Fresenius," and as far as the methods are the same have used the text as given in that work.

The division into groups is the same as given by Fresenius, viz.:—1st Group—K, Na, NH₄. 2nd Group—Ba, Ca, Sr, Mg. 3rd Group—Al, Cr. 4th Group—Co, Ni, Fe, Zn, Mn.

1. Take a small portion of the solution to be tested, in a test-tube, observe whether it is coloured or not (Note 1), boil to expel H₂S if present (Note 2), if FeO be present (Note 13) add a few drops of HNO₃ and boil to oxidise it to Fe₂O₃ (Note 3), add a little NH₄Cl, then NH₄OH cautiously, just to alkaline reaction, heat gently, and observe if a precipitate is produced; then add some (NH₄)₂S, no matter whether NH₄OH has produced a precipitate or not.

2. *a. Neither NH₄OH nor (NH₄)₂S produces a precipitate*, pass on to 17, for Fe, Co, Ni, Zn, Mn, Cr, Al are not present (Note 4), nor are phosphates, borates (Note 5), silicates, oxalates (Note 6), or fluorides (Note 5) of the alkaline-earth metals, nor silicic acid originally in combination with other metals.

3. *b. (NH₄)₂S produces a precipitate, NH₄OH having failed to do so*: absence of phosphates, borates (Note 5), silicates, oxalates (Note 6), and fluorides (Note 5) of the alkali-earths, of silicic acid originally in combination with other metals, and also if no organic matter is present of Fe, Al, Cr. Pass on to 5, 6, 7, 12; omit 8, 9, 10, 11.

4. *c. NH₄OH produces a precipitate before the addition of (NH₄)₂S*. The course of proceeding now depends upon whether (a) the original solution is simply aqueous and has a neutral reaction, or (b) the original solution is alkaline or acid (Note 7). In the former case pass on to 5, since phosphates, borates, &c., cannot be present. In the latter case regard must be had to the possible presence of all the bodies enumerated in 2, and also in the presence of organic matter, of the combinations of alkali-earth metals with citric and tartaric acids.

The solution must be tested for these acids, and, if found, the analysis must be carried on according to

* *School of Mines Quarterly*, Vol. xi., No. 3.

scheme for phosphates, &c. See *School of Mines Quarterly*, Vol. x., No. 3).

5. DETECTION OF BASES OF GROUPS 3 AND 4 IF PHOSPHATES, &c., ARE NOT PRESENT.

Mix the solution mentioned at beginning of 1, a portion of which you have submitted to a preliminary examination, with some NH_4Cl (Note 8), then with NH_4OH just to alkaline reaction (Note 9), and then $(\text{NH}_4)_2\text{S}$, until the fluid, after being shaken, smells distinctly of that reagent, shake the mixture until the precipitate begins to separate in flakes, heat gently for some time, and filter.

Keep the filtrate (Note 10), which may contain bases of groups 1 and 2 for examination according to 17. Wash the precipitate with water to which a very little $(\text{NH}_4)_2\text{S}$ (Note 11) has been added, then proceed with it as follows:—Remove the washed precipitate (Note 12) from the filter with a spatula, or by rinsing it with the aid of a wash-bottle through a hole made in the bottom of the filter into a test-tube, and pour over it cold dilute HCl (one part HCl , sp. gr. 1.12, with about five parts of water) in moderate excess.

6. a. The precipitate is not completely dissolved, a black residue being left.

This indicates Co and Ni. This indication is not certain, especially in the presence of much FeS , particles of which may become enveloped in the separated S, and thus be protected from the action of the HCl . Filter and wash.

Examine the filtrate according to 8.

7. Test a small portion of the precipitate in the borax bead, first in the oxidising, then in the reducing flame. If the bead in the oxidising flame is violet whilst hot, and of a pale reddish brown when cold, and turns gray and turbid in the reducing flame, nickel is present; but if the colour of the bead is blue in both flames, and whether hot or cold, cobalt is present. As in the latter case, the presence of nickel cannot be distinctly recognised, examine the remainder of the residue as follows:—Dissolve in HCl and a little HNO_3 , evaporate nearly to dryness, dilute with water, and filter, if necessary, from any particles of S, neutralise carefully with KOH , and then add a solution of KC_y , until the precipitate that first forms is completely dissolved; add a little more KC_y , and then bromine water in considerable quantity, taking care, however, to keep the solution alkaline with KOH . The nickel is precipitated as the black hydroxide $(\text{Ni}_2(\text{OH})_6)$. As the cobalt has already been found by the borax bead, no further test for it is necessary.

8. b. The precipitate dissolves completely (except, perhaps, a little S); absence of Co and Ni, at least in notable quantity.

Boil until H_2S is completely expelled; if iron is present (Note 13), add a little HNO_3 and boil, so as to oxidise it to the ferric state (Note 14), filter if any particles of S remain suspended in the solution, and evaporate nearly to dryness. The course of proceeding now depends on whether the colour of the solution indicates chromium or not.

9. Solution is coloured bluish green or violet, and indicates Cr.

Add Na_2CO_3 to strong alkaline reaction, then bromine-water in excess, heat gently for some time, keeping solution alkaline with Na_2CO_3 , and finally heat to boiling, filter, and wash residue.

a. Filtrate contains Na_2CrO_4 , and possibly $\text{Na}_2\text{Mn}_2\text{O}_8$; the latter is indicated by pink or purple colour of the solution (Note 15). Acidify solution with $\text{HC}_2\text{H}_3\text{O}_2$, and test for Cr with $\text{Pb}(\text{C}_2\text{H}_3\text{O}_2)_2$ —a yellow precipitate proves chromium.

b. Residue contains iron and aluminium as hydroxides, zinc and manganese as carbonates.

Dissolve in least possible quantity of HCl , and treat according to 10.

10. Colour of solution does not indicate Cr.

Neutralise carefully with Na_2CO_3 , dilute and add ex-

cess of $\text{NaC}_2\text{H}_3\text{O}_2$, boil and filter hot, wash precipitate with boiling water. Examine filtrate according to 12.

11. Precipitate consists of iron and alumina as basic acetates. Fuse on platinum with NaKCO_3 and a little KClO_3 (Note 16), dissolve in small quantity of boiling water, and filter.

a. Residue consists of Fe_2O_3 and possibly some alumina that has resisted the fusion.

Dissolve in a little HCl and test for iron with NH_4CyS .

b. Filtrate contains $\text{Na}_2\text{Al}_2\text{O}_4$; acidify with HCl , and then add $(\text{NH}_4)_2\text{CO}_3$ in slight excess—a white flocculent precipitate proves alumina.

12. Filtrate contains zinc and manganese, concentrate solution, add a little $\text{HC}_2\text{H}_3\text{O}_2$, heat to boiling and pass H_2S into it. Zinc is precipitated as ZnS (white) (Note 17), filter.

Filtrate contains manganese, add KOH in excess, a white precipitate turning brown on exposure to the air—Mn. Confirm result by testing in Na_2CO_3 bead in oxidising flame—green bead proves Mn.

Method using BaCO_3 in place of $\text{NaC}_2\text{H}_3\text{O}_2$.

13. Proceed in the same way as given in 1, 2, 3, 4, 5, 6, 7, 8. In 8, after evaporating nearly to dryness, to expel excess of acid, dilute with water, and neutralise carefully with Na_2CO_3 .

To the neutral solution add BaCO_3 in excess, digest in the cold for some time, filter, and wash. Examine filtrate according to 12 (Note 18).

14. Precipitate contains iron, aluminium, and chromium as hydroxides, together with excess of BaCO_3 . Dissolve precipitate in HCl , add NH_4OH just to alkaline reaction and filter (Note 19).

Reject filtrate. Dry the precipitate—

and fuse in platinum with $\text{Na}_2\text{CO}_3 + \text{KClO}_3$. Dissolve in fusion small quantity of boiling water, and filter.

15. Filtrate contains chromium and aluminium as Na_2CrO_4 and $\text{Na}_2\text{Al}_2\text{O}_4$, divide solution in two parts, a and b.

a. Make acid with $\text{HC}_2\text{H}_3\text{O}_2$, then add a solution of $\text{Pb}(\text{C}_2\text{H}_3\text{O}_2)_2$ —yellow precipitate—Cr.

b. Acidify with HCl , and then add a slight excess of $(\text{NH}_4)_2\text{CO}_3$ or NH_4OH and boil—white flocculent precipitate—alumina.

16. Residue left after treating fusion with water consists of Fe_2O_3 and possibly some Al_2O_3 . Test for iron by dissolving in HCl and adding NH_4CyS —red colour—iron (Note 13).

(To be continued).

NOTICES OF BOOKS.

Explosives Act, 1875. Fourteenth Annual Report of Her Majesty's Inspectors of Explosives, being their Annual Report for the Year 1889. London: Her Majesty's Stationery Office.

THIS report is in many respects gratifying. We find that the vigilance of the inspectors does not decrease, and that municipal authorities are slowly becoming alive to the importance of the Act and of its execution. The number of fatal accidents in the year was 7, one of them, it is worth noting, in an unlicensed factory. Although the average for the past eleven years was only 7.2, yet the present figure is a substantial improvement, since the number of factories, the average output in each, and the number of hands employed have increased. Hence, unless greater care and intelligence were brought to bear we might naturally expect an increased death-rate. This is the more evident as some new explosives are being introduced where the conditions of safety or danger are not so thoroughly known.

We learn from the Report that a new Chemical Committee has been appointed by the War Office "for the purpose of investigating and dealing with chemical questions relating to explosives for use in the Imperial service." The functions of this Committee are consequently entirely distinct from those of the Inspectors, who have to deal only with the question of public safety in the manufacture, transport, and storage of explosives for civil purposes.

During the year ten new factories have come into existence, the total number under licence being 122, exclusive of "toy firework factories."

One of the accidents, resulting in the death of one man and injuries to three others, took place on October 3 during the unlawful and surreptitious manufacture of Quick-Firing Ammunition by Sir W. Armstrong, Mitchell, and Co. (Limited) on board a barge on the Tyne. This case will yet form the subject of criminal proceedings; hence no comments on the occurrence are made further than a notice of the gross negligence of the Commissioners of the River Tyne, who had allowed this unlicensed manufacture to continue for several months.

Two women—the only persons present at the time—were killed in the packing room of the detonator factory at Polmont, belonging to Nobel's Explosives Company. This accident took place on November 15, and is supposed to be due to the fall of a heavy plate containing detonators upon a similar plate. The two above-mentioned cases and one which took place at Pain's factory, June 4, were the only one which led to official inquiries.

A fatal accident happened in June at the Factory of the Roburite Explosives Company (Limited), near Wigan. The cause of death here was not explosion or fire, but the inhalation of poisonous gases. The victim was cleaning an air-flue into which the fumes of three roburite mixing-pans were discharged. Respirators and other precautions were certainly in use. It is stated that these flues have since been cleaned, when needful, without sending men into them.

One accident—not fatal—led to the detection of an unlicensed and therefore wholly illegal "firework factory," which, as the Report adds, "is not creditable to the local authority."

Some of the accidents in the storage of explosives show gross ignorance on the part of the persons concerned. Thus, at Grangemouth a workman lighted a match "in a store-room in which oil (doubtless mineral oil) and gunpowder were unlawfully kept together." The explosion killed a bystander and injured several persons.

It is remarked that the Act gives the inspectors no power concerning the use of explosives. In an accident due to an improper apparatus used for thawing dynamite the jury recommended the passing of an Act to regulate the use of "high" explosives.

Especial care should be taken by all parties concerned not to leave detonators about. They are sometimes picked up by children who are quite ignorant of their nature.

Cases of malicious attempts against life by means of explosives have not been wanting. On Lord Clanricarde's estate near Woodford, Galway, an infernal machine was arranged in an empty house which it was expected would be entered by the police. The arrangements adopted by the conspirators were essentially identical with those of the infernal machines discovered at Liverpool and Glasgow in 1883, the bombs found on Daly in April, 1884, and the attempted explosion at the Times office in 1883. It is noteworthy that at Woodford the peasantry, instead of crowding round, as at other evictions, had kept entirely aloof.

On September 7 an attempt was made to blow up a house in the outskirts of Tipperary, in which Mr. A. H. Smith-Barry collects his rents.

At Rochdale, on November 29, an attempt was made to blow up the School Board offices. The intended *modus operandi* was to bring sulphuric acid in contact

with potassium chlorate and sugar. The failure, says the Report, "may be referred to a cause which it is not desirable to specify."

As illustrations of modern "progress" in Japan we find that dynamite and dynamitards have penetrated thither also. A set of 500 candles, sent as a present to a famous temple, were all filled with dynamite. An attempt was also made to assassinate the Foreign Minister by throwing a bomb into his carriage as he was returning from a Cabinet meeting. Neither investigation nor punishment followed, as the intending assassin escaped by the *hari-kari*.

Several explosion outrages have occurred in Spain, Italy, Switzerland, Russia, and the United States. At Seattle, in the latter country, one Schaeffer killed four persons with dynamite and dangerously wounded a fifth. He was at once lynched.

There is a very full account of the Antwerp explosion and fire on September 6. The deaths are said to have been 95, whilst 130 persons were wounded more or less severely. The owner of the establishment, one Corvilain, seems by no means to have adhered to the conditions imposed in his license. He incurred only five-and-a-half years imprisonment and a penalty of £430 as damages!

Certain New Double Iodides of Bismuth and Potassium.—Ch. Astré.—The author has isolated the following compounds:— $(\text{BiI}_3)_2 \cdot 4\text{KI}$; $(\text{BiI}_3)_2 \cdot 3\text{KI} + 2\text{H}_2\text{O}$; $(\text{BiI}_3)_2 \cdot 6\text{KI}$. The number of the known double bismuth and potassium iodides is thus raised to five. They may be considered as resulting from the union of 2 mols. of bismuth iodide with a number of mols. of potassium iodide varying from 1 to 6.—*Comptes Rendus*, vol. cx., No. 22.

On Benzoyl-tannin.—Dr. Carl Böttinger.—This compound was obtained by mixing a cold dilute watery solution of 3 grms. tannin with 5 c.c. strong soda-lye and shaking it up with benzoyl chloride. The substance, after purification, is a crystalline granular powder, insoluble in water, alcohol, and ammonia, but soluble in hot aniline, dimethylaniline, and phenylhydrazine.—*Justus Liebig's Annalen der Chemie*, ccliv., Part 3.

Volumetric Determination of Tannin in Wines.—MM. Roos, Cusson, and Giraud.—The authors prepare a 10 per cent solution of tartaric acid, which is saturated with ammonia until slightly acid. A solution of neutral lead acetate is then added until the precipitate no longer re-dissolves in the liquid, and the whole is filtered. This liquor completely precipitates tannin from its solutions. It is standardised by means of a solution of pure tannin in ether, proceeding as follows:—25 c.c. of the solution of tannin at 5 grms. per litre, i.e., 0.10 of tannin, are placed in a glass with the addition of 4–5 drops of ammonia. The solution of lead aceto-tartrate is dropped in from a burette, at first by 2 c.c. at a time. At the addition of each fresh quantity a drop is taken up with a glass rod and placed upon a double piece of Swedish filter-paper. The precipitate adhering to the rod remains upon the paper at the point touched, whilst the liquid spreads by capillarity and reaches the lower leaf. Near this spot he deposits a drop of a solution of sodium sulphide, taking care that the reagent mixes with the liquid of the first drop by capillarity without touching the precipitate. This precipitate (lead tannate) forms on the paper a spot with distinct outlines, which is darkened by the sodium sulphide, but which does not become surrounded with a brown halo until the moment when all the tannin is precipitated. The first rapid trial gives an approximation of about 2 c.c.; a second trial, made by adding 5 drops at a time, enables the standard to be fixed definitely. Samples of wine are then treated in the same manner.—*Journal de Pharmacie et de Chimie*, xxi., No. 2.

CORRESPONDENCE.

SULPHATES IN NITRIC ACID.

To the Editor of the Chemical News.

SIR,—I do not think there is much ground for Mr. Huxley's perplexity concerning the presence of sulphates in "pure" nitric acid. If he were accustomed to examine all the specimens supplied him he would be in no way surprised at any impurity. Out of five London firms with whom I have dealt for chemicals, one, and one only, has proved even moderately satisfactory in the quality of their "pure nitric acid," and them I caught tripping recently, and it was only after rejecting several samples that I got one reasonably clean, though even then it compared unfavourably with some re-distilled from the ordinary commercial acid in this laboratory without any special precaution whatever.

I believe the cause for this singular state of things lies in the fact that the manufacturer tries to produce a colourless acid at the sacrifice of purity. As to the contamination arising from sodium sulphate in the Winchester quarts, as alleged by the makers supplying Mr. Huxley, if it were not absurd on *a priori* grounds, would be disproved by Mr. Huxley's own experiment.

If every chemist instead of accepting whatever a manufacturer chooses to send him with the magic label "re-distilled puriss." were to regularly examine it, and resolutely and repeatedly send it back, some improvement might result. Moreover, manufacturers should be made aware that their liability for any loss in practice or reputation due to the use of impure chemicals labelled pure, by a chemist confiding enough to rely on that warranty, may be unpleasantly brought home to them through the medium of a court of law.—I am, &c.,

BERTRAM BLOUNT.

Laboratory,
Broadway, Westminster, S.W.

MEDICAL OFFICERS OF HEALTH AND PUBLIC ANALYSTS.

To the Editor of the Chemical News.

SIR,—The above subject, on which Mr. Rowland Williams writes (*CHEM. NEWS*, vol. lxi., p. 277), is one of much interest to Public Analysts and still more so to the public, whose interests are greatly in their hands.

I quite agree with the writer, that where the Medical Officer of Health is not well versed in practical chemistry he ought not to hold the double office, but this is no argument when he is competent and where the duties of Medical Officer of Health are insufficient to occupy his whole time. It could not, for example, be contended that the interests of the City of London suffered by the late Dr. Letheby performing the double function, or by Dr. Stevenson or Dr. Tidy holding similar dual offices.

The actual President of the Society of Public Analysts, who is a Medical Officer of Health as well as a Public Analyst, is a decisive proof that the two duties may be associated without disadvantage.

In Birmingham we have a well-known instance of the same kind, and another in the county of Warwick. In none of these instances has any question of incompetency or inefficiency arisen, although in the City of Birmingham alone about 1000 analyses of food, drink, and drugs are made every year.

But it is undeniable that where the Medical Officer of Health is required to perform analytical duties for which he is unqualified there is a great absurdity, and gross injustice is perpetrated, resulting either in little or nothing being done, or a breakdown painfully damaging to the "incompetent analyst." Besides this the work of the Public Analyst is brought into contempt, the place of the

trained analyst is usurped, and great hardship is inflicted on both traders and the public.

It is pointed out that membership of the Institute of Chemistry should be an "indispensable qualification" for a Public Analyst, and I quite agree with the suggestion, as it would be the best guarantee of efficiency.

Mr. Williams refers to a large town in Lancashire where the Town Council a short time since met for the purpose of selecting a Medical Officer of Health and Public Analyst. I do not know what town is indicated, but a friend of mine was quite recently a candidate for the double office also in a large town in the same county, and, although in addition to his holding as high medical and public health qualifications as it is possible to obtain, he is a sound practical chemist of unusually large experience in the special work required, a medallist in both practical and theoretical chemistry, and holds the "indispensable qualification" of membership of the Institute of Chemistry, his special fitness was ignored, and he was unsuccessful in his application for the appointment.

Can it be that the Town Council Committees are incompetent to make a proper choice of a candidate, or is it that "kissing goes by favour?"—I am, &c.,

JOHN WHITE, A.I.C.

Dudley Road, Birmingham,
June 10, 1890.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cx., No. 22, June 2, 1890.

Reduction of Alkaline Sulphates by Hydrogen and Carbon.—M. Berthelot.—It is well known that at about a red heat hydrogen reduces the alkaline sulphates, forming a sulphide and water. This is not an accurate account of the reaction, as there is always formed, along with the water, hydrogen sulphide, and the final product contains caustic alkali. There is produced at the outset a hydrosulphate of the sulphide and an alkaline hydrate; the fixed product formed containing hydrogen, which is commonly supposed to be absent. This primitive reaction is exothermic, 2.6 cal. being set free in case of potassium and 9.3 in the case of sodium. Carbon does not seem to exert a direct action in the industrial reduction of the sulphates which seems to be effected by carbon monoxide. In the present conditions of the manufacture of alkali the reduction of sodium sulphate is a consequence of the two fundamental reactions of hydrogen and carbon monoxide, especially when it is effected in revolver furnaces under the influence of the flame from gases rich in hydrogen, hydrocarbons, and carbon monoxide.

The Determination of the Molecular Weight at the Critical Point.—Philippe A. Guye.—The author lays down the proposition that the critical coefficient of a mixture formed of several different mols. is very approximately equal to the mean critical coefficient of the molecular mixture.

Chloro-Salts of Iridium and its Atomic Weight.—A. Joly.—The physical properties of iridium, as prepared in a state of purity by Mr. Matthey upon the principles ascertained by Sainte-Claire Deville and Debray differ from those formerly supposed. Its sp. gr. is found to be not 21.5, but 22.38. The atomic weight, calculated from the mean result of the author's experiments, is Ir = 192.75, which differs little from the mean found by M. Seubert, Ir = 192.744.

Manganese Oxides obtained in the Moist Way. Manganous Acid.—A. Gorgeu.—Not suitable for useful abstraction.

Soda Alum.—E. Augé.—The author shows that, contrary to the statements of the text-books, soda alum is very slightly efflorescent, and may be kept for months unchanged. Its solubility in water at 16° is only 51 per cent instead of 110 per cent. A solution of soda alum may be boiled indefinitely without ever losing the power of crystallising. In order to obtain soda alum it is merely necessary to concentrate the solution of the aluminium and sodium sulphates to 39°—43° Baumé, to place the paste obtained on plates of lead in an inclined position to collect the mother liquors which make up a fourth of the weight of the amorphous matter, and which carry off nearly all the impurities; crystallisation at the temperature of about 15°; drainage of the crystals.

The Bouquet of Fermented Beverages.—G. Jacquemin.—By adding the special ferments obtained from the wines of Ay, Beaune, Chablis, and Barsac, M. Jacquemin has obtained fermented liquors having the special bouquet of the wines in question from malt and from pure solutions. He has also, by a similar process, produced cider from barley.

MEETINGS FOR THE WEEK.

WEDNESDAY, 25th.—Society of Arts, 4. (Anniversary).

THURSDAY, 26th.—Royal Society Club, 6.30. (Anniversary).

PRACTICAL CHEMISTRY and QUALITATIVE ANALYSIS.

Specially adapted for Colleges and Schools.

By FRANK CLOWES, D.Sc.,
Professor of Chemistry in University College, Nottingham.

London: J. & A. CHURCHILL, 11, New Burlington Street.

THE MASON COLLEGE, BIRMINGHAM.
‘TANGYE’ TECHNICAL SCHOLARSHIP IN CHEMISTRY.

AN EXAMINATION IN THEORETICAL AND PRACTICAL CHEMISTRY of the above SCHOLARSHIP, which is of the value of £30, tenable for one year, will be held in the College, on THURSDAY and FRIDAY, July 3rd and 4th, 1890.

The holder of the Scholarship will be required to devote the whole of his time to the study of Chemistry in the Chemical Laboratory of the College.

Further particulars may be obtained on application.

R. S. HEATH, Principal.
GEO. H. MORLEY, Secretary.

Just published, Sixth Edition, revised and enlarged, 530 pp. 8vo., 10s. 6d.

THE PATENTEE'S MANUAL.

By JAMES JOHNSON,
Middle Temple, Barrister-at-Law, and
J. HENRY JOHNSON,
Assoc. Inst. C.E., Solicitor and Patent Agent.

This work explains clearly and concisely the Law and Practice of Letters Patent for Inventions, with references to all reported cases. The Appendix contains the Patent Statutes, Patent Office Rules, Forms, and Fees, the Rules of the Law Officers and of the Privy Council, the International Convention, and particulars of the Patent Laws of all Foreign States and British Possessions. The copious Index forms a clear analysis of the whole.

London:
LONGMANS, GREEN, and CO., Paternoster Row.
STEVENS and SONS, LIMITED, 119 and 120, Chancery Lane.

Silicates of Soda and Potash in the state of Soluble Glass, or in CONCENTRATED SOLUTION of first quality, suited for the Manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Soap Works, Widnes, Lancashire.

London Agents, COSTE and Co., 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

THE BANKHALL OIL AND CHEMICAL WORKS LIMITED (FORMERLY THACKER AND CO.), LIVERPOOL.

FOR SALE BY PRIVATE TREATY as a going concern the above old-established and well-known Oil and Chemical Works, including the whole of the Machinery and Plant and the Goodwill of the business. The Works stand on about 15,530 square yards of land, which is held on lease for seventy-five years from March, 1884, at a ground rent of £700 per annum. In addition there is a good private road on the East side of the Works which is occupied jointly with the Lancashire and Yorkshire Railway Co. The situation of the Works is everything that could be desired. They are bounded on the south and east by the Lancashire and Yorkshire Railway, on the west by the Leeds and Liverpool Canal, and on the north by Bankhall Street. There are sidings into the Works from the Lancashire and Yorkshire Railway, and there is also direct access to the Canal. The Works are also in close proximity to the Docks and to the London and North-Western, Midland, and Manchester, Sheffield, and Lincolnshire Railway Stations, and are only about 1½ miles from the Liverpool Exchange. An important feature in connection with these Works is that they are not liable to be restrained or prosecuted for emitting noxious odours, &c. The Buildings comprise extensive Oil and Cake Mills, with Elevator, Oil and Tallow Refineries, Oil Stores, Tar and Naphtha Distilleries, Soapery, large Warehouses, with very extensive Fireproof Vaults and Steam Hoist, Cooperage, Stables, and the usual Offices. The Machinery and Plant are comparatively new, in excellent condition, and capable of doing a very extensive manufacturing business. The business connection is a most valuable one. With a view to a speedy realisation a very moderate price will be accepted.

For orders to inspect the Works and to treat apply to the Liquidator, T. THEODORE ROGERS, 30, North John Street, Liverpool, or to Wm. F. MORECROFT and CO., Solicitors, 5, Castle Street, Liverpool.

COUNTY BOROUGH OF SALFORD.
(GAS DEPARTMENT).

TAR.

The Gas Committee invite Tenders for the purchase and removal of the surplus Tar to be produced at their Bloom Street, Regent Road, and Liverpool Street Works in twelve months from July 13th next.

The approximate quantity will be 4,500 tons. Forms of tender and conditions of contract may be obtained on application to the Gas Engineer, Gas Offices, Bloom Street, Salford.

Sealed tenders, endorsed ‘Tender for Tar,’ addressed to the Chairman of the Gas Committee, must be delivered to me on or before Thursday, the 10th prox., at 5 o'clock in the evening.

By order,

SAMUEL BROWN, Town Clerk.

Town Hall, Salford,
June 12, 1890.

NOW READY.

HARRIS'S TECHNOLOGICAL DICTIONARY OF INSURANCE CHEMISTRY.

Crown 8vo., full red cloth, gilt, 400 closely printed pages
Plain Copies 21/-, Interleaved Copies 25/- each
Post Free.

This work contains upwards of 1800 articles on Spontaneous Combustion (so-called), Chemical Affinity, Expansion of Gases, Inflammability of Vapours; Dust, &c., Explosions; Steam, Acids, Oils, Fibres, &c., &c.

The Fire-hazards arising from the above causes, and from the present heedless method of packing, warehousing, and general handling of raw and manufactured goods, also from the imperfect stowage of Coal, Cotton, and Mixed Cargoes, are clearly shown.

Specially written, without formulae, for Insurance Managers, Underwriter, Board of Trade and Dock Officials, Shippers, Merchants, &c. To be obtained from the Author and Publisher—

WILLIAM A. HARRIS, F.R.S.S.A., F.S.S., &c. SECRETARY,
Phoenix Fire Office, EXCHANGE, LIVERPOOL.

THE CHEMICAL NEWS.

VOL. LXI. No. 1596.

ON THE ANALYSIS OF CERTAIN SAMPLES OF TINNED MEAT.

By C. J. H. WARDEN, M.D., Chemical Examiner to Government;
and Assistant Surgeon C. L. BOSE, M.B.,
Assistant Chemical Examiner to Government.

(Concluded from p. 292).

In order to test the accuracy of alkali determinations made in this indirect manner, the following control experiments were performed:—A solution of pure potassium nitrate and sodium chloride was prepared containing 1.1366 grms. KNO_3 and 0.5326 grm. NaCl in 100 c.c. of distilled water. Of this solution we took 10 c.c. for analysis, and duplicate determinations were made by each of us with the following results:—

Standard solution containing, per cent,			
KNO_3 .	K_2O .	NaCl .	Na_2O .
1.1366	0.529	0.5326	0.273
1.1366	0.529	0.5326	0.273
1.1366	0.529	0.5326	0.273
1.1366	0.529	0.5326	0.273

Found by analysis, per cent,			
KNO_3 .	K_2O .	NaCl .	Na_2O .
1.237	0.577	0.4783	0.2557
—	—	0.4478	0.2373
1.260	0.590	0.430	0.228
1.250	0.586	0.427	0.225

The mean of these experiments shows the error of the process to be as follows:—

	Theory.	Found.	Error.
KNO_3	1.1366	1.2490	+0.1124 per cent.
K_2O	0.529	0.5843	+0.0553 "
NaCl	0.5326	0.4457	-0.0869 "
Na_2O	0.2730	0.2365	-0.0365 "

In the ordinary indirect estimation of the alkali metals, whether as chlorides or sulphates, or by Rose's method, in which the sodium-platinum chloride is decomposed and the sodium chloride extracted by water, gravimetric estimations are generally made, which is hardly necessary to indicate that when only very small amounts of salts have to be estimated, that greater accuracy is likely to result from volumetric than gravimetric methods of estimation. The method we have described appears to yield fairly accurate results, and is specially applicable to cases in which small amounts of sodium and potassium have to be estimated.

For the estimation of chlorine and phosphoric acid about 20 grms. of the fresh pulped meat were carefully weighed in a platinum dish and mixed with about 2 grms. of pure sodium carbonate,* dissolved in sufficient water to cover the pulp. The resulting magma was evaporated to dryness, carbonised below redness, and the residue first extracted with water and then with nitric acid, the solution being passed through a filter. The residue on the filter was dried and added to any particles remaining in the dish. The carbonaceous residue was then ignited until the whole of the carbon was consumed, the ash was again treated with dilute nitric acid, the solution being passed through the same filter; the filtrate and washings being collected in a 250 c.c. flask. The resulting solution was turbid from precipitation of phosphate of lime, the amount of nitric acid and ash being sufficient to neutralise the carbonate of soda. The alkaline solution was consequently rendered faintly acid by acetic acid, and diluted up to 250 c.c. A portion of this solution was

used for the estimation of chlorine. The greater part was concentrated and the phosphoric acid precipitated with molybdenum, but partially weighed as the phosphate of magnesium.

In the dried pulps, nitrogen was determined by Kjeldahl's method, and the results calculated back into the moist meat. The albumenoids were calculated from the nitrogen by using the factor 6.25.

The boiling water extractive was determined by boiling one grm. of the dry pulp with distilled water in a 100 c.c. flask, and, when cold, diluting up to 100 c.c. The liquid was then passed through a dry filter, and a portion of the very faintly opalescent filtrate evaporated to dryness in a platinum capsule for dissolved solids. The greater part of the filtrate was measured into an Erlenmeyer's flask, which was placed in boiling water until the water was evaporated off, and the extractive left as a varnish at the bottom of the flask. Sulphuric acid was then added to the dry residue in the flask for estimation of the nitrogen by Kjeldahl's method.

Fat was determined by very carefully weighing 0.5 to 0.6 of a grm. of the dry pulp into a small accurately stoppered weighing bottle, and adding a measured volume of light petroleum ether from a burette. The mixture was allowed to digest with agitation for about two days, then allowed to clear by subsidence, and a portion of the

perfectly clean supernatant liquid withdrawn by a small burette, and a carefully measured volume discharged into a tared beaker. After evaporating off the ether, the residual fat was heated to 100° C. and weighed. No correction was applied for increase in volume of the petroleum spirit due to dissolved fat. This method is one suggested by Dragendorff,* for the estimation of oil, in his scheme for the systematic analysis of vegetable substances by the aid of various solvents. As a control experiment, one of us estimated the fat in a sample in the manner described, while the other determined it by thoroughly exhausting a portion with petroleum ether with the following results:—

a. By Dragendorff's method, fat = 15.016 per cent.

b. By thorough exhaustion, fat = 15.030 "

Working in the manner indicated the general results of the determination of the samples are shown in next page.

In order to compare the composition of tinned with fresh meat, the following analyses by König† of fresh meat are appended.

Nature of samples.	Water.	Albumenoids.	Fat.	Ash
Very fat ox flesh, mean of 7 analyses	55.42	17.19	26.38	1.08
Moderately fat ox flesh, mean of 21 analyses:				
Minimum	68.50	16.23	1.17	0.71
Maximum	78.00	25.35	9.50	1.95
Mean	73.25	20.78	5.33	1.33

Mean	54.69	28.97	12.63	3.71	10.33	27.27	88.63

Calculating the albumenoids on the anhydrous and fat-free meat gives 90.34 as the percentage, figures which are also higher than the albumenoid content of the tinned meats. According to Playfair's experiments, it would appear that in roasting meat the loss is chiefly water, the proportion of carbon, hydrogen, nitrogen, and oxygen remaining the same.*

Summarising we may state that our results generally confirm those of other analysts, as indicating the lower nutritive value of tinned when compared with fresh meat. Our inferences are based on purely chemical data, but on physiological grounds there can also be no doubt that sodden tinned meat would be less easily assimilated than ordinarily cooked flesh, and that consequently its dietetic value would be even less than is indicated by its chemical composition.

THE SEPARATION AND DETECTION OF Al, Cr, Fe, Co, Ni, Zn, Mn, Ba, Sr, Ca, Mg, K, Na, NH₄†

By J. S. C. WELLS, Ph.D.
(Concluded from p. 299).

Metals of First and Second Groups.

17. To a small portion of the solution in which ammonia and ammonium sulphide have failed to produce a precipitate, or of the fluid filtered from such precipitate, add NH₄Cl (if not already present), NH₄OH, and (NH₄)₂CO₃, and heat gently for a few minutes (Note 20).

18. No precipitate forms.

Absence of Ba, Sr, and Ca, at least in notable quantity (Note 21). Traces, however, may be present; to detect them, proceed as follows:—Add to a portion of the solution some (NH₄)₂SO₄; if the fluid becomes turbid it contains traces of barium.

To another portion add some (NH₄)₂C₂O₄, and allow to stand a few minutes; if a precipitate forms, traces of calcium are present.

Treat the remainder of the solution, a portion of which you have just tested, according to 24.

19. A precipitate is formed.

Presence of Ba, Sr, and Ca. Treat the whole filtrate with NH₄OH and (NH₄)₂CO₃; heat gently for some time and filter; take two portions of the filtrate and test one with (NH₄)₂SO₄ for traces of barium, the other with (NH₄)₂C₂O₄ for traces of calcium, which may possibly be present; if found, mix the two solutions and filter, and test the filtrate for magnesium according to 24. The remainder of the filtrate, to which neither (NH₄)₂SO₄ nor (NH₄)₂C₂O₄ has been added, is tested for potassium and sodium according to 25 or 28, the method used depending on whether magnesium is present or not.

20. Precipitate produced by (NH₄)₂CO₃ (contains BaCO₃, SrCO₃, CaCO₃).

Dissolve in least possible quantity of HCl, H₂O₂. Take a small portion of this solution and add to it some CaSO₄.

The course of proceeding now depends on whether the CaSO₄ gives an immediate precipitate or not.

21. CaSO₄ causes an immediate precipitate—proves Ba. To the remainder of the acetic acid solution add a slight excess (Note 22) of K₂Cr₂O₇, and filter. Precipitate contains BaCrO₄ (yellow). To the filtrate add NH₄OH to alkaline reaction, and then (NH₄)₂CO₃; heat gently and filter. Reject filtrate. Dissolve the precipitate, consisting of SrCO₃ and CaCO₃, in acetic acid, divide solution into two parts, a and b.

22. a. Add an excess of CaSO₄, heat gently and shake well. A white precipitate proves Sr. (In dilute solutions the precipitate forms very slowly).

b. If strontium has been found in "a" (Note 23), add an excess of (NH₄)₂SO₄ to solution "b," boil, keeping solution alkaline with NH₄OH, and filter. Reject precipitate (Note 24).

To the filtrate add (NH₄)₂C₂O₄—a white precipitate shows presence of Ca.

If Sr is not present, the addition of the (NH₄)₂SO₄ is omitted, and the calcium tested for directly with NH₄OH and (NH₄)₂C₂O₄.

23. CaSO₄ does not give an immediate precipitate.

In this case add a little more of the acetic acid solution to it, and test for strontium according to 22, a. Then take balance of solution and treat it for calcium as directed in 22, b.

24. FILTRATE FROM (NH₄)₂CO₃ PRECIPITATE, OR SOLUTION IN WHICH THAT REAGENT HAS FAILED TO GIVE ONE.

Contains magnesium and the alkalis. Take the portion of the filtrate that has been freed from traces of Ba and Ca, by means of (NH₄)₂SO₄ and (NH₄)₂C₂O₄ (see 19), and add to it NH₄OH and Na₂HPO₄—a white crystalline precipitate proves the presence of Mg.

The method of testing for Na and K now depends on whether magnesium is present or not.

25. Magnesium is present.

As Mg interferes with the test for the alkalis, it must be removed before testing for them.

Evaporate the balance of the filtrate from the (NH₄)₂CO₃ precipitate (19) to dryness, and ignite until all ammonium salts are expelled. Dissolve the residue in a little water, add baryta-water as long as a precipitate forms, boil, filter; add to filtrate NH₄OH and (NH₄)₂CO₃, heat gently, filter and evaporate filtrate to dryness (add a little NH₄Cl during the evaporation, so that any alkaline hydroxide or carbonate will be converted into chloride) (Note 25); ignite gently until all ammonium salts are volatilised, then dissolve in a very little water, and test for Na and K, according to 26 and 27.

26. Test the concentrated solution in the flame on platinum wire. A strong yellow flame proves sodium. Confirm by adding to a portion of the solution some K₂H₂Sb₂O₇ (freshly prepared)—a white sandy precipitate indicates sodium. (In dilute solutions the precipitate forms very slowly; its formation is aided by rubbing watch-glass on which test is made with a glass rod).

27. To the remainder of the solution add a few drops of PtCl₄—a yellow crystalline precipitate proves K. If no precipitate forms on addition of PtCl₄, evaporate the solution nearly to dryness and add alcohol; this will show

* Parkes's "Hygiene."

† School of Mines Quarterly, Vol. xi., No. 3.

the presence even of traces of K, by leaving undissolved a yellow powder consisting of K_2PtCl_6 .

28. Magnesium is not present.

In this case it is only necessary to evaporate the solution to dryness, ignite carefully to drive off all ammonium salts, then dissolve residue, if any, in a very little water, filter if necessary, and test for Na and K according to 26 and 27.

29. Ammonia still remains to be tested for. Treat a portion of the original solution with KOH or $Ca(OH)_2$. Test the liberated gas, if any, with moistened red litmus paper; if it turns blue, ammonia is present (colour disappears on drying the test-paper).

Notes.

Note 1.—If the fluid is colourless, it contains no chromium. If coloured, the tint will to some extent act as a guide to the nature of the substance present; thus a green tint or violet tint turning green upon boiling, points to Cr; a light green to Ni; a reddish colour to Co; the turning yellow of the fluid upon boiling with HNO_3 to Fe.

It must be remembered, however, that these tints, except the last, are perceptible only if the metals are present in considerable quantity, and also that complementary colours, such as the green of Ni and the red of Co, will destroy each other, and that such a solution may be colourless.

Note 2.—The H_2S comes from the previous precipitation of the 5th Group metals, by that reagent. If not removed, it would cause a precipitation of sulphides on the addition of NH_4OH , and thus hide the reaction given by the latter.

Note 3.—The FeO should be oxidised to Fe_2O_3 , so that it will be precipitated on the addition of NH_4OH .

Note 4.—This only holds good for Al and Cr in the absence of non-volatile organic substances, especially acids such as citric and tartaric. Citric acid may also prevent the precipitation of Mn.

If organic matter is present, it should be removed by evaporating the whole of the solution used for the 3rd and 4th Groups to dryness and gently igniting.

It is a good plan to moisten the dry residue before igniting with a little HNO_3 (conc.). The ignited residue is then dissolved by boiling with a small quantity of strong HCl and filtering from any insoluble residue. The solution is now ready to be tested in the usual way.

Note 5.—The presence of much NH_4Cl has a great tendency to prevent the precipitation of borates and fluorides of the alkali-earth metals.

Note 6.—Magnesium oxalate is thrown down from HCl solution by NH_4OH only after some time, and never completely: dilute solutions are not precipitated by NH_4OH .

Note 7.—Phosphates, borates, &c., of the alkali-earth metals cannot exist in a neutral solution.

Note 8.— NH_4Cl is added to prevent the precipitation of magnesium and manganese; it also promotes the precipitation of the metals of the 4th Group as sulphides.

Note 9.—A large excess of NH_4OH should be avoided, as it increases the solubility of NiS in $(NH_4)_2S$, and dissolves some $Al_2(OH)_6$.

Note 10.—If the filtrate is dark brown, it indicates the presence of nickel, since NiS, under certain conditions, is slightly soluble in ammonium sulphide, especially if the latter contains any polysulphides (indicated by colour of the solution). Boil until $(NH_4)_2S$ is all decomposed and the free ammonia driven off, then add a few drops of dilute HCl, and filter from the precipitate of NiS and S. Make filtrate alkaline with NH_4OH , and proceed according to 17.

Note 11.—The addition of a little $(NH_4)_2S$ to the wash water prevents the oxidation of the sulphides to sulphates, a reaction likely to occur when they are exposed to the air.

Note 12.—Observe colour of precipitate—if pure white it indicates absence of iron, cobalt, and nickel.

Note 13.—Iron is tested for in the original solution with $K_3Fe(CN)_6$, and NH_4CyS in order to determine which oxide is present, since after treatment with H_2S or $(NH_4)_2S$ it is always in the form of a ferrous salt, owing to the reducing action of these reagents. When making the test with NH_4CyS , if the colour does not appear on the addition of this reagent, add an excess of HCl to the test; this will counteract the influence of phosphates, borates, &c., which interfere when present.

Note 14.—Iron must always be in the ferric form for precipitation by $NaC_2H_3O_2$ or $BaCO_3$.

If the iron is not completely oxidised, there is likely to form a red modification of ferric oxide that runs through the filter paper and is very insoluble.

Note 15.—If the colour of the solution indicates manganese, heat it with a few drops of alcohol, and filter from the precipitated oxide of manganese.

Note 16.—The $KClO_3$ is added to the fusion mixture to oxidise any chromium that might possibly have been left unacted on by the bromine, and then precipitated with the basic acetates.

Note 17.—Be careful not to mistake a slight precipitate of sulphur, which is quite likely to form in the hot acid solution, for one of ZnS. In case of doubt, confirm by the blowpipe test with $Co(NO_3)_2$. A very delicate way of making this test is to dissolve the supposed ZnS in a few drops of HCl, then add a drop or two of $Co(NO_3)_2$; precipitate mixture with Na_2CO_3 , boil, filter and wash, and ignite precipitate on platinum foil. On triturating the residue the green colour will be distinctly seen.

Note 18.—Instead of the separation given in 12, the following method may be used:—

To the filtrate from the $BaCO_3$ precipitate add H_2SO_4 (dilute) in sufficient quantity to precipitate all of the barium in the solution, heat to boiling, and filter.

To the filtrate add KOH in excess; the manganese precipitates as $Mn(OH)_2$ (turning brown on exposure to the air), filter and pass H_2S into the filtrate—a white precipitate proves Zn. The precipitate is sometimes dark coloured, owing to impurities; in doubtful cases always test it by the blowpipe. (See Note 17).

Note 19.—The precipitate is dissolved in HCl, and then precipitated with NH_4OH , in order to get rid of the excess of $BaCO_3$. In cases where there is only a slight excess of $BaCO_3$, this operation may be omitted.

Note 20.— NH_4OH is added to prevent the possible formation of any bicarbonate, and also because the precipitate of the carbonates is more insoluble in ammonia water than in pure water. Heating causes the amorphous precipitate to contract and become crystalline, in which condition it is much more readily filtered; also decomposes any bicarbonate.

Note 21.—Owing to the slight solubility of $BaCO_3$ and $CaCO_3$ in NH_4Cl , traces of these metals are often held in solution by the NH_4Cl present in the solution.

Note 22.—A large excess of $K_2Cr_2O_7$ is to be avoided, especially in presence of much acetic acid, since $BaCrO_4$ is slightly soluble in chromic acid. The filtrate should only be coloured a pale yellow by the excess of $K_2Cr_2O_7$ contained in it.

Note 23.—It is not necessary to wait to see if Sr is found in "a" before testing for Ca. Proceed just in the same manner as if Sr was present, adding $(NH_4)_2SO_4$, boiling and filtering, and testing filtrate with the oxalate for calcium.

Note 24.— $(NH_4)_2SO_4$ precipitates calcium from strong solutions, so that the formation of a precipitate on the addition of this reagent does not prove the presence of Sr, unless the precipitate is repeatedly boiled with the $(NH_4)_2SO_4$ and NH_4OH , which will finally remove all of the $CaSO_4$, leaving only the $SiSO_4$.

Note 25.—In cases where the alkalies are present in the original solution as sulphates, the addition of $Ba(OH)_2$ to remove the magnesium converts them into hydroxides, and the latter, on the addition of $(NH_4)_2CO_3$ to precipitate the barium, are changed to carbonates.

THE SEPARATION AND DETERMINATION OF ZINC IN PRESENCE OF IRON AND MANGANESE.

By J. RIBAN.

THE methods hitherto proposed for the difficult determination of zinc in presence of iron generally require the previous separation of the iron in a form which renders it unfit for direct weighing, and besides the metal carries down with it valuable proportions of zinc. Hence it is necessary to re-dissolve and re-precipitate it before proceeding to the ultimate determination of the zinc. We are thus led to the successive washing of two gelatinous precipitates of iron, an operation always long and troublesome if this metal is in notable quantity. Further, in the analysis of a great number of ferruginous zinc ores it may be desirable to determine this latter metal first, or even exclusively; the iron, manganese, &c., having but a secondary importance or none at all. Some methods used for the initial determination of zinc do not allow of its determination in presence of lime, which occurs in the gangue of certain ores.

The author proposes a process which gets rid of all these difficulties and permits of the direct gravimetric determination of zinc. It is founded on the following facts established in a former memoir (*Comptes Rendus*, cvii., p. 341). (1) Zinc, in presence of alkaline or ammoniacal hyposulphates, gives with sulphuretted hydrogen a precipitate of sulphide, dense, granular, easy to wash, and insoluble in the cold by hyposulphuric acid set free; (2), iron is not thrown down by sulphuretted hydrogen in presence of the hyposulphates, and zinc, if present, carries down mere traces of iron.

For the direct determination of zinc in presence of iron (ferric or ferrous) and manganese the solution is first brought to such a degree of dilution that it contains at most 0.1 grm. zinc in 100 c.c.; it is then saturated with a solution of sodium carbonate until there appears a slight permanent precipitate, which is re-dissolved in a few drops of dilute hydrochloric acid. A current of sulphuretted hydrogen is then passed into the cold liquid, when the greater part of the zinc is precipitated with sulphur, derived from the reduction of the ferric salt; a large excess of a solution of sodium hyposulphate is then added, and the current of sulphuretted hydrogen is continued. The last remains of the zinc are precipitated, but the iron remains in solution. An excess of hyposulphate is not injurious. For these determinations it is convenient to prepare a solution of known strength and to pour in double the theoretical quantity as approximately calculated for the double decomposition with the zinc and iron. The use of an excess of hyposulphate supersedes the precautions.

If after the precipitation of the zinc it is proposed to determine the iron by means of ammonia, as ferric oxide always carries down some proportion of alkaline salts, it is preferable to use ammonium hyposulphate, which is now also an article of commerce. The initial saturation of the free acid in the solutions is effected, not with sodium carbonate, but with ammonia or ammonium carbonate, until the yellow colouration of the solution containing iron passes to orange, the colour of the neutral or basic salts of this metal.

The precipitate of zinc sulphide, which is dense and collects readily, is white, sometimes greyish from the presence of traces of iron, which may be easily or quickly determined, as it will be seen. The precipitate is let stand for five or six hours at least, and is washed by decantation and filtration in hot water to which a solution of sulphuretted hydrogen has been added, when it very often takes a slightly violet tint; the washing is completed on the filter. The precipitate is ignited with sulphur in a current of hydrogen (H. Rose's apparatus) and weighed; it consists of zinc sulphide containing very small quantities of iron sulphide, which render it slightly

greyish. These traces are determined by dissolving the contents of the crucible in hydrochloric acid, peroxidising with a few drops of nitric acid, and then supersaturating with ammonia after the addition of a large excess of ammonium chloride to prevent the precipitation of the zinc. The quantity of iron carried down by the zinc is so slight that ammonia produces no precipitate in the cold, and it must be raised to a boil to cause a few light flocks of ferric hydroxide to appear. They are collected on a small filter and washed with solution of ammonium chloride. The weight of this peroxide is re-calculated into iron sulphide, which is deducted from the weight of the zinc sulphide as previously found, thus giving the nett weight of the latter.

If we wish to determine the iron in the liquids freed from zinc, it is sufficient to concentrate them and peroxidise with nitric acid, which throws its action immediately upon the iron, the hyposulphates being scarcely attacked. From the solution the iron is thrown down with ammonia in the ordinary manner.

The same method admits of the exact separation of zinc from manganese; zinc sulphide carries down merely inponderable quantities of manganese.

This method has been applied successfully to the analysis of ferruginous calamines; if they are at the same time plumbiferous it is necessary, first, to eliminate the lead, which would otherwise be precipitated along with the zinc by the sulphuretted hydrogen.—*Comptes Rendus* (cx., p. 1196).

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING MAY 31ST, 1890.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford

and C. MEYMOTT TIDY, M.B., F.C.S., Barrister-at-Law,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, Metropolitan Water Act, 1871.

London, June 7th, 1890.

SIR,—We submit herewith the results of our analyses of the 182 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from May 1st to May 31st inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 182 samples examined, all were found to be clear, bright, and well filtered, excepting two, one of which was recorded as "slightly turbid," and one as "very slightly turbid."

The variations in mean composition of the water supplied to London, noticeable from month to month, continue to be, as is usually the case, confined within so limited a range as to afford very little occasion for remark or comparison. During the past month the maximum proportion of organic carbon present in any single sample of Thames-derived water examined was found to be 0.173

part in 100,000 parts of the water, corresponding to about only three-tenths of a grain of organic matter per gallon. The mean proportion of organic carbon present in the May supply was found to be 0.156 part in 100,000 parts of the water, as against a mean of 0.148 part in the April and of 0.154 part in the March supply.

We are, Sir,
Your obedient Servants,

WILLIAM CROOKES.
WILLIAM ODLING.
C. MEYMOTT TIDY.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, June 5th, 1890.

Dr. W. J. RUSSELL, F.R.S., President, in the Chair.

MESSRS. W. B. Shuttlewood and H. R. Kenwood were formally admitted Fellows of the Society.

Certificates were read for the first time in favour of Messrs. Charles Edwin Day, 1, Merchiston Bank Terrace, Edinburgh; Robert Frost, St. James's Chambers, Duke Street, S.W.; George German, Huntingdon House, Ashby de la Zouch; Colin Gordon, Millwall Club, West Ferry Road, Millwall, E.; Frank Haydon, Ettrick, Putney Common, S.W.; Arthur E. Palmer, Ashley Mount, Tettenhall, Wolverhampton; Thomas Parkes, Grammar School, Stamford; Edward Cox Seaton, 35, George Street, Hanover Square, W.; James Mitchell Wilson, Hall Gate, Doncaster.

The following papers were read:—

45. "*The Production of Pure Metallic Copper in a Crystalline Condition.*" By C. C. DUNCAN, King's College, London.

The method of precipitating copper oxide from a boiling solution of copper sulphate with potassium hydroxide and then reducing in electrolytic hydrogen having been found unsatisfactory, as the last traces of sulphate could not be washed away, experiments were made on the reduction of the sulphate by zinc.

To a solution containing several grms. of purified sulphate made acid with chlorhydric acid, metallic zinc (containing only a trace of lead) was added in small fragments. Dark spongy-looking copper at once separated, and this soon protected the zinc from the action of the acid; consequently the copper was very slowly deposited: it was found to be in the form of feathery dendritic crystals.

A portion of the crystalline copper, well washed with dilute chlorhydric acid and distilled water, was dissolved in strong nitric acid free from sulphuric, the solution was diluted, and barium nitrate added; no precipitate of any kind formed, even after standing forty-eight hours, showing the absence of sulphur.

To discover whether the metallic copper contained zinc, two of the finest crystals (about 8 m.m. long) were again well washed and dried in hydrogen. These crystals were then fixed in an ordinary spark-stand, and the spark from a 2-inch Appa's coil, with a Leyden jar of one quart capacity in the circuit, was passed between them. The light from the copper terminals was analysed by one of Browning's two-prism spectroscopes, and the spectrum given by the copper was compared with that of zinc. None of the lines of zinc coincided with those given by the copper; it was therefore assumed that zinc was absent.

The bright lines given by the copper crystals agreed with those described by Thalèn ("*Mémoire sur la détermination des longueurs d'onde des raies métalliques.*" *Act. Nova Upsal.*, iii., vi., 1868, 29).

The spark and lines were extremely bright and no faint lines were to be seen (except the usual air-lines), showing the absence of any metallic impurity.

Microscopic examination proved the dendritic crystals to be built up of octahedrons. As the production of these crystals was quite accidental, experiments were made with different strengths of copper sulphate solutions, with and without free acid, in order to reproduce them.

In the literature relating to the reduction of metallic copper from its salts by means of metallic zinc, there is no mention whether the copper so reduced is in the crystalline state, except in a paper by Dr. Gladstone and Mr. Tribe (*Proc. Roy. Soc.*, xx., 1872, 219), who mention the deposition of metallic copper in a crystalline condition, but they make no remark on the purity or size of the crystals so formed.

In another paper, "On the Crystallisation of Silver, Gold, and other Metals" (*Proc. Roy. Institute*, vi., 1872, 428), Dr. Gladstone again refers to crystalline copper in the following terms:—

"Copper salts give round nodules which have no crystalline appearance when deposited from moderately weak solutions, but a very strong solution of the chloride—about 40 per cent—yields with zinc first a black thick

	CuSO ₄ .	Water.	Acid.	Results.
I.	10 grms.	400 c.c.	0	Copper was at once reduced in spongy state and then in minute dendritic crystals just visible to the unaided eye. The spongy copper proved to be composed of octahedrons under the microscope. The crystals did not increase in size on standing.
II.	20 grms.	400 c.c.	0	} Same as I.
III.	50 "	400 "	0	
IV.	10 "	400 "	10 c.c.	
				The dendritic crystals produced were larger than any of those in I., II., and III.
V.	20 "	400 "	10 "	} Same as IV.
VI.	10 "	400 "	100 "	
				Crystals of copper which were slightly larger than those produced in V.
VII.	20 "	400 "	200 "	} Dendritic crystals of copper were produced, several of which were 10 m.m. in length. Sulphur was detected in these crystals, and in most other crystals which had been reduced in a solution which was very strongly acid. No zinc was detected by the spectroscope.
VIII.	40 "	400 "	200 "	The crystals produced were only very slightly larger than those in VII., but more numerous.

growth, then arborescent fringes of red metal terminating in crystals of very appreciable size."

In all the experiments made by the author with acid and neutral copper solutions, dendritic crystals of copper were found which could be seen with the unaided eye; they were small in the case of neutral, and large in the case of acid solutions.

The accompanying tables give the quantity of copper sulphate, water, and chlorhydric acid (relative density 1.152) used in the different experiments, and the results.

As sulphur had been detected in several of the crystals deposited from the copper sulphate solutions, a few experiments were made with copper chloride free from sulphate.

	CuCl ₂ .	Water.	Acid.	Results.
I.	10 grms.	400 c.c.	0	Small dendritic crystals of copper were quickly produced. On standing, the crystals increased slightly in size.
II.	20 "	400 "	0	Numerous small dendritic crystals with several about 7 m.m. long. No impurity detected.
III.	10 "	400 "	20 c.c.	Two or three crystals about 11 m.m. long with the usual mass of smaller crystals. No impurities were detected.
IV.	40 "	400 "	20 "	Four or five crystals 12 m.m. long with the usual mass of smaller crystals. No impurity detected.
V.	140 "	500 "	40 "	This solution gave the finest crop of dendritic crystals yet produced. One crystal measured 15 m.m., and its lateral branches were composed of clumps of crystals. The crystals were erect, and had a beautiful metallic appearance. Several of the crystals were from 5 to 8 m.m. in length, two or three 12 to 13 m.m., and only a little spongy copper was to be seen. No impurity could be detected.

The pure crystalline copper is insoluble in pure nitric acid (free from nitrous acid). See Veley (*Proc. Roy. Soc.*, 1890).

Crystalline copper is said to have been obtained by using iron and aluminium as reducing agents. Thus Gore, in his text-book of "Electro-Metallurgy," pp. 203-204, refers to the use of iron in recovering copper from large deposits of the Tharsis and Rio Tinto mines in Spain. The copper is dissolved by means of chlorhydric acid, and the liquid is run into large vats filled with scrap

iron. In a short time all the copper is reduced in the form of feathery crystals upon the iron. The process is described by P. Argall and G. A. Kinahan in the *Sci. Proc. Roy. Dublin Soc.*, N.S., iii., 1883, 302-328, and on p. 309 the production of crystalline copper is mentioned. No reference is made to the purity or size of the crystals.

The reduction of copper from its sulphate by the aid of aluminium is mentioned in "Watts' Dictionary of Chemistry," 2nd Sup., 1875, p. 383, in a passage which is extracted from Cossa (*Nuovo Cimento* [2], iii., 75). The crystals of copper are described as follows:—"Aluminium foil immersed in a solution of sulphate or nitrate of copper is not acted upon at once, but after two days the foil becomes covered with crystals consisting partly of dendrites, but for the most part of well-defined octahedrons." It was found that if the solution of the copper sulphate is neutral, only octahedrons are produced; but that if an acid is present, dendrites are produced. Sulphur was the only impurity detected.

"Copper is immediately reduced by aluminium from a solution of cupric chloride, and likewise, though more slowly, from the acetate." It is not mentioned whether the copper is deposited in the crystalline or amorphous state, but the author has found, on experimenting with these substances, that dendritic crystals of copper are produced in both cases. No impurity could be detected.

Magnesium was found to reduce copper from a solution of copper sulphate in very small quantities, the copper being formed in small patches composed of dendrites and octahedrons. Magnesium added to a solution of copper chloride caused an evolution of gas, throwing down a green precipitate, and at the same time reducing the copper in the spongy state. The well-washed copper contained magnesium.

In a note by M. A. Commaille "On the Action of Magnesium on Neutral Metallic Salts" in the *CHEMICAL NEWS*, xiv, 188, it is mentioned "that copper sulphate gives with magnesium the metal (copper), the hydrated peroxide and a green subsalt. With the chloride no metal (copper) is precipitated, but a deposit of Brunswick green."

In experiments made by the author with the chloride, copper was reduced in appreciable quantity, but in an entirely amorphous state.

45. "The Action of Ethylic Oxalate on Camphor." By J. BISHOP TINGLE, Ph.D.

The author finds that camphor and ethylic oxalate in presence of metallic sodium interact according to the equation

forming *ethylic camphoroxylate*. This is an oily liquid, which decomposes on distillation; on hydrolysis it is converted into *camphoroxylic acid*, which crystallises in rhombic plates melting 88° C. On reducing this acid with sodium amalgam, a γ -lactone of the formula

is obtained, melting at 75-76°. Ethylic camphoroxylate and phenylhydrazine interact to form a *monophenylhydrazone*, which crystallises in white needles melting at 187-188° C. By the action of hydroxylamine a compound is formed which melts at 193° and will be further investigated. On ethylic camphoroxylate with aniline to 165°, *oxanilide* is produced.

46. "The Oxidation of Turpentine in Sunlight." By HENRY E. ARMSTRONG.

It was pointed out by Sobrero in 1851 (*C. R.*, xxxiii, 66) that when turpentine is exposed to light in presence of

moisture and oxygen a crystalline substance is formed which has the composition represented by the formula $C_{10}H_{18}O_2$; and that this substance is decomposed when boiled with dilute sulphuric acid, an oil being formed which has a powerful odour recalling both that of camphor and that of turpentine. The author's attention became directed to this substance about twelve years ago in the course of his studies of the terpenes and camphor, and in most years since, during the summer, he has carried on experiments on the oxidation of $C_{10}H_{16}$ hydrocarbons in sunlight, and has been able to confirm Sobrero's statements in every particular. As the crystalline product in question has not yet been named, it is proposed to term it—at all events, provisionally and until its constitution is determined—*sobrerol*.

Sobrerol is readily soluble in alcohol, and crystallises from this solvent usually in large, flexible, monosymmetric prisms having a peculiar hour-glass structure inside and showing hemihedrism. It is slightly soluble in water, benzene, chloroform, and petroleum spirit; the aqueous solution has a bitter taste. It melts at about 150° . The results obtained on analysis (carbon, 70.57 and 70.49 per cent; hydrogen, 10.71 and 10.74 per cent) show that, as Sobrero states, it has the formula—

and there can be very little doubt that it is a glycol; but, owing to its extreme sensitiveness, to the action of acids, it is difficult to prove this by the ordinary methods. Sobrerol is optically active in a high degree, the apparent specific rotatory power of the products from French turpentine in a 5 per cent. solution in alcohol (B.P.) being slightly above 150° . Sobrerol from American turpentine (from Savannah) was found to have about the same rotatory power, but in the opposite direction. The optical similarity of the two products is noteworthy, inasmuch as the American has less than half the rotatory power of French turpentine. It would seem that only the terpenes proper, and not the citrenes, &c. (cf. *Chem. Soc. Trans.*, 1879, 734; *J. Soc. Chem. Ind.*, 1882, 478) form sobrerol. To ascertain whether this be the case, and what are the crystallographic and optical relationship of the products obtained from terpenes from different sources, the author is engaged in conjunction with Mr. W. J. Pope—to whom he is indebted for assistance in this research—in studying the behaviour of pure $C_{10}H_{16}$ hydrocarbons of all kinds.

When boiled with dilute sulphuric acid, sobrerol is readily converted into the oil referred to by Sobrero; the product is undoubtedly identical with the isomeride of camphor which Wallach and Otto have obtained by treating turpentine with nitrous acid (*Annalen*, ccliii, 249), and which they have provisionally named *pinol*; as the compound is not an *ol*, i.e., an alcohol, it may be suggested that it might appropriately be termed *sobrerone*. The product from sobrerol begins to boil at 150 – 160° , but passes over almost entirely at about 183° , leaving a small amount of a viscid oil; it readily combines with bromine, forming a dibromide (bromine found 50.78 per cent) which crystallises very beautifully in forms of the rhombic system, the lengths of the axes being in the ratio $a : b : c = 0.5696 : 1 : 1.5553$, dimensions which almost absolutely agree with those quoted by Wallach and Otto, viz., $a : b : c = 0.5700 : 1 : 1.5553$. The dibromide was found to melt at 93.5° , 94° being the melting point given by Wallach and Otto.

The formation of sobrerone from sobrerol is of interest as serving to explain its formation by Wallach and Otto's method: very probably sobrerol is first produced, and is at once acted on by the acid. Sobrerol is probably always the initial product of oxidation of turpentine. It may be expected that sobrerone will be found among the oxygenated constituents of some essential oils, and it is proposed to search for it.

If, as appears probable, sobrerol be a glycol, the formation of sobrerone from it is analogous to that of pinacol from pinacolone; but in this latter case, an isomeric change

takes place, pinacolone being a ketone, $CM_3 \cdot CO \cdot CH_3$, and not the oxide corresponding to pinacolone. Wallach and Otto's observations, however, show that sobrerone is not a keto-compound. It would, therefore, appear to follow that sobrerone is an oxide formed by withdrawal of the elements of a water molecule from two hydroxyls attached to contiguous carbon atoms.

47. "The Structure of Cycloid Hydrocarbons." By HENRY E. ARMSTRONG.

The appearance of Bamberger's remarkable paper (*Annalen*, cclvii, 1; *Ber.*, 1890, 1124), in which formulae are proposed for naphthalene, anthracene, &c., apparently analogous to that suggested by v. Baeyer and the author for benzene, renders it desirable that the cases in which this formula is applicable should be carefully considered, especially as the somewhat novel conceptions which the author would associate with this symbol tend to limit the extension of the hypothesis.

Although superior to all other symbolic expressions in almost every respect, Kekulé's formula is, nevertheless, admittedly open to the objections (1) that it apparently involves the existence of two ortho- and two meta-derivatives; and (2) that it represents benzene as containing three pairs of carbon-atoms in the condition of those in ethylene. The *centric* formula was developed to meet these objections. It represents benzene as a symmetrical configuration, and is suggestive of only three derivatives. The six affinities which in Kekulé's symbol act in pairs, as in ethylene, are assumed actually to neutralise each other much as the affinities do in paraffins, but without constituting cross linkages within the ring as represented in the Claus formula, for example: the behaviour of the hydrotrepthalic acids, of quinone and of anthracene, and among others, Kekulé's researches on the constitution of pyridine, of which he recently gave an account in Berlin, affording, in the author's opinion, abundant evidence of the non-existence of such cross linkages. The conception in his mind, to which, however, expression has not hitherto been given, has always been that the centric affinities act within a cycle rather than merely towards the centre in the manner pictured, and that there are peculiarities in the carbon-atom which render such a form of action possible: benzene, in fact, according to this view, may be represented by a double ring. It would appear that when an additive compound is formed the inner cycle of affinity suffers disruption, and, such a cycle being no longer possible, the contiguous carbon-atoms to which nothing has become attached of necessity acquire the ethylenic or unsaturated condition.

An extension of the hypothesis to naphthalene was suggested in September last year in a paper read at the British Association meeting at Newcastle (*B. A. Report*, 1889, 175). The following is the symbol there proposed:—

This symbol again involves the admission of the unusual conception that an affinity can act in two directions (cf. *Phil. Mag.*, June, 1888), the two carbon-atoms common to the two nuclei being represented as exerting an influence in both nuclei. In this case also the "centric" affinities are regarded as acting within a cycle composed, however, of 10 carbon-atoms; but no separation of the central carbon-atoms, such as Bamberger suggests, is supposed to have taken place. It becomes possible on this hypothesis, in a measure, to understand that a radicle in the one nucleus should, as is known to be the case, exercise an influence in a radicle in the other nucleus.

It appears to have hitherto been supposed that anthracene has a symmetrical structure: the author contends,

however, that this is not the case, and that it is to be represented by the formula

wherein C is the centric nucleus of benzene; but anthraquinone—which, strictly speaking, is derived from dihydroanthracene and not from anthracene—is symmetrical and contains two centric benzene nuclei, thus:—

The behaviour of anthracene and anthraquinone appears to be entirely in accordance with these conclusions. Phenanthrene may be regarded as composed of two lateral "centric" nuclei, to which is conjoined a median nucleus in which the only two "available" carbon-atoms are in the ethylenic condition.

The behaviour of anthracene is more nearly that which it may be supposed the hypothetical hydrocarbon having the structure indicated by Kekulé's benzene symbol would manifest. Pyrene, probably, is still more closely related to the ethylenic form of benzene, and has little, if any, resemblance to the centric form. Two formulæ may be assigned to this hydrocarbon.

The first of these is the symbol of a phenanthrene derivative; but the behaviour of pyrene is so entirely unlike that of phenanthrene that it may be regarded as out of the question; the second would appear to be entirely in accordance with the results of Bamberger's researches.

It is contended that the formulæ now suggested serve to explain the exceptional physical properties of hydrocarbons such as anthracene and pyrene.

DISCUSSION.

Dr. JAPP desired to know what precise mechanical conception Dr. Armstrong wished to express by the broken bonds in his centric formula. They appeared to denote attractive forces which stopped half way—in other words, attractive forces which did not attract. In this way the centric formula would resolve itself into a benzene hexagon with triadic carbon.

Professor RAMSAY said that he did not see the necessity of substituting an unusual conception for the one in common use, which, in his opinion, gave a sufficient and clear mental picture of the relations between benzenoid compounds. In the case of crotonic and isocrotonic acids, an isomeric change is known whereby the position of the "double bond" is shifted. The difficulty in unreservedly accepting Kekulé's benzene formula, caused by the fact that two ortho-compounds are unknown, while they are required by his conception, was, to some extent, removed by Kekulé himself by his supposition that the double bonds were not stationary, but were sometimes between carbon-atoms 1 and 2, and sometimes between 2 and 3. In order to explain the fact that a change from the symbol—

to the symbol—

is possible, it may be conceived that so long as no external influence is exerted on the benzene ring, it has the constitution suggested by Kekulé. It is probable that two isomeric ortho-compounds are impossible, because, if formed by substitution of hydrogen-atoms 1 and 2, a change would take place whereby the double bond, connecting 1 with 2, would be dissolved and replaced by a single bond, while the double bonds would then exist between 1 and 6, 3 and 2, and 5 and 4. Or the contrary may be the case, and the single bond may be the more unstable form of union, in which case, if an ortho-compound were formed between 2 and 3, the position of the bonds would also be reversed. The case of a change of position of double bonds in the crotonic acids renders this hypothesis not untenable.

Mr. CROMPTON agreed with Professor Ramsay in his remarks, and thought that objections to the Kekulé symbol, based on the view that, because this symbol contained double bonds, benzene should behave as an olefinic compound, were unjustifiable. A double bond was nothing more than an incomplete representation, on paper, of an unsaturated condition or want of equilibrium in the molecule, a state of things that might be due to totally different and distinct causes in the two cases. The behaviour of benzene in this respect must, therefore, differ from that of ethylene. The difference would have to be looked for in the different configurations of the molecules; but it was just this point that received no representation, or only an inadequate one, in the plane formulæ at present in use. The problem would, no doubt, only be finally solved when satisfactory space formulæ for these compounds had been discovered.

In reply to Dr. Japp, Dr. ARMSTRONG said that the broken bonds were intended to figure as resultants, much as the conjoined effect of two forces acting from different directions was expressed by their resultant. Referring to Professor Ramsay's remarks, he expressed the opinion that the isomerism of the crotonic acids was not sufficiently understood to serve as an argument in such a case. However well the non-existence of isomeric ortho- and meta-derivatives might be accounted for by Kekulé's oscillation hypothesis, it was impossible in this way to explain the fact that benzene, on the whole, behaved as a saturated and not as an ethylenic compound; there was also no reason to suppose, as Mr. Crompton had suggested, that "double bonds" in a ring would behave differently from those in an open chain: the whole of v. Baeyer's recent work was in contradiction to any such assumption, and Thomsen's and other observations left little doubt that in the formation of benzene there is a considerable "outgoing of affinity" beyond that which takes place when ethylenic union is effected. He scarcely thought that the introduction of geometric considerations would materially advance the solution of the problem under discussion. Whatever the ultimate fate of his hypothesis, he was convinced that a settlement of many practical problems—those relating to laws of substitution and isomeric change, for example—required the knowledge of the inner structure of the cycloid hydrocarbons; and such speculations, even if proved to be entirely false, at least served to suggest fresh lines of experimental inquiry, and on this account were not only permissible, but also desirable.

49. "Tertiary Butyl Mercaptan." By LEONARD DOBBIN, Ph.D., Chemical Laboratory of the University of Edinburgh.

The author finds that when tertiary butyl iodide is digested at a gentle heat with a sufficient quantity of zinc sulphide, an interaction takes place which results in the formation of tertiary butyl mercaptan. It is a colourless, extremely volatile liquid which boils at 65–66°, possessing an overpowering disagreeable smell, recalling that of other mercaptans; it solidifies in a freezing mixture of snow and salt to a white semi-translucent mass; it forms white insoluble compounds with mercuric chloride and with silver nitrate.

Products of higher boiling-point are formed at the same time as the mercaptan; these are believed to be triisobutylene, and probably also tertiary butyl sulphide. This part of the subject is under investigation.

50. "Desylacetophenone." By ALEX. SMITH, B.Sc., Ph.D., Chemical Laboratory of the University of Edinburgh.

The author finds that a dilute solution of potassium cyanide in alcohol and water acts in many cases as a condensing agent. By boiling equimolecular proportions of benzoin and acetophenone in dilute alcohol with very little potassium cyanide, a condensation product, *desylacetophenone*, is formed,—

which is the saturated compound corresponding to Japp's anhydracetophenone-benzil. It may be got perfectly pure and white by re-crystallisation from acetic acid and alcohol. It melts at 126°. It is easily transformed into *triphenylfurfurane*, *triphenylpyrrole*, and *triphenylthiophen*, showing its constitution to be that given above. It forms a mono- and a di-hydroxime; by its interaction with one molecular proportion of phenylhydrazine, two molecular proportions of water being given off, an oiazone (pyridazine) is formed. This latter compound is converted by excess of phenylhydrazine into $\alpha\alpha'\beta\beta'$ -N-tetraphenylpyrrole.

A large quantity of another substance having the formula $\text{C}_{29}\text{H}_{22}\text{O}_2$ is formed at the same time as the desylacetophenone. It would seem that the benzoin, or a part of it, acts as a benzaldehyde,—

From acetone and benzoin the only substance isolable, if not, indeed, the only one formed, is that corresponding to the last-mentioned product from acetophenone. It has the formula $\text{C}_{24}\text{H}_{20}\text{O}_2$. The properties and constitutions of these two substances are still under investigation, as are also some other applications of the new interaction.

NOTICES OF BOOKS.

Alkali Works Regulation Act, 1881. Twenty-sixth Annual Report on Alkali, &c., Works by the Chief Inspector. Proceedings during the Year 1889, presented to the Local Government Board and to the Secretary for Scotland. London: Eyre and Spottiswoode.

THE Chief Inspector, in his introduction, refers to a difference between the inspection carried on under this Act and that conducted by sanitary inspectors under the Public Health Act. In this latter case "the senses of smell and sight are sufficient to determine whether a nuisance exists, "though the toleration which ballast-burning in urban districts still enjoys is proof positive that men's notions on the definition of a nuisance are not uniform. The inspector under the Alkali Act has to determine the quality and quantity of any noxious gas found to be escaping, to ascertain if it exceeds the limits of tolerance, and the best practicable means of

minimising its emission. The Act, it must be observed, does not force the manufacturer to use any particular means for the suppression of the nuisance. The inspector, however, frequently finds it his duty to suggest and advise. "He cannot consistently complain of the imperfections in an operation unless he can show the possibility of attaining a better result. To this end he must possess a wide, a varied, and a profound chemical knowledge combined with abundant tact." As he, further, cannot well avoid becoming acquainted with the details of construction of the plant in the works inspected, and with the entire *modus operandi*, an inspector who sells or otherwise reveals trade secrets which have thus come under his cognisance certainly merits very severe punishment. German legislation, we must add, is pointing in this direction.

The number of works which come within the purview of the Act is declining. There are in England 116 alkali works, and in Scotland 16; other works scheduled in the Act, 787 in England and 113 in Scotland, making a total of 1032 registered works. This shows a decrease in the alkali works of 3, and in other scheduled works of 20, making, in England alone, a decrease of 23. The number of separate processes under inspection is increasing, as several distinct processes are often carried on in one establishment and by one and the same firm or company. It is interesting to find that the amount of hydrochloric acid vapour from the decomposition of salt is distinctly below one-half of the statutory limit. As regards the acid gases escaping from the lead chambers, they are below one-third of the legal limit, and are still diminishing yearly. The acids given off from chemical manure works is also decreasing. In 1883 the proportion was 0.5 grain SO_2 per cubic foot; it is now 0.349 grain, and in one district (East Lancashire and Yorkshire) reached 0.2 grain.

One firm only, manufacturers of ammonium sulphate, has been prosecuted under the Act.

The salt industry has decreased upon the whole by about 12 per cent, in consequence, doubtless, of the rise in price inaugurated by the "salt-ring." The production in Durham has, however, increased by 50 per cent.

The consumption of salt in the Leblanc soda process is slightly less than in 1888, viz., 584,203 tons as against 585,498 tons. Meantime, the proportion of salt consumed in the ammonia process is steadily increasing.

The production of ammonium sulphate is gradually increasing. Its value, taken at £12 per ton, has now risen to £1,500,000 yearly, and in the opinion of the Chief Inspector, this quantity might be increased ten-fold.

The recovery of sulphur from the vat-waste of the Leblanc process is now an established fact. The Chance process is in successful operation in twelve alkali works, although the plant required is very costly. There is little prospect of a permanent reduction of the sale price of sulphur. Were it to be lowered, many of the Sicilian mines would doubtless be closed. The amount of tank-waste deposited has now ceased to increase, but some time must elapse before the old heaps and their attending nuisance can disappear.

The influence of certain modern appliances in developing the intelligence of the workmen is fully acknowledged. As instances are mentioned the black-ash revolver, the gas-furnace, and the apparatus used in the recovery of sulphur by the Chance process.

Attempts are being made to suppress, or at least lessen, the injurious effects of salt works, the fumes from which, in the district of Winsford, have devastated the country for miles. Reference is here made to the value of the triple effect principle, by which, in many cases where evaporation is carried on, a vast saving of fuel and consequently of nuisance is effected. This system has been adapted to the salt manufacture by Dr. Pick, of Galicia, and is now being introduced at Shirleywich, in Staffordshire.

A Manual of Pharmaceutical Testing for the Man of Business and his Assistant; comprising Simple Instructions for the Testing of the Chemicals of the "British Pharmacopœia" with such Materials and Appliances as are in common use at the Dispensing Counter. By BARNARD S. PROCTOR, F.I.C. London: Offices of the *Chemist and Druggist*.

THE position of the pharmacist as regards his customers and the medical faculty is greatly changed. Time was when he could manufacture in his back shop or store-rooms the few and simple chemicals required in his business. Hence he might be supposed to know without special testing the quality of the articles in his jars and bottles and drawers. Now he is compelled to purchase from the manufacturer and the wholesale dealer. It is self-evident that he cannot afford to take for granted the skill, the care, and above all the honesty of those who supply him. Hence he is bound, in obedience to the reasonable requirements of the law, no less than in justice to the public, the medical profession, and to his own reputation, to examine all articles which come into his hands. It may possibly be thought that the ordinary manuals of analytical chemistry, qualitative and quantitative, will fully answer the requirements of the case. This, however, is a mistake. The Pharmacopœia lays down certain standards to which all chemicals sold by the chemist and druggists and used in medicine or in making up prescriptions must conform. Our author indicates the simplest, speediest, and most inexpensive manner of ascertaining if these requirements are obeyed. Whether a chemical is absolutely pure—in many cases a vain undertaking under the circumstances—he does not inquire. So long as no substance is present which would interfere with their efficacy, and so long as their strength or degree of concentration is practically correct, he is satisfied, and in so doing he is justified. "There are," he tells us, "sundry cases in which any deviation from the B. P. tests would not be legitimate, there is no alternative but to follow that process." In other cases simpler tests are given where those laid down in the B. P. are unsatisfactory, and certain errors, clerical or typographical, are pointed out. Thus, the instruction to add silver nitrate and barium chloride to an acidified solution of potassa is duly explained as an error.

All things being considered, we hold that there is not merely room, but actual need, for Mr. Proctor's treatise. It is of great importance for the pharmacist, especially in the outset of his professional career, to know when he has fulfilled all righteousness, and is consequently safe and can await the visits of any inspector with equanimity. We cordially echo the author's hope that this hand-book will encourage the habit of testing the chemicals used in medicine, and we believe that it will prove a safe and useful guide.

CORRESPONDENCE.

A RAPID METHOD FOR THE DETERMINATION OF ALUMINIUM IN IRON AND STEEL.

To the Editor of the Chemical News.

SIR,—Take 10 grms. of the iron or steel and dissolve the same in a mixture of 50 c.c. of strong HCl and 30 c.c. of water in a No. 8 beaker; when dissolved add 5 c.c. of a saturated solution of sodium phosphate, then 100 c.c. of water. To this solution add dilute ammonia until the free acid is neutralised; then take up the precipitate carefully with dilute HCl until the solution becomes clear, afterwards add 2 c.c. (not more) of strong HCl and boil; whilst boiling pour in 50 c.c. of a saturated solution of sodium hyposulphite; cover over and boil for one hour. Filter, wash well with hot water, afterwards wash the residue

from filter into the same beaker in which it was boiled, and dissolve in 100 c.c. of a 10 per cent solution of HCl, boil and filter off the sulphur. Evaporate filtrate to 5 c.c., then wash into a platinum dish, and neutralise with pure sodic hydrate (made from sodium). After neutralising add 2 grms. sodic hydrate in excess and boil for 30 minutes, dilute and filter from the iron, after washing the filtrate is made acid with HCl; then precipitate the aluminium down with ammonia; boil, filter off the aluminium phosphate, which is then dissolved in a small quantity of HCl and evaporated to dryness to separate the silica. Re-dissolve in HCl and filter, to the filtrate add 5 c.c. of ammonium phosphate, then ammonia with a few drops of ammonium acetate, and boil for 30 minutes; filter and wash residue well with hot water containing a little ammonium phosphate, ignite, and weigh the precipitate as $AlPO_4$, which contains 22.358 per cent aluminium.

This process, though appearing complicated, can be easily executed in six hours.—I am, &c.,

CHARLES PHILLIPS.

Phillips and Barker,
Chemical and Metallurgical Laboratories,
Fitzalan Square, Sheffield,
June 17, 1890.

UNAUTHORISED REPORTS.

To the Editor of the Chemical News.

SIR,—While reading the article on "Analytical Touts" (CHEM. NEWS, vol. xli., p. 195) the thought crossed me that it is not uncommon to find "pithy and concise reports, productive of excellent business results," manufactured from the simple returns of chemists who would not willingly mislead. Even the titles appended to one's name are at times subject to most curious enlargement. Having recently made a report to a company doing business some two thousand miles from here, I was favoured with a copy of the same in printed form. Judge of my surprise at seeing myself rated (in addition to my legitimate position in this institution) as "Chemist to the Board of Health of the State of New York" and "Consulting Chemist to the United States Government."—I am, &c.,

W. P. MASON.

Rensselaer Polytechnic Institute,
Department of Analytical Chemistry,
Troy, N.Y., June 10, 1890.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cx., No. 23, June 9, 1890.

Action of Alkalies and Alkaline Earths, of Alkaline Silicates, and of Certain Saline Solutions, upon Mica. Production of Nepheline, Sodalite, Amphigene, Orthose, and Anorthite.—Charles and Georges Friedel.—Only few experiments have been hitherto made upon the transformations which rocks and minerals have undergone under the influence of the various agents, physical or chemical, which must have been in action during geological periods. They have therefore thought it interesting to submit the minerals which form rocks to the action of water, with the addition of a certain quantity of alkalies, earths, silicates, and salts at high temperatures, reproducing thus the conditions which have been produced in Nature. They have used a thick tube of steel, lined with platinum, which, when two-thirds full of water, may be heated to about 500°. The subject of the experiments has been mica, and the result has been the production of the minerals mentioned above, i.e., five of the minerals found in the eruptive blocks of Somma.

The Isomeric Conditions of Chromium Sesquibromide. The Blue Sesquibromide.—A. Recoura.—The solid blue bromide, if kept for some time at 100°, is transformed into its green isomer without a change of composition. It does not appear to be produced spontaneously at ordinary temperatures. If a solution of the blue bromide is left to crystallise there are formed, at first, long blue crystalline needles; then when the water has almost disappeared we see appear, among these needles, small green crystals which gradually pervade the entire mass. On the other hand, a saturated solution of the green bromide remains green, and in time deposits green crystals. If a solution of the green bromide, mixed with free hydrobromic acid, is let stand, it remains green for an indefinite time, and does not pass into the violet modifications.

Separation and Determination of Zinc in Presence of Iron and Manganese.—J. Riban.—(See p. 307).

Composition of Clays and Kaolins.—Georges Vogt.—The author's researches show that no process of levigation enables us to separate the hydrated aluminium silicate from the foreign bodies which accompany it. The alkalies contained in clays may have been introduced either by micas or by felspars.

Synthesis of the Carbon Fluorides.—C. Chabrie.—The author has obtained methylene fluoride, CH_2F_2 . He obtains this gas by heating to 180°, for half an hour, 1.7 grms. methylene chloride with 5.08 grms. silver fluoride prepared by Gore's process, and rendered anhydrous with the precautions described by Guntz.

Products of the Saccharification of Starchy Matter by Acids.—G. Flourens.—In opposition to Gruber, O'Sullivan, Brown, and Heron, the author concludes that there is produced in the action of acids upon starch only a single dextrine, as admitted by Payen, which is accurately determined by its high rotatory power, which approaches that of soluble fecula.

Decomposition of Organic Manures in the Soil.—A. Muntz.—In this paper the following conclusions are reached:—In the soils which are incapable of nitrification in consequence of their chemical constitution, the nitrogen of the organic matters is converted into ammonia. The same result happens in soils when nitrification is checked by compactness or where the nitric ferment has been killed. Even when the nitric fermentation is very energetic organic manures give rise to ammonia.

Journal de Pharmacie et de Chimie.
Series 5, Vol. xxi., No. 2.

Two New Sugars extracted from Quebracho.—C. Tanret.—Both these papers have been already noticed.

Volumetric Determination of Tannin in Wines.—NM. Roos, Cusson, and Giraud.—(Already inserted).

A Falsification of Milk.—Dr. Perron.—In order to baffle the use of the lactobutylometer, a novel fraud has been devised. Some oil of low sp. gr., and not possessing a bad taste, is emulsified with yolk of egg and added to the milk after the cream has been abstracted.

Fustus Liebigs Annalen der Chemie.
Vol. ccliv., Part 3.

On the Euxanthon Group.—C. Graebe.—The author has produced euxanthon synthetically by heating 5 grms. resorcylic acid and 6 grms. hydroquinoncarbonic acid with 12 parts of acetic anhydride to a boil for four hours in a small retort with an ascending condenser. The product was then submitted to distillation. Acetic acid and anhydride passed over, and the last portions of the anhydride contained a little euxanthon. On heating more strongly the bulk of the euxanthon sublimed over, whilst much carbon remained in the retort. The syn-

thetic euxanthon has the same composition and properties as the natural kind obtained from Indian yellow.

Communications from the Agricultural-Chemical Laboratory of the University of Göttingen.—Papers by Dr. H. J. Wheeler and B. Tollens on xylose or wood-sugar, a second pentaglucose, and researches on wood-gum.

Communications from the Chemical Institute of Marburg.—Researches by W. Roser on narcotine.—Narcotine is a meconine hydrocartonine, and, like hydrastine, is closely connected with another opium alkaloid, papaverine. Both opium alkaloids are derivatives of a benzyloquinoline. Narceine has no connection with narcotine.

On Benzoyl-tannin.—Dr. Carl Böttlinger.—(Already inserted).

Action of Ammonia and Ethylendiamine upon Tetrachloridiacetyl.—S. Levy.—Not susceptible of useful abstraction.

ERRATUM.—P. 162, col. 1, for "Francis Wallis" read "Francis Watta."

THE BANKHALL OIL AND CHEMICAL WORKS, LIMITED (Formerly Thacker and Co.), LIVERPOOL

FOR SALE BY PRIVATE TREATY as a going concern the above old-established and well-known Oil and Chemical Works, including the whole of the Machinery and Plant and the Goodwill of the business. The Works stand on about 15,530 square yards of land, which is held on lease for seventy-five years from April 30, 1885, at a ground rent of £700 per annum. In addition there is a good private road on the East side of the Works which is occupied jointly with the Lancashire and Yorkshire Railway Co. The situation of the Works is everything that could be desired. They are bounded on the south and east by the Lancashire and Yorkshire Railway, on the west by the Leeds and Liverpool Canal, and on the north by Bankhall Street. There are sidings into the Works from the Lancashire and Yorkshire Railway, and there is also direct access to the Canal. The Works are also in close proximity to the Docks and to the London and North-Western, Midland, and Manchester, Sheffield, and Lincolnshire Railway Stations, and are only about 1½ miles from the Liverpool Exchange. An important feature in connection with these Works is that they are not liable to be restrained or prosecuted for emitting noxious odours, &c. The Buildings comprise extensive Oil and Cake Mills, with Elevator, Oil and Tallow Refineries, Oil Stores, Tar and Naphtha Distilleries, Soapery, large Warehouses, with very extensive Fireproof Vaults and Steam Hoist, Cooperage, Stables, and the usual Offices. The Machinery and Plant are comparatively new, in excellent condition, and capable of doing a very extensive manufacturing business. The business connection is a most valuable one. With a view to a speedy realisation a very moderate price will be accepted.

For orders to inspect the Works and to treat apply to the Liquidator, T. THEODORE ROGERS, 30, North John Street, Liverpool, or to Wm. F. MORECROFT and CO., Solicitors, 5, Castle Street, Liverpool.

COUNTY BOROUGH OF SALFORD.
(GAS DEPARTMENT).

TAR.

The Gas Committee invite Tenders for the purchase and removal of the surplus Tar to be produced at their Bloom Street, Regent Road, and Liverpool Street Works in twelve months from July 13th next.

The approximate quantity will be 4,500 tons.

Forms of tender and conditions of contract may be obtained on application to the Gas Engineer, Gas Offices, Bloom Street, Salford. Sealed tenders, endorsed "Tender for Tar," addressed to the Chairman of the Gas Committee, must be delivered to me on or before Thursday, the 10th prox., at 5 o'clock in the evening.

By order,

SAMUEL BROWN, Town Clerk.

Town Hall, Salford,
June 12, 1890.

TAR.

The Directors of the Nuneaton Gas Company invite Tenders for the surplus TAR to be produced at their works for one year from the 1st of July next. Quantity about 150 tons. Tenders, sealed and endorsed, must reach me not later than the 10th July.

JOHN H. BLAND, Secretary.

Nuneaton, 19th June, 1890

FOAM.*

By the Right Hon. LORD RAYLEIGH, M.A., D.C.L., LL.D.,
F.R.S., Professor of Natural Philosophy, R.I.

WHEN I was turning over in my mind the subject for this evening, it occurred to me to take as the title of the lecture, "Froth." But I was told that a much more poetical title would be "Foam," as it would so easily lend itself to appropriate quotations. I am afraid, however, that I shall not be able to keep up the poetical aspect of the subject very long; for one of the things that I shall have most to insist upon is that foaming liquids are essentially impure, contaminated—in fact, dirty. Pure liquids will not foam. If I take a bottle of water and shake it up, I shall get no appreciable foam. If, again, I take pure alcohol, I get no foam. But if I take a mixture of water with 5 per cent. of alcohol there is a much greater tendency. Some of the liquids we are most familiar with as foaming, such as beer or ginger-beer, owe the conspicuousness of the property to the development of gas in the interior, enabling the foaming property to manifest itself; but of course the two things are quite distinct. Dr. Gladstone proved this many years ago by showing that beer from which all the carbonic acid had been extracted in vacuo still foamed on shaking up. I now take another not quite pure but strong liquid, acetic acid, and from it we shall get no more foam than we did from the alcohol or the water. The bubbles, as you see, break up instantaneously. But if I take a weaker acid, the ordinary acid of commerce, there is more, though still not much, tendency to foam. But with a liquid which for many purposes may be said to contain practically no acetic acid at all, seeing that it consists of water with but 1-1000th part of acid, the tendency is far stronger: and we get a very perceptible amount of foam. These tests with the alcohol and acetic acid are sufficient to illustrate the principle that the property of foaming depends on contamination. In pure ether we have a liquid from which the bubbles break even more quickly than from alcohol or water. They are gone in a moment. In some experiments I made at home I found that water containing a small proportion of ether foamed freely; but on attempting two or three days ago to repeat the experiment, I was surprised to find a result very different. I have here some water containing a very small fraction of ether, about 1-240th part. If I shake it up, it scarcely foams at all; but another mixture made in the same proportion from another sample shows more tendency to foam. This is rather curious, because both ethers were supposed to be of the same quality; but one had been in the laboratory

longer than the other, and perhaps contained more greasy matter in solution.

Another liquid which foams freely is water impregnated with camphor. Camphor dissolves sparingly; but a minute quantity of it quite alters the characteristics of water in this respect. Another substance, very minute quantities of which communicate the foaming property to water, is glue or gelatine. This liquid contains only 3 parts in 100,000, of gelatine, but it gives a froth entirely different from that of pure water. Not only are there more bubbles, but the duration of the larger bubbles is quite out of proportion to that of water bubbles. This sample contains 5 parts in 100,000, nearly double as much; but even with but 1 part in 100,000, the foaming property is so evident as to suggest that it might in certain cases prove valuable for indicating the presence of minute quantities of impurities. I have been speaking hitherto of those things which foam slightly. They are not to be compared with, say, a solution of soap in water, which, as is well known to everybody, froths very vigorously. Another thing comparable to soap, but not so well known, is saponine. It may be prepared from horse chestnuts by simply cutting them in small slices and making an infusion with water. A small quantity of this infusion added to water makes it foam strongly. The quantity required to do this is even less than in the case of soap; so the test is more delicate. It is well known that rivers often foam freely. That is no doubt due to the effect of saponine or some analogous substance. Sea-water foams, but not, I believe, on account of the saline matter it contains; for I have found that even a strong solution of pure salt does not foam much. I believe it has been shown that the foaming of sea-water, often so conspicuous, is due to something extracted from seaweeds during the concussion which takes place under the action of breakers.

Now let us consider for a moment what is the meaning of foaming. A liquid foams when its films have a certain durability. Even in the case of pure water, alcohol, and ether, these films exist. If a bubble rises, it is covered for a moment by a thin film of the liquid. This leads us to consider the properties of liquid films in general. One of their most important and striking properties is their tendency to contract. Such surfaces may be regarded as being in the condition of a stretched membrane, as of india-rubber only with this difference, that the tendency to contract never ceases. We may show that by blowing a small soap bubble, and then removing the mouth. The air is forced back again by the pressure exerted on the bubble by the tension of the liquid. This ancient experiment suffices to prove conclusively that liquid films exercise tension.

A prettier form of the same experiment is due to Van der Mensbrugghe, who illustrated liquid tension by means

* A Lecture delivered at the Royal Institution of Great Britain, March 28, 1890

of a film in which he allowed to float a loop of fine silk, tied in a knot. As long as the interior of the loop, as well as the exterior, is occupied by the liquid film, it shows no tendency to take any particular shape: but if, by insertion of, say, a bit of blotting paper, the film within the loop be ruptured, then the tension of the exterior film is free to act, and the thread flies instantaneously into the form of a circle, in consequence of the tendency of the exterior surface to become as small as possible. The exterior part is now occupied by the soap film, and the interior is empty. Many other illustrations of this property of liquids might be given, but time does not permit.

In the soap film, as in the films which constitute ordinary foam, each thin layer of liquid has two surfaces; each tends to contract; but in many cases we have only one such surface to consider, as when a drop of rain falls through the air. Again, suppose that we have three materials in contact with one another,—water, oil, and air. There are three kinds of surfaces separating the three materials, one separating water and oil, another oil and air, and a third surface separating the water from the air. These three surfaces all exert a tension, and the shape of the mass of oil depends upon the relative magnitudes of the tensions. As I have drawn it here (Fig. 1), it is implied that the tension of the water-air surface is less than the sum of the other two tensions—those of the water-oil surface and the air-oil surface; because the two latter acting obliquely balance the former. It is only under such conditions that the equilibrium of the three materials as there drawn in contact with one another is possible. If the tension of the surface separating water and air exceeded the sum of the other two, then the equilibrium as depicted would be impossible. The water-

FIG. 1.

air tension, being greater, would assert its superiority by drawing out the edge of the lens, and the oil would tend to spread itself more and more over the surface.

And that is what really happens. Accurate measurements made by Quincke and others show that the surface tension separating water and air is really greater than the sum of the two others. So oil does tend to spread upon a surface of water and air. That this is the fact we can prove by a simple experiment. At the feet of our chairman, our Honorary Secretary, is a large dish, containing water which at present is tolerably clean. In order to see what may happen to the surface of the water, it is dusted over with fine sulphur powder, and illuminated with the electric light. If I place on the surface a drop of water, no effect ensues; but if I take a little oil, or better still a drop of saponine, or of soap-water, and allow that to be deposited upon the middle of the surface, we shall see a great difference. The surface suddenly becomes dark, the whole of the dust being swept away to the boundary. That is the result of the spread of the film, due to the presence of the oil.

How then is it possible that we should get a lens-shaped mass of oil, as we often do, floating upon the surface of water. Seeing that the general tendency of oil is to spread over the surface of water, why does it not do so in this case? The answer is that it has already spread, and that this surface is not really a pure water surface at all, but one contaminated with oil. It is in fact only after such contamination that an equilibrium of this kind is possible. The volume of oil necessary to contaminate the surface of the water is very small, as we shall see presently; but I want to emphasize the point that, so far as we know, the equilibrium of three surfaces in contact with one another is not possible under any other conditions,

That is a fact not generally recognised. In many books you will find descriptions of three bodies in contact, and a statement of the law of the angles at which they meet; that the sides of a triangle, drawn parallel to the three intersecting surfaces must be in proportion to the three tensions. No such equilibrium, and no such triangle, is possible if the materials are pure; when it occurs, it can only be due to the contamination of one of the surfaces. These very thin films, which spread on water, and, with less freedom, on solids also, are of extreme tenuity; and their existence alongside of the lens proves that the water prefers the thin film of oil to one of greater thickness. If the oil were spread out thickly, it would tend to gather itself back into drops, leaving over the surface of the water a film of less thickness than the molecular range.

One experiment by which we may illustrate some of these effects I owe to my colleague, Professor Dewar. It shows the variation in the surface tension of water, due to the presence on it of small quantities of ether. I hold in my hand masses of charcoal, which can be impregnated with ether. The greater part of the surface of the charcoal is covered with paraffin wax, and, in consequence, the ether which has already penetrated the charcoal can only escape from it again on one side. The result is that the water in the rear of this boat of charcoal will be more impregnated with ether than the part in front, so the mass of charcoal will enter into motion, and the motion will extend over a considerable interval of time. As long as the ether remains in sufficient quantity to contaminate the water in the rear, so long is there a tendency to movement of the mass. The water covered with the film of ether has less tension than the pure water in front, and the balance of tensions being upset, the mass is put in motion. If the nature of the case is such that the whole surface surrounding the solid body is contaminated, then there is no tendency to movement, the same balance in fact obtaining as if the water were pure.

Another body which we may use for this purpose is camphor. If we spread some camphor scrapings on a surface of pure water, they will, if the surface is quite clean, enter into vigorous movement, as you now see. This is because the dissolved camphor diminishes the surface tension of the water. But if I now contaminate the water with the least possible quantity of grease, the movements of the camphor will be stopped. I merely put my finger in, and you observe the effect. There is not much poetry about that! A very slight film, perfectly invisible by ordinary means, is sufficient so to contaminate the water that the effect of the dissolved camphor is no longer visible.

I was very desirous to ascertain, if possible, the actual thickness of oil necessary to produce this effect, because all data relating to molecules are, in the present state of science, of great interest. From what I have already said, you may imagine that a quantity of oil required is very small, and that its determination may be difficult. In my experiments,* I used the surface of water contained in a large sponge bath three feet in diameter. By this extension of the surface, I was able to bring the quantity of oil required within the range of a sensitive balance. In Diagram 2, I have given a number of results obtained at various dates, showing the quantity of oil required to produce the effects recorded in the fourth column. Knowing the weight of the oil deposit, and the area of the water surface upon which it was uniformly spread, it was easy to calculate the thickness of the film. It is seen that a film of oil about $\frac{1}{4}$ millionth of a millimetre thick is able to produce this change. I know that large numbers are not readily appreciated, and I will therefore put the matter differently. The thickness of the oil film thus determined as sufficient to stop the motions of the camphor is one-fourth of the wave length of yellow light. Another way of saying the same thing is that this thickness of oil bears to one inch the same ratio that one second of time bears to half a year.

* *Proc. Roy. Soc.*, March, 1890.

DIAGRAM 2.

A Sample of Oil somewhat Decolourised by Exposure.

Date.	Weight of Oil.	Calculated Thickness of Film in Micro-millimetres.	Effect upon Camphor Fragments.
	M.grm.		
Dec. 17..	0.40	0.81	No distinct effect.
Jan. 11..	0.52	1.06	Barely perceptible.
Jan. 14..	0.65	1.32	Not quite enough.
Dec. 20..	0.78	1.58	Nearly enough.
Jan. 11..	0.78	1.58	Just enough.
Dec. 17..	0.81	1.63	Just about enough.
Dec. 18..	0.83	1.68	Nearly enough.
Jan. 22..	0.84	1.70	About enough.
Dec. 18..	0.95	1.92	Just enough.
Dec. 17..	0.99	2.00	All movements very nearly stopped.
Dec. 20..	1.31	2.65	Fully enough.
<i>A Fresh Sample.</i>			
Jan. 28..	0.63	1.28	Barley perceptible.
Jan. 28..	1.06	2.14	Just enough.

When the movement of the camphor has been stopped by the addition of a minute quantity of oil, it is possible, by extending the water surface enclosed within the boundary, without increasing the quantity of oil, to revive the movements of the camphor; or, again, by contraction to stop them. I can do this with the aid of a flexible boundary of thin sheet brass, and you see that the camphor recovers its activity, though a moment ago it was quite dead. It would be an interesting subject for investigation to determine what is the actual tension of an oily surface contaminated to an extent just sufficient to stop the camphor movements; but it is not an easy problem. Usually we determine surface tensions by the height to which the liquids will rise in very fine tubes. Here, however, that method is not available, because if we introduce a tube into such a surface, there is no proof that the contamination of the inner surface in the tube is the same as that prevailing outside. Another method, however, may be employed which is less open to the above objection, and that is to substitute for the very fine or capillary tube, a combination of two parallel plates open at their edges. We have here two such plates of glass kept from absolutely closing by four pieces of thin metal* inserted at the corners, the plates being held close against these distance-pieces by suitable clamps. If such a combination be inserted in water, the liquid will rise above the external level, and the amount of the rise is a measure of the surface tension of the water. You see now the image on the screen. A is the external water surface; B is the height of the liquid contained between the glass plates, so that the tension may be said to be measured by the distance AB. If a little oil be now deposited upon the surface, it will find its way between the plates. The fall which you now see shows that the surface tension has been diminished by the oil which has found its way in. A very minute quantity will give a great effect. When the height of the pure water was measured by 62, a small quantity of oil changed the 62 into 48, and subsequent large additions of oil could only lower it to 38. But after oil has done its worst, a further effect may be produced by the addition of soap. If Mr. Gordon now adds some soap, we shall find that there is a still further fall in the level, showing that the whole tension now in operation is not much more than one-third of what it was at first. This is an important point, because it is sometimes supposed that the effect of soap in diminishing the tension of water is due to merely the formation upon the surface of a layer of oil formed by decomposition of the soap. This experiment proves the contrary, because we find that soap can do so much more than oil. There is indeed, something more or less corresponding to the decomposition of the soap and the formation of a superficial layer of oil. But the decomposition takes place in a very peculiar

manner, and under such conditions that there is a gradual transition from the soapy liquid in the interior to the oily layer at the top, and not, as when we float a layer of oil on water, two sudden transitions, first from water to oil, and secondly from oil to air. The difference is important, because, as I showed some years ago, capillary tension depends on the suddenness of change. If we suppose that the change from one liquid to another takes place by slow stages, though the final change may be as before, the capillary tension would absolutely disappear.

There is another very interesting class of phenomena due to oil films, which I hope to illustrate, though I am conscious of the difficulty of the task,—namely, the action of oil in preventing the formation of waves. From the earliest times we have records of the effect of oil in stilling waves, and all through the Middle Ages the effect was recognised, though connected with magic and fanciful explanations. Franklin, than whom, I suppose, no soberer inquirer ever existed, made the thing almost a hobby. His attention was called to it accidentally on board ship from noticing the effect on the waves caused by the greasy debris of a dinner. The captain assured him that it was due to the oil spread on the water, and for some time afterwards, Franklin used to carry oil about with him, so as never to miss a chance of trying an experiment. A pond is necessary to illustrate the phenomena properly, but we shall get an idea of it by means of this trough six feet long, containing water.† Along the surface of the water we shall make an artificial wind by means of a fan,‡ driven by an electro-motor. In my first experiments I used wind from an organ bellows, which is not here available. Presently we shall get up a ripple, and then we will try the effect of a drop of oil put in to windward. I have now put on the drop, and you see a smooth place advancing along. As soon as the waves come up again, I will repeat the experiment. While the wind is driving the oil away, I may mention that this matter has been tested at Peterhead. Experiments were there made on a large scale to show the effect of oil in facilitating the entrance of ships into harbour in rough weather. Much advantage was gained. But here a distinction must be observed. It is not that the large swell of the ocean is damped down. That would be impossible. The action in the first instance is upon the comparatively small ripples. The large waves are not directly affected by the oil; but it seems as if the power of the wind to excite and maintain them is due to the small ripples which form on their backs, and give the wind, as it were, a better hold of them. It is only in that way that large waves can be affected. The immediate effect is on the small waves which conduce to that breaking of the large waves which from the sailor's point of view is the worst danger. It is the breaking waters which do the mischief, and these are quieted by the action of the oil.

I want to show also, though it can only be seen by those near, the return of the oil when the wind is stopped. The oil is at present driven to one end of the trough;‡ when the wind stops it will come back, because the oil film tends to spread itself uniformly over the surface. As it comes back, there will be an advancing wave of oil; and as we light the surface very obliquely by the electric lamp, there is visible on the bottom of the trough a white line, showing its progress.

Now, as to the explanation. The first attempt on the right lines was made by the Italian physicist, Marangoni. He drew attention to the importance of contamination upon the surface of the water, and to its tendency to spread itself uniformly, but for some reason which I cannot understand, he applied the explanation wrongly.

* The width is 8 inches, and the depth 4 inches. The sides are of glass; the bottom and ends of wood, painted white.

† For this fan and its fittings the Institution is indebted to the liberality of the Blackman Ventilating Company.

‡ May, 1890. Any moderate quantity of oil may be driven off to leeward; but if oleate of soda be applied, the quieting effect is permanent.

More recently Reynolds and Aitken have applied the same considerations with better success. The state of the case seems to be this:—Let us consider small waves as propagated over the surface of clean water; as the waves advance, the surface of the water has to submit to periodic extensions and contractions. At the crest of a wave the surface is compressed, while at the trough it is extended. As long as the water is pure there is no force to oppose that, and the wave can be propagated without difficulty; but if the surface be contaminated, the contamination strongly resists the alternate stretching and contraction. It tends always, on the contrary, to spread itself uniformly; and the result is that the water refuses to lend itself to the motion which is required of it. The film of oil may be compared to an inextensible membrane floating on the surface of the water, and hampering its motion; and under these conditions it is not possible for the waves to be generated, unless the forces are very much greater than usual. That is the explanation of the effect of oil in preventing the formation of waves.

The all-important fact is that the surface has its properties changed, so that it refuses to submit to the necessary extensions and contractions. We may illustrate this very simply by dusting the surface of water with sulphur powder, only instead of dispersing the sulphur, as before, by the addition of a drop of oil, we will operate upon it by a gentle stream of wind projected downwards on the surface, and of course spreading out radially from the point of impact. If Mr. Gordon will blow gently on the surface in the middle of the dusty region, a space is cleared;* if he stops blowing, the dust comes back again. The first result is not surprising, but why does the dusty surface come back? Such return is opposed to what we should expect from any kind of viscosity, and proves that there must be some force directly tending to produce that particular motion. It is the superior tension of the clean surface. No oil has been added here, but then no water surface is ever wholly free from contamination; there may be differences of degree, but contamination is always present to some extent. I now make the surface more dirty and greasy by contact of the finger, and the experiment no longer succeeds, because the jet of wind is not powerful enough to cleanse the place on which it impinges; the dirty surface refuses to go away. or if it goes in one direction it comes back in another.

(To be continued).

NOTE ON THE RECENT CONSTRUCTION OF THREE MODIFIED FORMS OF VOLTAIC CELLS.

By H. N. WARREN, Research Analyst.

THE first voltaic cell of which I wish to make mention, and which is used practically in the same manner as an ordinary Bunsen cell, consists of a zinc outer cylinder excited by dilute sulphuric acid, but enclosing a porous pot containing a saturated solution of arsenic acid in place of the nitric acid of commerce. The circuit is completed by inserting into the acid a carbon rod, the connections being made in the usual manner. The battery evolves a constant supply of electricity, the electromotive force being about 1½ volts, the reaction terminating with the production of arsenious acid, and the solution of an equivalent proportion of zinc. This form of cell evolves no noxious odours similar to what is experienced when using the nitric acid battery, but unfortunately, owing to a somewhat osmotic passage of the arsenious acid into the outer vessel, it occasions a danger of forming arseniuretted hydrogen through coming into contact with the zinc cylinder. To overcome this danger naturally necessitates

the placement of the same either out of doors or where a good draught can be assured.

The second cell or bromine battery, another modification of the first, differing only in minute details, is comprised by adopting for the round porous pot that of the flat form, and bounded on either side by flat plates of zinc; the inner cell being furnished with a platinum plate in place of the graphite rod, and excited by water which has been saturated with bromine, a small excess of the latter being also allowed to remain at the bottom of the cell in order to replenish the waste. The cell when in full action affords a constant current of electricity, the chief secondary compound formed being apparently hydrobromic acid, the bromine of which may be again set free by the addition of a small quantity of bleaching-powder.

The third, a modification of the copper sulphate battery, which has taken the name of the asbestos battery, not that that substance plays any decided action as regards an exciting agent, but serves admirably to prevent too intimate a contact between the copper and zinc plates. The battery may be arranged either single or compound, and if the latter be desired, consists in arranging a various number of zinc coils coated both sides with asbestos paper, and bound over in close proximity with thin copper foil; the coils may be for convenience sake arranged by placing one inside the other, the battery being excited by immersing the whole in a saturated and acidified solution of copper sulphate, the supply being maintained by an ordinary receiver containing a further quantity of crystals. The action of the asbestos may be thus readily explained. When to a solution of copper sulphate containing a coil of metallic copper, there is introduced one of zinc for a few moments, a most energetic action is set up, which nevertheless soon terminates with the deposition of metallic copper; this exciting power thus established owing to the small space allowed between the asbestos and the zinc, and at the same time the excellent conducting power of the large surface of copper exposed on either side of the zinc plates, immediately conveys any current which would otherwise be lost on to the terminus.

NOTES ON QUANTITATIVE ANALYSIS.*

By L. H. FRIEDBURG, Ph.D.

THE following chapters make but little claim to originality, and treat only of well-known facts. But as every chemist during a long period of analytical occupation develops for himself a particular *modus operandi*, based upon results obtained, it is proper to recommend what he deems to be valuable. In this sense I offer the following descriptions given below, omitting all reference to literature or authorship of the different methods; premising only that not one is described that I have not myself frequently used.

A.—ACIDIMETRY AND ALKALIMETRY.

The test liquids used are hydrochloric acid and ammonium hydrate. It is customary to prepare normal or decinormal solutions. With solids, provided they are pure, this may be arrived at to a degree of accuracy practically sufficient. With solutions of gases, such as HCl or NH₃, the preparation of a normal solution, even if performed with the greatest care and the best standardised measuring vessels or specific gravity apparatus, we cannot omit quantitative determination of at least one of the liquids prepared. The following figures will show that in trying to prepare normal solutions of the aforesaid liquids a difference of 0.1957 per cent of HCl and 0.0740

* This experiment is due to Mr. Aitken.

* From the *Journal of the American Chemical Society*, vol., xii., No. 5.

per cent of nitrogen were quantitatively determined. For very accurate work such determination ought to be made, and no attempt to normalise afterwards by dilution or concentration is necessary or desirable. The measuring of new quantities of liquids is a source of new errors at best. The sacrifice of the advantage of rapid final calculation of results with such solutions is well balanced by greater accuracy obtained.

900 c.c. hydrochloric acid, *puriss.*, sp. gr. 1.20, were mixed with about 8000 c.c. of distilled water, while 450 c.c. of the commercially pure strong ammonium hydrate were added to about 6400 c.c. of dist. water. The mixtures were allowed to stand for a week. Then it was ascertained how these two liquids would neutralise each other by volume. The whole length of the burettes was used, and in the last determination they were filled up again. It was found, using cochineal as an indicator, that:—

- a. 20 c.c. HCl were neutralised by 25 c.c. NH_4OH .
- b. 20 " " " " 25 " NH_4OH .
- c. 20 " " " " 24.95 c.c. NH_4OH .

20 c.c. HCl therefore corresponded to 25 c.c. NH_4OH .

Next, three different weighed quantities of HCl were taken and neutralised (using the same indicator) with ammonia. The results were:—

- a. 19.7861 grms. HCl required 24.30 c.c. NH_4OH ;
consequently, 1 grm. HCl required 1.228 c.c. NH_4OH .
 - b. 5.8800 grms. HCl required 7.20 c.c. NH_4OH ;
therefore, 1 grm. HCl required 1.224 c.c. NH_4OH .
 - c. 15.4551 grms. HCl required 19.00 c.c. NH_4OH ;
or, 1 grm. HCl required 1.229 c.c. NH_4OH .
- 1 grm. HCl, therefore, was neutralised by 1.23 c.c. NH_4OH .

Finally, three chlorine determinations were made. The silver chloride was dried as usual, but only that part of it which would spontaneously leave the filter when emptied into the porcelain crucible was determined as horn silver; the filter and the remaining amount were burned in a weighed platinum spiral until the silver was reduced to a metallic state, adhering as a little knob to the wire, which was again weighed. Following are the results:—

- a. 0.9710 grms. HCl gave 1.66603 grms. AgCl, equal to 0.42362 HCl.
- b. 1.8240 grms. HCl gave 0.3023 grms. AgCl, equal to 0.0769 HCl.
- c. 7.8802 grms. HCl gave 1.31663 grms. AgCl, equal to 0.33478 HCl.

From these analyses the following amounts of HCl in one grm. of the liquid were calculated:—

- a. 1 grm. HCl contains 0.04249 grm. HCl gas.
- b. 1 grm. HCl contains 0.04218 grm. HCl gas.
- c. 1 grm. HCl contains 0.042485 grm. HCl gas.

A noticeable loss having occurred in the determination b, the average of a and c was taken; 1 grm. HCl contains 0.04249 gaseous HCl. The difference between the average taken from all three determinations, and of that from the two mentioned, however, is only 0.0001 grm.

From all the above it follows that:—

- 1 grm. HCl solution is neutralised by = 1.23 c.c. NH_4OH solution.
- 1 grm. HCl solution contains = 0.04249 gr. HCl gas.
- 1 c.c. NH_4OH solution contains = 0.013264 grm. nitrogen.
- 1 c.c. NH_4OH solution is neutralised by = 0.8 c.c. HCl solution.
- 1 c.c. HCl solution contains = 0.034543 grm. HCl gas.
or = 0.033596 grm. chlorine.

These solutions were prepared in February, 1888. The HCl solution was kept in a large flask with doubly perforated rubber stopper, one hole of which allowed the escape of the liquid by means of a syphon (or self-feeding burette), while the second opening was connected with a small flask containing a few c.c. of the same liquid as the large one. The ammonia bottle was closed with a doubly perforated cork. A small flask, containing a little liquid of the same strength, a second small flask, which is kept empty, and finally a cylinder containing cotton, solid KOH, and again cotton, are attached, in the above sequence, to one opening, the other serving for the outlet of the liquid.

These liquids are kept standing in the laboratory, not exposed to direct sunlight, but subject to the natural variations of temperature during the year. Nevertheless, they have not changed during these last two years under the given conditions. To-day, as two years ago, 20 c.c. of the HCl solution is saturated by 25 c.c. of the ammonia solution, while both solutions, when used in a nitrogen determination of urea which had been six times re-crystallised and finally dried over sulphuric acid, then heated with soda-lime, was shown to have retained the previously determined percentage, the urea analysis yielding figures of *absolute* correctness.

(To be continued).

THE ELECTROMOTIVE FORCE OF METALLIC SALTS.*

By CLARENCE L. SPEYERS.

(Concluded from p. 294).

In the following tables the column headed *v* contains the number of litres of water in which a grm. equivalent of the salt has been dissolved, that headed E. F. the corresponding electromotive force in volts (10^8 C. G. S.), and that headed Δ the difference between successive values of E. F. Any deviation from the mean exceeding 1 per cent is noted in the tables. The observations have all been duplicated, and sometimes quadruplicated.

Until more data have been accumulated, the above results cannot be most intelligently discussed, but a glance at the tables will show a few interesting facts.

1. The electromotive force always increases on dilution; the increment of nitric, acetic, and sulphuric acids is very slight, it is true, but still sufficiently marked, in the opinion of the writer, to be unmistakable. At any rate, there is no diminution, and therefore the equivalent electromotive force (electromotive force $\times$ equivalent weight, due account being taken of the quantity contained in the liquid) increases rapidly.

2. Hydrochloric acid has a much lower value than the other three acids, which form a group by themselves, with approximately equal values. It may appear strange that this acid should have an electromotive force so much inferior to that of acetic acid, but the agreement of repeated measurements indicated that they were correct.

3. The electromotive force of a mixture of equal equivalents of an acid with hydrochloric acid is not the mean of the two values, but is only slightly greater than that of hydrochloric acid. The increment also belongs to this acid. Nitric, acetic, and sulphuric acids have an electromotive force so nearly alike that no conclusion can be drawn from their mixtures.

4. Turning to the zinc salts, we find a drop in electromotive force of 33(Cl), 59(NO_3), 166(Ac), and 129(SO_4) millivolts. The first observed values, $\frac{1}{2}$ equivalent, are compared. The increment, however, has been increased. As the solutions are diluted, the fall due to substitution of zinc for hydrogen appears to approach that observed with chlorine, 33 millivolts.

by h the weight of resin contained in a weight = 100 of the mixture, we have—

For the mixture of linseed oil in refined resin oil $[\alpha]_D = + \frac{1}{2} h$; ditto linseed oil and selected white oil, $[\alpha]_D = + \frac{1}{2} h$; ditto linseed oil and fine rectified oil, $[\alpha]_D = + \frac{1}{2} h$. The first mixture is that which is most commonly met with. In practice it is sufficient to measure $[\alpha]_D$ with the polarimeter or to value h in refined resin oil according to the formula $h = [\alpha]_D \frac{1}{\frac{1}{2}}$.

As the oils in question are deeply coloured it is better to operate in a tube of 10 c.m., and to calculate h by the formula $h = \alpha_D \frac{1}{\frac{1}{2}}$.

2. *Assay of a Paint.*—To detect oil of resin in commercial paint we operate as follows:—

a. We put in a flask a certain quantity of paint, add ether, agitate and let settle. The ether having dissolved the paint floats at the top. The tube of the polarimeter is filled with the ethereal solution. If the rotation observed is null, the resin oil is present. In the contrary case, if $[\alpha]_D$ is the rotation to the right measured for the thickness of 20 c.m., a study of the rotatory power of the ethereal solutions of resin oil and of linseed oil mixed with resin oil has shown that the proportion of resin oil added may be calculated by the formula—

$$h = \frac{[\alpha]_D}{43^1}$$

b. We put in a flask a weight p_1 of the ethereal solution; we heat to 100° in the water-bath so as expel the ether; the oil, which only boils about 300°, remains in the flask; let p_2 be its weight. We determine thus the proportion—

$$\frac{p_1}{p_2} \times 100 = h,$$

for 100 of the oil (linseed oil and resin oil) contained in the ethereal solution examined with the polarimeter.

If $h_1 = h$ we may conclude that the paint contains oil of resin without linseed oil.

In the ordinary case h_1 is greater than h ; then—

$$\frac{h}{h_1} \times 100$$

will be the percentage of resin oil contained in the linseed oil which has been used in making up the paint.—*Comptes Rendus*, vol. cx., p. 1273.

RECENT SYNTHETICAL EXPERIMENTS IN THE SUGAR SERIES.*

PROFESSOR EMIL FISCHER'S researches on the sugars of the glucose group have been remarkably successful, and recently he has effected the synthesis of both dextrose and levulose. A year ago, in the *American Chemical Journal*,† the experiments were described by means of which he had succeeded in preparing a new synthetical sugar, which he called acrose, and which was found to be an isomer of dextrose and levulose. Acrose possesses all the general properties of dextrose and levulose, and only differs from these natural sugars in being optically inactive. Fischer has now succeeded in determining the constitution of acrose, and in his recent papers‡ he has shown that it is the inactive modification of levulose. It bears the same relation to ordinary levulose that racemic acid bears to ordinary tartaric acid; and just as racemic acid can be split into dextro- and levo-tartaric acids, so from acrose ordinary levulose and a new levulose having an equal but opposite rotatory power can be obtained.

The obstacles that are encountered in this kind of work are very great, and one can gain some idea of the diffi-

culty of determining the constitution of a sugar by remembering that, according to the Le Bel-Van't Hoff hypothesis,* a compound with four asymmetric carbon atoms like dextrose can exist in sixteen stereometric forms. Nevertheless Fischer has not only determined the constitution of acrose and effected the synthesis of levulose, but he has also discovered the inactive and the levo-modifications of mannite and of the new sugar, mannose. He has shown that mannose and dextrose have the same constitution and that one may be converted into the other. He has further prepared all these substances synthetically, and, what is also of very great importance, he has developed and perfected the methods of transforming the sugars and their derivatives into one another to such an extent that the synthesis of the remaining members of the glucose group will probably be effected in the near future. In fact, so great are the additions to our knowledge resulting from these researches that Fischer's work may well be said to mark the beginning of a new epoch in the history of the carbohydrates.

Mannose.

This new sugar was discovered by Fischer‡ in studying the oxidation-products of the poly-acid alcohols with the aid of phenylhydrazine. It is obtained, together with levulose, by the oxidation of mannite with nitric acid, and it can readily be distinguished from the other sugars on account of the insolubility of its hydrazone. Mannose has the composition represented by the formula $C_6H_{12}O_6$, and is therefore isomeric with dextrose and levulose, and, like these, it reduces Fehling's solution, and undergoes fermentation when mixed with yeast. It is optically active, and turns the plane of polarised light to the right, but not so strongly as dextrose. Its specific rotatory power is $+12.96$, that of dextrose being $+58.7$. Reduction with sodium amalgam converts it into mannite. Mannose has not yet been obtained in crystalline condition. The white solid sugar deliquesces rapidly in moist air, and is extremely easily soluble in water. It dissolves with difficulty in absolute alcohol, and is insoluble in absolute ether. Like dextrose and levulose, mannose can be converted in furfural and levulinic acid. Treatment with bromine-water converts it into mannonic acid, an isomer of gluconic acid.

But the distinguishing characteristic of mannose is its behaviour with phenylhydrazine. The cold aqueous solution of the sugar, when treated with phenylhydrazine, gives at once a crystalline precipitate of mannose phenylhydrazone, whereas the hydrazones of dextrose and levulose and the other sugars are readily soluble in water. When heated with more phenylhydrazine, the mannose hydrazone is converted into an osazone, which is identical in all its properties with phenylglucosazone, the compound that is obtained from dextrose and levulose under similar circumstances. As glucosazone can be converted into levulose, it is therefore possible by this means to transform mannose into levulose.

*Constitution of Mannose.**—As mannose differs in properties from both dextrose and levulose, it was at first supposed that its constitution was different from that of either of these sugars. Thus, the formula of dextrose being—

and that of levulose—

the formula—

suggested itself for mannose. In order to obtain experimental evidence either for or against this formula, mannose was treated with hydrocyanic acid, according to Kiliani's§ method of determining the constitution of

sugars. Direct addition took place, and from the resulting compound mannose-carbonic acid was obtained. This acid, upon reduction with hydriodic acid, was converted into normal heptioic acid. This result indicates that the constitution of mannose cannot be represented by the formula given above, because a sugar whose constitution is represented by that formula would by this process have been converted into an isoheptioic acid. But the fact that normal heptioic acid was obtained indicates that mannose contains an aldehyd group, and that its constitution must be expressed by the same formula as that which represents the constitution of dextrose. Mannose and dextrose are, therefore, physical isomers. To explain this isomerism recourse must be had to the Le Bel-Van't Hoff hypothesis, according to which it is possible to foresee the existence of eight optically active and eight inactive compounds of the formula of dextrose. Both compounds are dextro-rotatory, but as one of them turns the plane of polarised light to a much greater extent than the other, Fischer at first supposed that dextrose and mannose were optical isomers, that they were the dextro- and levo-modifications of the same structural system, and that the rule which usually holds in such cases, namely, that the one isomer turns as far to the left as the other to the right, was modified in this case in some unknown manner by the remaining asymmetric carbon atoms. This supposition was not confirmed by subsequent experiments, for, as will be shown below, another mannose similar in all its properties to the one here described, but possessing an equal but opposite rotatory power, was obtained from arabinose carbonic acid.

Reduction of the Acids of the Sugars.*

Before proceeding to describe how the optical isomer of mannose was obtained, it is necessary to call attention to a reaction which is of some importance, and which is a general one for the acids of the sugar series. Ordinarily the carboxyl group of organic acids cannot be reduced to the aldehyd group by means of nascent hydrogen. This reduction, however, takes place readily, as has been discovered by Fischer, in the case of the sugar acids that yield lactones. If gluconic acid lactone, for example, be treated with sodium amalgam, and the solution be acidified from time to time, it soon acquires the power of reducing Fehling's solution, and by continued action a solution of sugar is obtained. The solution contains dextrose, and when it is treated with phenylhydrazine it gives glucosazone. In the same way mannonic acid, obtained by the oxidation of mannose with bromine-water, was reduced with sodium amalgam and mannose again obtained. Other sugar acids behaved in the same way—in short, the method appears to be a general one, and one of very great importance in connection with the synthesis of the sugars. It is possible by means of this method, together with Kiliani's reaction, to build up a sugar from one containing a smaller number of carbon atoms. For, by treating a sugar with hydrocyanic acid, an addition-product is obtained from which an acid containing one carbon atom more than the original sugar can be prepared. This acid can then be reduced with sodium amalgam, and thus converted into the corresponding sugar. The process of lengthening the chain of carbon atoms can then be repeated. Thus far only acids that form lactones have been reduced with sodium amalgam, and it appears that this property is in some way connected with the power of forming lactones.

Electrolysis of Aluminium Fluoride by Igneous Fusion.—Adolphe Minet.—The author has operated upon aluminium fluoride, and has obtained from one horse-power an hourly production of 30 gms. aluminium. —*Comptes Rendus*, vol. cx., No. 23.

* Ber. d. Chem. Ges., xxii., 2204.

PROCEEDINGS OF SOCIETIES.

PHYSICAL SOCIETY.

June 20, 1890.

Prof. W. E. AYRTON, F.R.S., President, in the Chair.

Prof. A. W. WORTHINGTON made a communication on "*The Stretching of Liquids.*"

The three known methods by which this may be effected, viz., the barometer tube method, the centrifugal method, and the method of cooling, were described, and the precautions necessary in filling the tubes and in freeing the liquids from air discussed. With non-volatile liquids, such as sulphuric acid, the tubes are put in communication with a good pump, and before sealing, the liquid in the tube is kept at a higher temperature than that in the communicating vessel, in order that a stream of vapour may be passing outwards and carry with it any air liberated from the glass during the process of sealing.

Before using tubes by the centrifugal method the author finds it advantageous to subject them to considerable "jarring" at intervals. This usually breaks the liquid column and liberates a small bubble of air, which may then be floated out. By repeating this many times, the adhesion of the liquid is greatly increased. With these precautions he had subjected water to a tension of 7.5 and sulphuric acid to 12 atmospheres. The cooling method of Berthelot (*Ann. de Chimie*, xxx., 1852) was then tried. In this method the liquid nearly fills a strong closed glass tube at a particular temperature. On slightly heating it expands and fills the whole tube, any residual air being dissolved. On cooling again, the liquid remains extended and still fills the tube, until at last it lets go with a violent "click," and the bubble of residual air and vapour reappears. The tension of the liquids tested under these circumstances have usually been calculated from the relative change of volume on the assumption that the coefficient of extensibility is the same as that of compressibility.

The author exhibited and described an apparatus by which the tension and the extension can be measured simultaneously. The tension is ascertained from the enlargement of the ellipsoidal bulb of a thermometer sealed into the containing vessel, and the extension calculated from the volume of the bubble after the click. The tension thermometer had been calibrated by internal pressure, and in determining the extension correction is made for the change of volume of the apparatus. By this method he had subjected alcohol to a tension of 17 atmospheres, and found that the coefficient of extensibility is much less than that of compressibility. It is not clear as to what causes the liquid to let go of the glass, but it is found that the bubble can be caused to reappear by passing an electric current through a wire sealed in the capillary tube.

Sir Wm. THOMSON remarked that Prof. Worthington's paper was a curious commentary on the usual mathematical definitions of "a liquid," as a substance which offered no resistance to being separated into parts. Speaking of freeing liquids from air, he said the beneficial effect of jarring could easily be shown by tapping an ordinary "philosophical hammer"; separation of the column always leaves a bubble, which can then be floated off. He had also found that in freeing liquids from air by boiling it was advantageous to have a long escape tube, so that part of the liquid condenses and runs back.

Mr. C. V. BOYS read a paper on "*The Measurement of Electro-magnetic Radiation,*" by himself, Messrs. A. E. BRISCOE, and W. WATSON.

When Mr. Gregory described his new electric radiation-meter on Nov. 1, 1889, one of the authors said that the observed effect might be due to some cause other than expansion by heating, and that if it was a true heating

effect it might be measured thermally. The present communication describes experiments undertaken to investigate the question. The first method employed was developed from the idea that if two fine wires be placed near together, and both act as resonators to a primary oscillator, the electro-dynamic attraction caused by the electric currents up and down the wires and the electrostatic repulsion between the charges on them, might result in the relative motion of the two wires. From theoretical considerations, based on the assumptions that the currents are harmonic in time and space, the authors inferred that the electro-dynamic effect would preponderate at the middle of the wires, whilst the electrostatic repulsion would be greater at the ends. To cause the attractions and repulsions to conspire in producing rotation cranked resonators, A B C (see fig.) were made; one

was fixed and the other suspended by a quartz fibre, to turn about a middle line, D E. These were enclosed in a glass vessel, and on starting the oscillator a turning movement was observed in a direction opposite to that expected. This motion was eventually traced to the electrostatic influence of the oscillator, for although the imperfectly conducting surface of the glass acted as a perfect screen from such action when the potentials of the oscillation were varied slowly, it did not do so for changes occurring about 500,000,000 times per second. After adopting means to avoid this disturbance, and constructing lighter resonators, the experiments were repeated with negative results. From the dimensions of the quartz fibre used it was estimated that a force of 158-1,000,000ths of a grain could have been detected with certainty; this would have corresponded to about 1-300th of an ampère in each resonator. It is hoped that by further increasing the sensitiveness of the apparatus and using parabolic reflectors the effect sought for may be detected.

In the second method of attacking the subject, a Joule's dynamic air-thermometer was employed. This consisted of a glass tube with a partition along the middle extending nearly to the ends. If one side of the tube be warmed, convection currents circulate and deflect an index placed in the stream. A small mirror suspended about one edge and counterpoised was used for an index, and was so sensitive that it was impossible to get the air still enough by any ordinary method of screening. However, by the ingenious device of putting the thermometer within a larger tube kept rotating by clockwork, the difficulties were surmounted. A doubled wire placed in one side of the thermometer served as resonator, and on starting the oscillator a large deflection resulted. A similar deflection was caused by applying about $\frac{1}{2}$ of a volt to the ends of the wire. This proved that the effect observed by Mr. Gregory is due to heating. The least rate of heating observable with the air thermometer was found to correspond to 1 calorie (gramme-water-centigrade) per 24 hours in the whole tube, or 1 calorie per centimetre of wire in 103 days.

Dr. LODGE asked Sir William Thomson whether, when electric pulses travel along parallel wires with the velocity of light, any action could exist between them, for two charged spheres travelling together at that velocity exert no mutual attraction or repulsion.

In reply, Sir WILLIAM said he was inclined to think Mr. Boys' treatment of the subject was in the main correct, but it was quite possible that at such velocities the

ordinary laws might be modified by the fact that the time taken for the force to be propagated from wire to wire is comparable with that required for the pulse to travel the whole length of the wire. As an example of the peculiar effects of rapid discharges he said he had seen two copper wires which had been flattened against each other by lightning.

Mr. BOYS thought that in his resonators a condition analogous to stationary waves would exist, for the pulses are reflected from the ends.

Dr. LODGE said he had that afternoon observed the action of parallel strips when Leyden-jar discharges were passed through them. The strips gave a kick at each discharge.

Mr. GREGORY mentioned that in trying to increase the sensitiveness of his meter so as to measure the variation with distance, he had found that two resonators in proximity interfered with each other. He had, however, succeeded in increasing the sensibility about five-fold.

Prof. WORTHINGTON asked if it was possible to measure the energy of the oscillator, and also whether the quantity caught by the resonator could be estimated from the solid angle it subtended at the source of energy, wherever that might be.

Prof. PERRY considered it easier to infer the energy of the source from that received by the resonator.

Dr. LODGE said the energy of the source could be easily measured. The power radiated was enormous whilst it lasted, vastly exceeding that of tropical sunshine; if it could be made continuous, the apparatus would soon be red hot. The energy radiated, he said, converges on the resonators, and hence the solid angle method of estimating the amount received would be erroneous. Moreover, the source was not at the oscillator, but at a quarter wave-length from it, and most of the energy returns to the oscillator; only a small fraction is splashed off and sent into space. Small oscillators radiate powerfully because the quarter wave-lengths are small; whereas the slow oscillators, or alternators used commercially, radiate very little of their energy. The exact law of variation of intensity of radiation with distance was rather complicated, but the theory had been completely worked out by Stokes in 1848.

Mr. BLAKESLEY thought the energy that returns to the oscillator would be available for subsequent radiations.

Dr. LODGE pointed out that wires or other resonators placed within the quarter wave-length would intercept part of the returning energy.

Two communications, "*Notes on Secondary Batteries*," by Dr. GLADSTONE and Mr. HIBBERT, and "*An Easy Rule for Calculating Approximately the Self-Induction of a Coil*," by Prof. PERRY, were taken as read.

In the first of these the authors show cause for believing that the beneficial effect produced by adding sodium sulphate to the ordinary electrolyte is due partly to its facilitating the reduction of lead sulphate and also to its power to diminish local action between the electrolyte and different parts of the lead plates. As regards the chemical actions which take place during the working of ordinary cells, they see no reason to doubt the view put forward by one of them in 1882, that the substance produced in the voltaic reaction is ordinary lead sulphate, $PbSO_4$. They also conclude that the high E.M.F. of a cell immediately after stopping the charging current is due to the inequality of acid strength near the two plates, and the gradual fall of E.M.F. is caused by the equalisation of strength produced by diffusion.

Prof. PERRY's rule relates to hollow cylindrical coils, and is expressed by the following formula:—

$$L \text{ (in secohms)} = \frac{n^2 a^2 \div 10^7}{1.844a + 3.1c + 3.5b}$$

Where n = number of windings.

a = mean radius of winding in centimetres.

b = axial length.

c = radial depth of winding,

and b and c are less than $\frac{a}{2}$.

The time-constant of such a coil is given in terms of the volume of copper (V) in cubic centimetres by—

$$\frac{L}{R} = \frac{V \div 1000}{0.728a + 1.33c + 1.5b}$$

and the conditions for making this small are pointed out in the paper.

A paper by the Rev. T. Pelham Dale was postponed till next meeting.

NOTICES OF BOOKS.

The Extra Pharmacopœia: with the additions introduced into the British Pharmacopœia, 1885. By W. MARTINDALE, F.C.S.

Medical References, and a Therapeutic Index of Diseases and Symptoms. By W. WYNN WESTCOTT, M.B. Sixth Edition. London: Lewis.

British Pharmacopœia, 1885, Addendum, 1890. Summary of Suggestions and List of Articles to be included.

THE authors, in their preface, very judiciously contend that medicines should be combined extemporaneously to suit the disease, instead of, as is now too commonly the case, the patient being treated by ready-made compounds prepared to suit imaginary cases. They give a list of the additions to the British Pharmacopœia made at the revision in 1885, as well as other important changes. It is complained that the range of doses ordered is too limited, the minimum being often too large and the maximum too small.

The last-mentioned pamphlet contains a list of articles recommended for official introduction by the medical authorities—to wit, the Royal Colleges of Physicians and Surgeons of London, the Society of Apothecaries of London, the Royal Colleges of Physicians and Surgeons of Edinburgh, the Faculties of Physicians and Surgeons of Glasgow, the Universities of Edinburgh, Aberdeen, and St. Andrews, the King's and Queen's College of Physicians of Ireland, and the Apothecaries Hall of Ireland.

Practical Chemistry for Medical Students Required at the First Examination of the Conjoint Examining Board in England. By S. RIDEAL, D.Sc., F.I.C., F.C.S., F.G.S. London: H. K. Lewis.

THE work before us is avowedly examinational. It is to furnish the student, or rather the examinee, with just so much knowledge of chemical analysis as will be required from him on one particular occasion. Instructions are given by identifying fifteen metals and seven acids, the former being present "as metal, oxide, sulphides, or simple salts." Mixtures and complex compounds do not lie within the scope of this manual. For the selection of the substances dealt with, the insertion of some and the omission of others, the author is not responsible. He who would be the "guide, philosopher, and friend" of our modern alumni, whether his teachings are *viva voce* or are conveyed through the medium of printers' ink, must not even by implication question the wisdom of "examining boards." Against the "hints for work" and the tests laid down, nothing can be said. But have they not all been already given in works of all sizes and of many prices?

A Novel Method of Preparing Anhydrous Aluminium Chloride.—C. F. Mabery (*Berichte*).—The author causes gaseous hydrochloric acid to act upon an alloy of aluminium and copper. The copper is not attacked.—*Moniteur Scientifique*, March, 1890.

CORRESPONDENCE.

MEDICAL OFFICERS OF HEALTH AND PUBLIC ANALYSTS.

To the Editor of the Chemical News.

SIR,—Referring to Mr. White's letter (*CHEMICAL NEWS*, vol. lxi., page 301), I am sure nobody would think of doubting the ability of men like Drs. Tidy, Stevenson, Hill, and Adams to fill the positions which they respectively hold to the satisfaction of everyone concerned, as these gentlemen have made chemistry a special study, in addition to being thoroughly qualified from a medical point of view.

When I last wrote I had in my mind the above named "Medico-Public Analysts," as well as one or two others of lesser note, but their undoubted efficiency seems to me to emphasize all the more forcibly my contention as regards the incompetency of many candidates for similar positions. The fact is, in filling vacancies of this nature, the chemical aspect of the question is often altogether ignored, or, at any rate, regarded as of secondary importance, it being taken for granted, I suppose, that the work will be done somehow.

An instance occurs to me in which a very unsuitable man was chosen to fill the dual offices of Medical Officer of Health and Public Analyst in a large town in the Midlands. He obtained the appointment, I understand, entirely through local influence.—I am, &c.,

ROWLAND WILLIAMS.

Laboratory and Assay Office,
28, Pall Mall, Manchester.
June 24th, 1890.

ESTIMATION OF ALUMINA IN IRON AND STEEL.

To the Editor of the Chemical News.

SIR,—I notice in your last issue a letter from Mr. Charles Phillips describing a method for the determination of aluminium in iron and steel, and which is substantially the same as that described by Mr. J. E. Stead in a paper read before the Society of Chemical Industry at Newcastle early in December, 1889.

As no mention is made of this paper in your correspondent's letter, I think it only fair to Mr. Stead to call the attention of your readers to his work in this direction.

I enclose you copy of the paper referred to, which I think will clearly show Mr. Stead's priority.—I am, &c.,

C. H. RIDSDALE.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cx., No. 24, June 16, 1890.

On the Different Isomeric Inosites and on their Heat of Transformation.—M. Berthelot.—The author has found that the two symmetric inosites have substantially the same solution-heats, precisely as is the case with the two symmetrical tartaric acids. The mixture of the two solutions (previously brought to an identical temperature) produces no thermic phenomenon. The neutral inosite, by compensation, shows a solution-heat of -7.47 cals. higher in absolute value than each of the active inosites, a fact identical with that observed in the three corresponding tartaric acids.

Combinations and Reactions of Gaseous Ammonia and of Gaseous Hydrogen Phosphide upon the Halogenous Compounds of Arsenic.—M. Besson.— PH_3 in excess gives, at common temperatures at least, with arsenic bromide and iodide, products analogous to those resulting from the decomposition at 300° of the corresponding ammonium compounds. There is this difference: that as nitrogen has no affinity for arsenic, these two bodies remain isolated, whilst phosphorus and arsenic unite.

A New Method of Forming Crystalline Metallic Oxychlorides. Researches on Copper Oxychlorides.—G. Rousseau.—The author's new method of forming oxychlorides, described in a former communication, is confined to those of tin, antimony, titanium, bismuth, zinc, and iron. On heating for three days to between 180° and 200° , a solution containing 1 mol. copper chloride and 6 mols. of water, he obtained crystallised atacamite. The crystals are very small on operating in presence of marble, but if grobertite is used fine crystals are obtained, identical with those of natural atacamite.

Combination of Phosphorus Pentafluoride with Hyponitric Acid.—Emil Tassal.—Phosphorus pentafluoride yields, with hyponitric acid, an addition compound, NO_4PF_5 , and not substitution-products, as with the corresponding compounds of chlorine. Phosphorus pentafluoride is only decomposed after the prolonged action of very strong induction-sparks. Its resistance to chemical and physical agents should lead to an explanation of the formation of addition-compounds in preference to substitution-compounds.

Formation-heat of Uric Acid and the Alkaline Urates.—C. Martignon.—The formation-heat of uric acid, setting out from its elements, = +148.1 cal.; that of bibasic potassium urate = +256.2 cal.; that of the monobasic potassium salt = +207 cal. For the sodium salts we have 310.9 cal. for the bibasic urate and 237.6 cal. for the monobasic urate. Uric acid should decompose tri- and bibasic sodium phosphates, liberating respectively 4.9 and 0.5 cal., and giving rise to the monobasic phosphate called *acid*. This prevision agrees with experience, and is one of the causes of the acidity of urine. The formation-heat of ammonium urate is = 183 cal.

Chloralimide and its Isomer; a Reversible Isomeric Transformation.—MM. Béhal and Choay.—The isomer in question—*isochloralimide*—is more soluble than its isomer in all organic solvents; it is insoluble in water and melts at at 103° — 104° .

On a Sophistication of Linseed Oil.—A. Aignan.—(See p. 7).

100.00

A red colouring-matter obtained during the same reaction gives, upon cotton mordanted with tannin and

antimony, a fast catechu brown having a good lustre. Upon wool prepared with potassium dichromate it gives fine shades which bear fulling. This new colour has several advantages over Bismarck brown.

New Method of Analysis for Industrial Waters which have to Undergo a Chemical Purification and for the Feed-waters of Steam-boilers.—Leo Vignoa.—This process, which refers merely to the hardness of the waters, has been already noticed. The author points out that the carbonic acid in distilled water prepared a few days ago may amount to 5 c.c.

Process for Dissociating Common Salt into Chlorine and Sodium Carbonate by Means of the Electric Current.—W. Hempel.—The products may be kept from reacting on each other by the interposition of a diaphragm between the two electrodes. The diaphragm is composed of a layer of asbestos paste, kept tightly compressed between the two electrodes, which are circular plates, the cathode of iron and the anode of carbon. The current must have at total tension of 5.7 volts. A metric horse-power (980 volt-ampères) produced by a dynamo gives, per hour, 64 grms. chlorine and 25 grms. sodium carbonate.—*Berichte*.

New Mineralogical Deposits at Tarapaca.—C. Ochsenius.—An account of beds of astrakanide and tamarugite in Chile. The particulars may be found in the *Chemiker Zeitung*.

Formation of Hydrogen Sulphide by the Action of Steam upon Lyes of Calcium Hydrosulphate.—H. Deutecom and F. Rothe (*Chemische Industrie*).—This paper cannot be given without the accompanying tables.

Generalities on Glasses.—From *Dingler's Polytechnic Journal*. A series of analyses of different qualities of glass.

A New Optical Glass (Dingler).—A notice of the glass containing phosphoric and boric acids, and used for the object-glasses of microscopes. It is said that by its means magnitudes of 1-820,000 m.m. can be recognised.

The Solubility of Sulphides in Glass.—H. Rich. Zsigmondy.—Previously noticed.

The Oriental Enamel on Bricks and its Imitations.—J. Beck (*Journal für Praktische Chemie*).—Already noticed.

Colouring-Matters.—A series of notes summarised by E. Grandmoulin, of the Chemical School of Mulhouse.

The Industrial Society of Mulhouse.—Session of January 15th, 1890.—M. Descroix, of Villefranche, has used a system of dyeing aniline blacks by "pulverisation." He has abandoned the process on sanitary grounds, as the health of the workmen suffered from the dust of aniline salt and potassium dichromate diffused in the air.

M. Jeanmaire gave some details on the injury to cloth occasioned by iron-mordants. Reducing agents, such as phosphorous and arsenious acids, sodium bisulphite, &c., if added to the mordant, retard the injuries, whilst oxidisers promote them. A cloth which had been worked in ferrous acetate at 5° B. left rolled up for a month and then dunked was weakened to the extent of 60 to 70 per cent. The action was especially manifest after dunging. If cloth is steamed immediately after mordanting it does not suffer, but if it is left folded up and then steamed the attack is manifested.

Journal de Pharmacie et de Chimie.
Series 5, Vol. xx., No. 12.

Simultaneous Determination of Carbon and Sulphur in Organic Matter.—M. Prunier.—Already inserted.

New Monobromo-camphor.—M. Cazeneuve.

On the Camphamimes, a New Class of Bases derived from Camphor.—M. Cazeneuve.—These two papers have been previously noticed.

On Eucalyptols.—M. Pannetier.—This product is a simple mixture of salicylic acid, of phenol, and of essence of eucalyptus.

Poisoning by an Edible Fungus (*Helvella esculenta*).—B. Studer, M. Demme, and J. Berlinerblau.—The fungus in question belongs to the class of *Ascomycetes*, and is commonly eaten in some parts of Germany. In the case in question its ingestion was followed by colic and vomiting. These effects are traced to the fact that during the desiccation of the mushrooms putrid fermentation had set in, determining the formation of putrefaction-alkaloids.

Vol. xxi., No. 1.

Falsification of Tea in China.—M. Riche.—Certain teas seized at Dunkirk and Paris did not differ decidedly from genuine tea in their ash and in their proportion of tannin. But they gave no crystalline theine at all, but in its stead a greenish viscid substance. It is remarked that the highest percentage of tannin found in this investigation was 16.80.

Falsification of Tea in China.—E. Collin.—The same subject from a morphological point of view. The author gives cuts showing the structural peculiarities of true and spurious teas, both as seen with the naked eye and with the microscope. He remarks that this fraud is more readily detected by means of the lens than by chemical analysis. Every true tea-leaf, of whatever variety, has serrated edges.

On the Castor Oil Seed.—E. Villejean.—M. Stillmarck finds that the residual cake from the extraction of castor oil contains a considerable proportion of a poison which is tasteless, more violent than arsenic, and which cannot be extracted from the human body by any known means. The fatal dose for a man of 60 kilos. is 18 c.m., a quantity found in 3 grms. of the castor-oil cake. This poison, which has received the name *ricinus*, is neither an alkaloid, nor a glucoside, nor an organic acid, but an albumenoid.

Fraudulent Jalap.—M. Flückiger.—The roots of jalap, which in 1842 yielded 17 per cent of resin, now rarely yield more than 12, sometimes only 7.50. The Mexican dealers extract the resin from the roots by treatment with alcohol.

Are the Hyposulphites good Antiseptics?—Prof. Perroncito.—The author shows that cultures of chicken-cholera do not lose their pathogenic properties by being kept for forty-eight hours in contact with solutions of hyposulphite (sodium thiosulphite) at 25 to 50 parts per thousand.

Journal für Praktische Chemie.
New Series, Vol. xli., Nos. 1 and 2.

Researches from the Laboratory of the University of Freiburg.—These researches comprise:—Contributions to the knowledge of the homologues of anthracene and anthraquinone, by Karl Elbs; a memoir by Ad. Claus and M. Posselt on orthooxyquinoline anasulphonic acid; a paper by Ad. Claus and G. Pollitz on α -bromquinoline; and a memoir by Ad. Claus and W. Rüppel on di- β -naphthylene ketone-oxide.

Researches from the Chemical Laboratory of Prof. Alex. Saytzeff at Kasan.—This consists of an investigation of the first oxide of the pentavalent alcohol of diallylcarbinol.

Certain Derivatives of Piazine.—P. W. Arhenius.—An account of the action of chromic acid upon derivatives of diacididihydropiazine and of the dichlordiacipiazines.

Action of Hydroxylamine Hydrochlorate upon Para-dioxyparaquinones.—Fr. Kehrmann and W. Tiesler.—Not adapted for abstraction.

Studies on Diastase.—C. J. Lintner and F. Eckhardt.—The authors conclude that both to gluten and mucidine

there adheres a substance as little known as the diastatic ferment which passes into a ferment on treatment with dilute acid or with water alone. This hypothetical substance may receive the name of fermentogen or zymogen. Bacteria cannot be concerned in the origin of diastase, since they do not exist in the interior of the grains of corn.

Vol. xli., No. 3.

Researches on the Sulphonicamides.—P. Hebenstreit.—The sulphonic cyamides form no acid alkaline salts. We must hence assume that they are distinguished from the other known derivatives of cyanamide by their tendency to polymerisation. The insolubility both of the acids and their salts in ether is noteworthy. The acids obtained are crystalline. The aromatic sulphonic cyamides contain crystalline water, one molecule being so firmly bound that when the acids are decomposed it participates in the formation of the resulting products. Benzol-sulphonic cyamide forms, when heated, benzolsulphonamide, but benzolcyanamide forms when heated a polymer. The sulphonic cyamides are strong acids and form definite salts with bases.

Researches from the Laboratory of the University of Freiburg.—These comprise contributions to a knowledge of the homologues of anthracene and anthraquinone, by K. Elbs; on the sulphonic acids of the normal propylbenzol, by Ad. Claus and O. Weizel; and on para-oxyquinoline-sulphonic acid, by Ad. Claus and M. Posselt.

MISCELLANEOUS

University College, Dundee.—A scholarship, of the value of £30 a year, has just been placed at the disposal of Prof. Percy Frankland at University College, Dundee, St. Andrew's University, by Miss E. F. Forster, of London. It is intended that the student holding the same shall devote the whole of his time to the prosecution of original research. The scholarship, which will be known as "The Forster Scholarship," has been awarded for this year to Mr. John MacGregor, M.A.

THE CHEMICAL NEWS.

VOL. LXII. No. 1598.

RAFFINOSE, MELITOSE, OR MELITRIOSE.*

By ARTHUR R. LING, F.I.C.

IN view of the discussion now going on amongst technical chemists in the sugar industry as to the presence of raffinose† in certain commercial beet-root sugars, notably those recovered from low syrups, I have been induced to compile the following *resumé* of the chemical work which has been done on this compound, there being, so far as I am aware, no such account in English chemical literature at the present time.

The fact that raffinose possesses a high dextro-rotatory power renders its detection and estimation in commercial sugars a matter of *a priori* importance, since the percentage of cane-sugar in the same is invariably determined by the optical test.

The history of the compound commences in the year 1842, when Johnston (*Mem. Chem. Soc.*, i., 159) separated a sugar from a species of eucalyptus indigenous to Tasmania. He ascribed to it the formula $C_{12}H_{28}O_{16}$, and showed that it contained water of crystallisation. It was next examined by Berthelot in 1856 (*Annales chim.* [3], xlv., 66), who gave it the name melitose, and found that it had a specific rotatory power $[\alpha]_D = 88$, that it was converted by the action of dilute acids into a mixture of a fermentable sugar—probably glucose—and a non-fermentable sugar, eucalyn.

Ritthausen, in 1884 (*Four. Pr. Chem.* [2], xxix., 351), and Böhm (*Ibid.*, xxx., 37) obtained a sugar from cotton seed, which the former regarded as identical with Berthelot's melitose, whilst the latter considered it a distinct substance, and called it gossypose.

In the year 1876 Loiseau (*Compt. rend.*, lxxxii., 1058) separated a crystalline sugar from the beet-root molasses of Messrs. Sommer et Cie. which had the composition $C_{18}H_{32}O_{16.5}H_2O$, and possessed a relative rotation to that of cane-sugar, 159 : 100; this he called raffinose. Tollens (*Ber.*, xviii., 26) expressed the view that raffinose was identical with the sugar from cotton-seed, and probably also with Berthelot's melitose, but he confirmed Loiseau's number for the rotatory power. This was finally established by Scheibler (*Ber.*, xviii., 1779) and by Rischbiet and Tollens (*Ibid.*, 2611; *Annalen*, ccxxxii., 169).

O'Sullivan has separated raffinose from barley (*Chem. Soc. Four. Trans.*, 1886, 70), and v. Lippmann (*Ber.*, xviii., 3087; *xxi. Ref.*, 889) has demonstrated its presence in beet-roots themselves.

In his first experiments Tollens (*loc. cit.*) favoured the formula $C_{12}H_{22}O_{11.3}H_2O$ of Berthelot, Ritthausen, and Böhm, inasmuch as he found that raffinose lost about 13 p.c. of water at 100°, and that decomposition begins above this temperature, but it was subsequently shown by Scheibler (*loc. cit.*), that when the compound is dried, first in a partial vacuum over concentrated sulphuric acid for about a fortnight, and then at 100°, a loss of about 15 p.c. of water is attained, which corresponds to that demanded by Loiseau's formula, $C_{18}H_{32}O_{16.5}H_2O$. Rischbiet and Tollens then showed that the amount of

mucic acid obtained on oxidising raffinose with nitric acid was, assuming that the compound yields a third of its weight of galaetose, consistent with Loiseau's formula, but from a consideration of the sodium derivative, which they found contained 6—7 p.c. of sodium, they were led to double this formula. The determinations of the molecular weight made since by Tollens and Mayer (*Ber.*, xxi., 1566) and by Brown and Morris (*Chem. Soc. Four. Trans.*, 1888, 619), who employed Raoult's freezing-point method, as well as that of de Vries (*Compt. rend.*, cvi., 751), who determined the isotonic coefficient, point, however, to the simpler formula.

In molasses rich in raffinose the latter separates out on standing, whilst from such as contains less Scheibler's method (*Ber.*, xviii., 1409) may be employed for its isolation. This consists in converting the mixed sugars into the mono-strontia compounds and cooling, when about 75 p.c. of the cane-sugar separates out as mono-strontia saccharate; the filtrate is boiled with an excess of strontium hydroxide, and the precipitate containing the di-strontia compounds of raffinose and cane-sugar decomposed by a current of carbonic anhydride. The process is then repeated, a syrup being ultimately obtained consisting chiefly of raffinose, the compound being finally purified by crystallisation from alcohol.

Raffinose crystallises in needles or prisms which are almost insoluble in absolute alcohol but very easily soluble in water. Its specific rotatory power is, according to Landolt (*Ber.*, xxi., 198), $[\alpha]_D = 104.5$, which represents the mean of the values obtained by Scheibler, Tollens, Rischbiet and Tollens, v. Lippmann, Loiseau, and Ritthausen. Beythien and Tollens have more recently given the value $[\alpha]_D = 104.4$ (*Annalen*, cclv., 195).

It has been shown by Rischbiet and Tollens (*Annalen*, ccxxxii., 110) that when raffinose is warmed on the water-bath with dilute acids under fixed conditions, the specific rotatory power is reduced to about one-half,* but that if more concentrated acid be employed and the heating continued for a longer time the reduction in rotation reaches one-fifth, with the formation of a certain amount of humus matter (cf. Scheibler and Mittelmeier, *Ber.*, xxii., 1684). This has been confirmed by numerous observers. Rischbiet and Tollens (*Ber.*, xviii., 2611) have shown further that when raffinose is heated for a considerable time with acids, levulinic acid is produced, and have confirmed Berthelot's statement that mucic acid is formed when raffinose is oxidised with nitric acid, the amount obtained under the conditions given being 22—23 per cent of the weight of raffinose.† Raffinose does not reduce Fehling's solution until after heating with acids, and, like cane-sugar, it is stable in alkaline solution. It possesses only a very faint sweet taste. Rischbiet and Tollens (*Annalen*, ccxxxii., 110) have found that raffinose is completely fermentable with yeast. Berthelot (*Compt. rend.*, cix., 548) finds, however, that an active yeast completely ferments it, but a weak yeast only about one-third, whilst Loiseau (*Compt. rend.*, cix., 614) states that fermentation is complete with a low fermentation yeast, but only reaches one-third with a high one. There appears to be no sharp qualitative test for the recognition of raffinose.

The fact that raffinose yields compounds with bases has long been known, and has been specially studied by Scheibler and by Beythien and Tollens (*Ber.*, xxii., 1047; *Annalen*, cclv., 195). Di-strontia raffinose,—

baryta raffinose, $C_{18}H_{32}O_{16.2}BaO$, di-baryta raffinose,

* An abstract of this paper was read at the Conference of Chemists held at the Beetroot Sugar Association's Rooms on June 26, 1890, to consider the methods for the detection and estimation of raffinose.

† Throughout this paper I have made use of the name raffinose, since, although the objection that it is based on the misconception that the compound is formed during a process of refining from cane-sugar has been urged against it by several eminent German chemists, it is more generally known in England by this name.

* Scheibler and Mittelmeier (*Ber.*, xxii., 3120) state that a dilute solution of the invertase of yeast has an action at the ordinary temperature similar to that of dilute acids at a higher temperature, whilst a strong solution at 40° determines the complete inversion.

† Assuming that galaetose forms a third part of the total inversion product, since this sugar yields about 75 p.c. of mucic acid on oxidation with nitric acid, the amount obtainable from raffinose should be 22.7 p.c. (Rischbiet and Tollens, *loc. cit.*).

molecule, and further that of R₁₁ and R₁₃ to that of the dextrose and galactose residues in the milk-sugar molecule.

Emil Fischer has proposed the following constitutional formula for milk-sugar—

Schiebler and Mittelmeier consider this to be the most probable formula for melibiose also, but that the difference between the latter and milk-sugar lies in the difference of the combination of the carbinol groups of the dextrose with the aldehyd group of the galactose.

Schiebler and Mittelmeier have found (*Ber.*, xxiii., 1441) that raffinose forms an undecacetyl derivative, C₁₈H₂₁O₅·(OC₂H₃O)₁₁, which is easily soluble in hot alcohol and is precipitated on cooling as an amorphous powder. It melts at 99–100°, has a bitter taste, does not reduce Fehling's solution, and possesses a specific rotation at 17° in 8 per cent. alcoholic solution, [α]_D = 92.2. The existence of this compound indicates that raffinose contains eleven hydroxyl groups, and the presence of a larger number is not conceivable.

THE POISONING OF A FAMILY BY MUSSELS.

By A. B. GRIFFITHS, Ph.D., F.R.S. (Edin.), &c.

ACCORDING to the daily papers "an analysis is being made of the mussels by which Mrs. O'Connor and her four daughters were poisoned at Seapoint, near Dublin, and also of the water where they were gathered. The children had been in the habit of taking mussels from a tidal pond into which the sewage flows, and although it was agreed by the medical men at the inquest that mussels in a healthy state are not poisonous, it was stated that they frequently become so when found in the vicinity of impure water."

There is little doubt that the poisoning was due to the action of alkaloids (ptomaines), developed, by the agency of putrefactive microbes, in the muscular tissues of the mussels in question. Ptomaines belonging to the pyridine and hydropyridine series of organic bases are readily formed when the muscular tissues of the *Invertebrata* (as well as the *Vertebrata*) undergo putrefaction.

Such compounds as:—

Lutidine (C ₇ H ₉ N).	Hydrolutidine (C ₇ H ₁₁ N).
Collidine (C ₈ H ₁₁ N).	Hydrocollidine (C ₈ H ₁₃ N).
Parvoline (C ₉ H ₁₃ N).	—
Coridine (C ₁₀ H ₁₅ N).	Hydrocoridine (C ₁₀ H ₁₇ N).

have been isolated from putrid albuminous substances.

These bases are easily extracted by the methods of Gautier,* Brieger,† and Stas.

Gautier, Brieger, Nencki, Guareschi, Mosso, and the author of this note, have extracted poisonous animal alkaloids belonging to the pyridine and hydropyridine series, as well as certain oxygenised bases, from putrid muscular tissues.

Bearing on the subject of poisoning by mussels, it may be stated that Dr. O. de Coninck (*Comptes Rendus de l'Académie des Sciences*, vol. cvi., p. 858) has recently isolated both collidine and coridine from the muscular tissue of *Sepia officinalis* (the cuttle-fish) after putrefaction.

There is no doubt that pyridine and other bases of a poisonous nature are constant products of the putrefaction

of muscular tissues, not only of the *Vertebrata* but also of the *Invertebrata*.

Hence there is every reason to believe that the poisoning of Mrs. O'Connor and her daughters was due to the formation of poisonous alkaloids by the action of putrefactive microbes on the muscular tissues of the mussels.

FOAM.*

By the Right Hon. LORD RAYLEIGH, M.A., D.C.L., LL.D.,
F.R.S., Professor of Natural Philosophy, R.I.

(Concluded from p. 4).

I WANT now to bring to your notice certain properties of soap solutions, which, however, are not quite so novel as I thought when I first came upon them in my own inquiries.† If we measure by statical or slow methods the surface tension of soapy water, we find that it is very much less than that of clean water. We can prove this in a very direct manner by means of capillary tubes. Here, shown upon the screen, are two tubes of the same diameter, in which, therefore, if the liquids were the same, there would be the same elevation; one tube dips into clean water, and the other into soapy water, and the clean water rises much (nearly three times) higher than the soapy water.

Although the tension of soapy water is so much less than that of pure water when measured in this way, I had some reason to suspect that the case might be quite different if we measured the tensions immediately after the formation of the surfaces. I was led to think so by pondering on Marangoni's view that the behaviour of foaming liquids was due to the formation of a pellicle upon their surfaces; for if the change of property is due to the formation of a pellicle, it is reasonable to suppose that it will take time, so that if we can make an observation before the surface is more than say $\frac{1}{100}$ of a second old, we may expect to get a different result. That may seem an impossible feat, but there is really no difficulty about it; all that is necessary is to observe a jet of the substance in question issuing from a fine orifice. If such a jet issues from a circular orifice it will be cylindrical at first, and afterwards resolve itself into drops. If, however, the orifice is not circular, but elongated or elliptical, the jet undergoes a remarkable transformation before losing its integrity. As it issues from the elliptical orifice, it is in vibration, and trying to recover the circular form; it does so, but afterwards the inertia tends to carry it over to the other side of equilibrium. The section oscillates between the ellipse in one direction and the ellipse in the perpendicular direction. The jet thus acquires a sort of chain-like appearance, and the period of the movement represented by the distance between corresponding points A, B, Fig. 3, is a measure of the capillary tension to which these vibrations of the elliptical section about the circular form are due. A measure, then, of the wave-length of the recurrent pattern formed by the liquid gives us information as to the tension immediately after escape; and if we wish to compare the tensions of various liquids, all we have to do is to fill a vessel alternately with one liquid and another, and compare the wave-lengths in the various cases. The jet issues from a flask, to which is attached below a tubular prolongation; the aperture is made small in order that we may be able to deal with small quantities of liquid. You now see the jet upon the screen (Fig. 3), it issues from the orifice; it oscillates, and we can get a comparative measure of the tension by observing the distance between corresponding points (A, B).

If we were now to take out the water, and substitute

* *Comptes Rendus*, vol. xciv., p. 1357; p. 1598; vol. xcvi., p. 263; p. 325.

† Über Ptomaines.

* A Lecture delivered at the Royal Institution of Great Britain, March 28, 1890.

† I here allude to the experiments of Dupré, and to the masterly theoretical discussion of liquid films by Professor Willard Gibbs.

for it a moderately strong solution of soap or saponine, we should find but little difference, showing that in the first moments the tension of soapy water is not very different from that of pure water. It will be more interesting to exhibit a case in which a change occurs. I therefore introduce another liquid, water containing 10 per cent. of alcohol, and you see that the wave-length is different from before. So this method gives us a means of investigating the tensions of surfaces immediately after their formation. If we calculate by known methods how long the surface has been formed before it gets to the point B, at which the measurement is concluded, we shall find that it does not exceed $\frac{1}{100}$ of a second.

FIG. 3.

Another important property of contaminated surfaces is what Plateau and others have described as superficial viscosity. There are cases in which the surfaces of liquids—of distilled water, for example—seem to exhibit a special viscosity, quite distinct from the ordinary interior viscosity, which is the predominant factor in determining the rate of flow through long narrow tubes. Plateau's experiment was to immerse a magnetised compass needle in water; the needle turns, as usual, upon a point, and the water is contained in a cylindrical vessel, not much larger than the free rotation of the needle requires (Fig. 4). The observation relates to the time occupied by the needle in returning to its position of equilibrium in the meridian, after having been deflected into the east and west positions, and Plateau found that

FIG. 4.

in the case of water more time was required when the needle was just afloat than when it was wholly immersed, whereas in the case of alcohol the time was greater in the interior. The longer time occupied when the needle is upon the surface of water is attributed by Plateau to an excessive superficial viscosity of that body.

Instead of a needle I have here a ring of brass wire (Fig. 5), floating on the surface of the water. You see upon the screen the image of the ring, as well as the surface of the water, which has been made visible by sulphur. The ring is so hung from a silk fibre that it can turn upon itself, remaining all the while upon the surface of the water. Attached to it is a magnetic needle, for the purpose of giving it a definite set, and of rotating it as

required by an external magnet. On this water, which is tolerably clean, when the ring is made to turn, it leaves the dust in the interior entirely behind. That shows that the water inside the ring offers no resistance to the shearing action brought into play. The part of the surface of water immediately in contact with the ring no doubt goes round; but the movement spreads to a very little distance. The same would be observed if we added soap.

FIG. 5.

But if I add some saponine, we shall find a different result, and that the behaviour of the dust in the interior of the ring is materially altered. The saponine has stiffened the surface, so that the ring turns with more difficulty; and when it turns, it carries round the whole interior with it. The surface has now got a stiffness from which it was free before; but the point upon which I wish to fix your attention is that the surface of pure water does not

FIG. 6.

behave in the same way. If, however, we substitute for the simple hoop another provided with a material diameter (Fig. 6), lying also in the surface of the water, then we shall find, as was found by Plateau in his experiment, that the water is carried round. In this case, it is no longer possible for the surface to be left behind, as it was with the simple hoop, unless it is willing to undergo local expansions and contractions of area. The difference of behaviour proves that what a water surface resists is not shearing, but expansions and contractions; in fact, it behaves just as a contaminated surface should do. On this

supposition, it is easy to explain the effects observed by Plateau; but the question at once arises, can we believe that all water surfaces hitherto experimented upon are sensibly contaminated? and if yes, is there any means by which the contamination may be removed? I cannot in the time at my disposal discuss this question fully, but I may say that I have succeeded in purifying the surface of the water in Plateau's experiment, until it behaved like alcohol. It is therefore certain that Plateau's superficial viscosity is due to contamination, as was conjectured by Marangoni.

I must now return to the subject of foam, from which I may seem to have digressed, though I have not really done so. Why does surface contamination enable a film to exist with greater permanence than it otherwise could? Imagine a vertical soap film. Could the film continue to exist if the tension were equal to all its parts? It is evident that the film could not exist for more than a moment; for the interior part, like the others, is acted on by gravity, and, if no other forces are acting, it will fall 16 feet in a second. If the tension above be the same as below, nothing can prevent the fall. But observation proves that the central parts do not fall, and thus that the tension is not uniform, but greater in the upper parts than in the lower. A film composed of pure liquid can have but a very brief life. But if it is contaminated, there is then a possibility of a different tension at the top and at the bottom, because the tension depends on the degree of contamination. Supposing that at the first moment the film were uniformly contaminated, then the central parts would begin to drop. The first effect would be to concentrate the contamination on the parts underneath and diminish it above. The result of that would be an increase of tension on the upper parts. So the effect would be to call a force into play tending to check the motion, and it is only in virtue of such a force that a film can have durability. The main difference between a material that will foam and one that will not is in the liability of the surface to contamination from the interior.

I find my subject too long for my time, and must ask you to excuse the hasty explanations I have given at some parts. But I was anxious above all to show the principal experiments upon which are based the views that I have been led to entertain.

COLORIMETRIC METHOD FOR ESTIMATING TANNIN IN BARKS, &c.

By SAMUEL J. HINSDALE, Fayetteville, N.C.

DISSOLVE 0.04 grm. potassic ferricyanide in 500 c.c. water, and add to it 1.5 c.c. (about 22 drops) *Liquor Ferri Chloridi*. Call this *Iron Mixture*.

Dissolve 0.04 grm. "Pure Tannin" (gallotannic acid), which has been dried at 212° F. in 500 c.c. of water. Call this *tannin solution*.

Exhaust 0.8 grm. oak bark with boiling water, and make it up to 500 c.c. with cold water.

Place six 2-ounce clear glass tumblers (or beaker glasses) on a white surface, and in one of them, with a dropping pipette (about four inches long and one-quarter inch wide), about half filled, put five drops of the infusion of bark, and in the others, with the same pipette (after rinsing), put 4, 5, 6, 7, and 8 drops of the "tannin solution." (The drops of the infusion and of the tannin solution must be uniform. The use of the same pipette, about half filled, insures that).

Now, add to each 5 c.c. of "iron mixture," and in about one minute add to each tumbler about 20 c.c. water, and within three minutes observe the shades of colour. The number of drops of "tannin solution" used in the tumbler which corresponds in shade of colour to the tumbler containing the infusion of bark indicates the percentage of tannin in the bark, i.e., if it is the one in

which seven drops were placed the tannin strength of the bark is seven per cent.

It is best to observe the shades of colour horizontally rather than vertically, and to hold up the infusion tumbler, with the one which most nearly corresponds, opposite to a white wall, with your back to the light.

The above is written for oak bark, but the same process will answer for any substance containing less than 10 per cent of tannin.

The results are necessarily in terms for commercial gallotannic acid, and not in those of pure tannin or of the particular tannin in the material assayed.

For substances containing between about 10 and 20 per cent, it is best to dilute the infusion with an equal part of water and proceed as above, using five drops of the diluted infusion, and for the answer, double the result. Thus, if the diluted infusion of tea required eight drops tannin solution to correspond, call the percentage sixteen.

For substances containing less than 1, or 1 per cent, exhaust 8 grms. instead of 0.8 grm., and take one-tenth of the result for the answer. For substances containing more than 20 per cent, as galls, sumach, catechu, &c., you may dilute the infusion with two, three, or more times its bulk with water, and calculate as above (as with tea) or you may use 1, 2, 3, or 4 drops of the undiluted infusion in the first glass and make the calculation thus, i.e.:—As the number of drops of infusion used is to the number of drops "tannin solution" used (to correspond), so is 5 to the answer—thus, suppose two drops infusion were used and the corresponding tumbler contained fifteen drops tannin solution—2 : 15 :: 5 ; answer, 37.5 per cent.

The object in diluting the infusions is because the infusion glass may be of too deep a blue shade. It is better that it should just produce a light blue.

The tumblers must be perfectly clear and clean.

The "iron mixture," "tannin solution," and infusion must be freshly prepared and not exposed to the rays of the sun.

The water used must be free of iron and tannin.

THE USE OF NITROSO-β-NAPHTHOL FOR THE DETERMINATION OF IRON AND ITS SEPARATION FROM MANGANESE AND ALUMINIUM.

By L. L. DE KONINCK.

MM. KNORRE and Ilinski have introduced a new reagent, nitroso-β-naphthoquinonoxime. This reagent produces, in certain conditions easily realised, the precipitation of copper, iron, nickel, and cobalt from their saline solutions. Meinecke applies it in the following manner to the determination of iron. The solution free from nitrate, containing the iron as much as possible in the state of ferric chloride or sulphate, is gradually mixed with ammonium carbonate until there is produced a very slight precipitate, which is re-dissolved by one drop of hydrochloric acid. Into the liquid thus obtained there is poured, drop by drop, a solution of nitrosonaphthol in an equal weight of acetic acid at 50 p. c. The quantity of the reagent employed ought to be weighed, so as to have at least 10 parts to 1 part of iron. The precipitate formed is composed of ferric naphtholate mixed with the ferrous salt if the iron is not exclusively in the ferric state, besides the excess of the reagent, which is sparingly soluble in the aqueous liquid. The ferrous naphtholate is more difficult to wash than the ferric salt, whence it is well to peroxidise the iron by bromine by means of bromine or potassium chlorate before proceeding to precipitation. It is known that the precipitation is complete if a drop of the liquid, which has become clear on standing, produces a reddish brown precipitate with a

drop of a cobaltous solution. It is best to operate in the cold to avoid the precipitation of a basic salt of aluminium, and because the precipitate obtained in heat is difficult to wash. It must be washed until the washings leave no fixed residue upon a slip of platinum foil, dried until the contents can be extracted without tearing the filter. It is introduced into a tared porcelain crucible of a sufficient size, folding down the edges of the filter. The crucible is gradually heated, covered with its lid, upon a plate of asbestos until little detonations are no longer produced. The temperature is raised and the residue is ignited uncovered. The product is ferric oxide. Von Knorre advises not to operate upon more than 0.3 gm. The precipitate is not always free from foreign matter. Copper (which is often present in spathic ores in appreciable quantities) and cobalt are carried down, and the phosphoric acid is precipitated either totally or in part. The phosphorus is found entirely in the precipitate if we add ammonium acetate to the neutralised ferric solution before precipitating. The process admits of the separation of iron and manganese, the ferric precipitate being completely free from the latter metal. But the manganic precipitate obtained afterwards by bromine or ammonium sulphide is not more completely free from impurities than if it had been obtained by one of the old methods. It may contain small quantities of silica, nickel, and even iron.

Nitrosonaphthol may be advantageously used for separating iron from aluminium and for determining the latter. According to Von Knorre the separation of iron and aluminium is made by pouring an acetic solution of naphthol at 1-20th into the metallic solution containing a notable excess of acetic acid. Meinecke operates on a solution slightly acid, and with a concentrated solution of the reagent as indicated above. The filtrate from the ferric precipitate is evaporated to expel the excess of acetic acid, and thus prevent the presence of ammonium salts in large proportion. The alumina is then precipitated by ammonia. If much manganese is present it is better to separate the iron and the manganese from other metals by an ordinary process, and to use naphthol only for the respective separation of iron and aluminium.

The presence of the reagent does not interfere with the determination of magnesium and calcium by means of ammonium phosphate and oxalate.—*Revue des Mines* (vol. ix., p. 243).

RECENT SYNTHETICAL EXPERIMENTS IN THE SUGAR SERIES.*

(Concluded from p. 9).

Synthesis of Mannose and Levulose.†

WHEN mannose is oxidised with bromine-water it is converted into mannonic acid. A thorough examination of the properties of mannonic acid showed that it has almost identically the same properties as arabinose-carbonic acid. The latter compound was discovered by Kiliani,‡ and is obtained from the addition-product which is formed by the union of hydrocyanic acid and arabinose. The lactones of these acids are so similar in properties that they would be regarded as identical were it not for the fact that they rotate the plane of polarised light in opposite directions. As their rotatory power is very nearly equal, but in opposite directions, it seemed very probable that they were optical isomers. This supposition proved to be true, for, on mixing solutions of equal weights of the two lactones, an optically inactive compound of the same composition was obtained. This inactive lactone can be transformed into inactive salts and other derivatives, and it is only possible by certain special

methods, to be described below, to again resolve it into its optically active constituents. The three lactones can by reduction be converted into sugars, and these in turn into three hexacid alcohols, and the corresponding members of these three series of reduction-products bear the same relation to each other as do the original lactones. Thus, from the lactone of mannonic acid, mannose and ordinary mannite are obtained, while from the lactone of arabinose-carbonic acid a levo-mannose and a levo-mannite are obtained; and finally, reduction of the inactive lactone gives two corresponding inactive derivatives. The relation of these compounds is shown by Table I.

To avoid confusion, the compounds of the three series are designated by prefixing the letters *d*, *i*, and *l* to their names according to the rotatory power of the sugar of the series. The letter *d* or *l* before the name of a compound does not necessarily imply that the compound is either dextro- or levo-rotatory, but merely that it is a derivative of a dextro- or levo-rotatory sugar. Thus, the two phenylhydrazine derivatives of *d*-mannose are levo-rotatory.

In a recent paper* the preparation and properties of the new sugars *l*-mannose and *i*-mannose and their derivatives are described. Both of them, like *d*-mannose, are stereometric isomers of dextrose. *l*-Mannose can only be fermented with great difficulty, and, like *d*-mannose it is characterised by the insolubility of its hydrazone. *l*-Phenylglucosazone is the optical isomer of ordinary or *d*-phenylglucosazone, and *l*-mannite of ordinary *d*-mannite.

That *i*-mannonic acid is really the optically inactive modification of *d*- and *l*-mannonic acid was shown by splitting it up into its two active components. Two methods were used for this purpose; the first one consisted in subjecting it to fermentation with *Penicillium glaucum*. The *d*-mannonic acid was consumed by the ferment, while the *l*-acid remained behind and was isolated. The second method depended upon the unequal solubility of the strychnine salts of the two acids in absolute alcohol; the salt of the *d*-mannonic acid being much more soluble than the *l* variety, can be readily separated from the latter. A separation of the optically active constituents of *i*-mannose was brought about by fermentation with yeast. When yeast acts upon *i*-mannose, the *d*-mannose is rapidly consumed and the *l*-mannose remains behind.

Perhaps the most important and interesting discovery made in the course of this admirable investigation was the observation that *i*-mannite and α -acrite are identical substances. α -Acrite, it will be remembered, is the hexacid alcohol obtained by the reduction of acrose, the new synthetical sugar which had been built up from glycerin, acrolein bromide, and from formic aldehyd. α -Acrite has identically the same properties that *i*-mannite has, and, like the latter compound, it can be converted into *i*-mannose. α -Acrosazone also is identical with *i*-phenylglucosazone. As, therefore, acrose and *i*-mannose give the same osazone with phenylhydrazine, it follows that the constitution of acrose must be represented by one of the two formulæ:—

i-Mannose.

and—

i-Levulose.

If acrose has the constitution represented by the first one, then it is identical with *i*-mannose, and, like the latter substance, it ought to give a difficultly soluble hydrazone when its solution is treated with phenylhydrazine. Acrose was therefore prepared by direct synthesis from acrolein bromide, and its solution was tested with phenylhydrazine. Under no circumstances

TABLE II.

could the formation of an insoluble hydrazone be observed. This result, therefore, leads to the conclusion that acrose is *i*-levulose, and its constitution must be represented by the second formula. The synthetical sugar obtained from α -acrosazone was also examined in the same way, and, as was to be expected, it also proved to be *i*-levulose.

Further evidence in favour of the view that acrose is

i-levulose was obtained by observing the changes which it undergoes upon fermentation. When acrose was mixed with yeast it was found that one of the optical components, *d*-levulose, was consumed much more rapidly than the other, and after the fermentation had continued for some time, the *l*-levulose was recognised and separated from the solution by means of its osazone. So also the α -acrite, like *i*-mannite, was converted into

i-mannose and *i*-mannonic acid. But the latter compound can be separated into its optically active constituents, and these in turn can be transformed, on the one hand, into *l*-mannose and *l*-mannite, and on the other hand into ordinary mannose and mannite, and into levulose. Thus the complete synthesis of levulose and of the three series of mannite derivatives has been effected. The successive steps in the synthesis are indicated in Table II.

Synthesis of Dextrose.

As has been shown above, *d*-mannose and dextrose have the same constitution and must be regarded as stereometric isomers. Both sugars give the same osazone when treated with phenylhydrazine. It follows, therefore, that the difference between them is due to the asymmetry of the carbon atom as_1 in the formula:—

Fischer also regarded it as highly probable that in mannose the carbon atom as_1 was optically inactive, and that it plays a rôle similar to that of the two carbon atoms in racemic acid. If this supposition is true, then mannonic acid would be related to gluconic acid in the same way that racemic acid is related to one of the active tartaric acids, or this relationship would be analogous to that of racemic acid to mesotartaric acid. In his last paper* Fischer shows that the latter is the true relation. Each of these acids can be transformed into the other. When either one is heated with quinoline to a temperature of 140° , a mixture of the two acids is obtained. This transformation is analogous to that which has been observed in the case of racemic and mesotartaric acids. When either one of these is heated with water to a temperature of 170° — 180° , a mixture of both is obtained.

For the purpose of preparing dextrose, mannonic acid was heated with quinoline, and from the mixture of acids thus obtained the gluconic acid was separated by means of its brucine salt. The brucine salt was decomposed, and the gluconic acid was found to be identical in properties with the gluconic acid obtained by the oxidation of dextrose. The acid was thereupon reduced with sodium amalgam, and from the liquid, *anhydrous crystalline dextrose*, identical in all its properties with ordinary dextrose, was obtained.

The synthesis of dextrose, therefore, is achieved, for, as will be seen in the table printed above, *d*-mannonic acid has been prepared from acrose, and acrose has been made from formic aldehyd.

NOTES ON QUANTITATIVE ANALYSIS.†

By L. H. FRIEDBURG, Ph.D.

(Continued from p. 5).

B.—ANALYSIS OF INSOLUBLE SILICATES, MAINLY PORPHYRIES, &c.‡

A QUANTITY sufficient for eight different assays is crushed, powdered, and sifted through fine muslin. No pressure should be used while dusting, but the muslin which covers a jar and carries the powder is covered by a piece of chamois, and both pieces are tied around the neck of the dry jar. The chamois is then gently tapped with the fingers.

First Portion.

SiO_2 ; Fe; Al; (Mn); Ca; Mg.

The powder is mixed in a platinum crucible with eight times its weight of absolutely dry powdered sodium car-

bonate. The crucible is covered and then heated with the blast lamp. At the beginning of this operation the sleeve at the mouth of the blowpipe is drawn so far forward that an agitated blue flame results. The effect is, that the entire crucible (cover and all) became at once red hot, thus avoiding any decrepitation inside. After a time the sleeve is pushed back, allowing the ordinary flame to play. This is continued for about fifteen minutes, until the mass flows without bubbles. Then the crucible is suddenly cooled by turning off the gas and blowing the cold air from the bellows against it. The cake will subsequently fall out easily, without the necessity of pressing or distorting the crucible. If the fused mass looks merely greenish, this indicates only traces of sodium manganate, but if more intense colouration is visible the presence of manganese must be taken into account in the course of the analysis. The cake is put into a separate beaker containing a little water, the crucible and cover are put into another beaker. Both beakers receive a gradual addition of HCl and are gently heated. After all is dissolved, except gelatinous SiO_2 , the heating is continued until no more CO_2 is present. The combined liquids from the two beakers are then transferred to a platinum dish and evaporated to dryness on the water-bath. The lumps of gelatinous SiO_2 must be frequently crushed so that they cannot enclose soluble silicic acid. The residue is moistened with a few drops of conc. HCl, then diluted with water, and filtered with the pump. The filter with SiO_2 is (after complete washing) put while moist into a platinum crucible, heated, and weighed until the weight is constant. The silicic acid is then treated with HF (free from all residue), and a few drops of H_2SO_4 upon the water-bath, until all volatile matter is driven off; the residual H_2SO_4 is expelled over a free flame; the residue, if any, is heated to redness and weighed. The treatment with HF and H_2SO_4 may be repeated if necessary. In case the residue should be considerable it must be quantitatively tested for Al, Fe, Ca, and Mg, otherwise a qualitative test is sufficient.

The filtrate from the SiO_2 determination is heated and oxidised by a few drops of HNO_3 , after which Fe and Al are precipitated with a very slight excess of NH_4OH , and the unavoidable excess of this latter is boiled off immediately. Care should be taken not to expose this liquid too long to the air. It would attract CO_2 and precipitate Ca. If an interruption is unavoidable, the beaker must be placed upon a dish containing a layer of NH_4OH and a larger beaker must be inverted over the smaller one, its edge immersed in the layer. The precipitate consists of Fe_2O_3 and Al_2O_3 , with small traces of SiO_2 , Ca, and Mg.

This precipitate may be treated in two different ways, according as it is smaller or larger, especially as regards the quantity of iron present.

1. *For Small Quantities of Iron.*—The precipitate is heated and weighed, then fluxed with potassium bisulphate in a closed crucible at low temperature, so as just to make the mass flow, cooled, dissolved in water; the iron is reduced with zinc and the solution titrated with permanganate. In case HCl was used to dissolve the reduced iron, H_2SO_4 is added before titration, in excess, because the sulphate solution is lighter in colour than the chloride, and also because strong dilution is desirable.

2. *The Precipitate is abundant, and much Iron is present.*—Dissolve in HCl and digest for half an hour in a platinum dish with an excess of KOH upon the water-bath. The details of manipulation are as follows:—The precipitate being washed thoroughly, is, for the greatest part, brought into the platinum dish by means of a platinum spatula. The remaining portions on the filter are dissolved in a hot mixture of equal parts of conc. HCl and H_2O by means of a pipette. The solution is allowed to run into the main precipitate in the platinum dish. The filter is washed with water; this filtrate running into a beaker. The mass in the platinum dish is then cautiously treated with KOH solution, a few pieces of solid KOH

* *Ber. d. Chem. Ges.*, xxiii, 799.

† From the *Journal of the American Chemical Society*, vol., xii, No. 5.

‡ This process, with few changes, was commonly used in Bunsen's laboratory.—L. H. F.

are added, digestion for half an hour upon the water-bath follows, and the mass is then diluted with the wash filtrate which was collected separately in the beaker and filtered through the aforesaid filter. This filtrate contains the Al_2O_3 . Acidulate with HCl , so that solution just takes place after the first precipitation, and precipitate with freshly prepared ammonium sulphide. This latter is used in preference to ammonium hydrate, because Al_2O_3 is less soluble in the former; the $(\text{NH}_4)_2\text{S}$ must be freshly prepared in order to avoid polythionic salts, as well as ammonia resulting from decomposition by age.

The previously mentioned precipitate containing Fe_2O_3 (and traces of CaO , MgO , and SiO_2) is heated and weighed. Of course, the crucible during this heating must remain open, in order to avoid reduction by gases from the flame. Dissolve in conc. HCl , filter from SiO_2 , re-precipitate iron with NH_4OH , and add the filtrate to the liquid containing these substances. SiO_2 and Fe_2O_3 are to be treated as described before, and weighed separately.

Should the remaining filtrate now be too abundant it must be concentrated after acidulation with HCl . A little NH_4OH is added to precipitate remaining Al_2O_3 , and, if this is still present, the ammonia is driven off and the precipitate filtered, added to the first precipitate, heated, and weighed as Al_2O_3 .

The combined filtrates, concentrated as above, contain Mn , Ca , and Mg for determination. If enough Mn were present this must first be precipitated by means of ammonium sulphide. Wash with water containing some $(\text{NH}_4)_2\text{S}$, re-dissolve in HCl , boil the solution to separate sulphur, and filter. Concentrate the filtrate, precipitate with Na_2CO_3 , boil in order to destroy manganese carbonate which might have formed, wash with boiling water, heat, and weigh as Mn_2O_4 .

Before precipitating Ca , the filtrate must be acidulated with HCl , thus separating sulphur, and then filtered. Render slightly alkaline with NH_4OH and add ammonium oxalate, boiling. Filter after twelve hours. Put the moist well-washed filter, with precipitate, into a platinum crucible, heat strongly for fifteen minutes before the blast lamp, and weigh as CaO . This weight must be controlled. Re-dissolve the CaO in HCl , re-precipitate as above, and add the filtrate to the liquid containing Mg . Heat the CaO to constancy before the blast-lamp. Test it with the spectroscope for Ba and Sr .

Before precipitating Mg (particularly if this is present in small quantity only) drive off the ammonium salt as thoroughly as possible. Dissolve in a little HCl until the liquid is slightly acid, add sodium phosphate, then ammonium hydrate until a turbidity sets in, then a quantity of ammonium hydrate equal to one-third of the volume of the liquid: filter after four hours and wash with a mixture of one part of NH_4OH and three parts of water. Formerly, a period of twenty-four hours was deemed necessary for this precipitation, but, generally, four hours are fully sufficient. The precipitate is washed until no more chlorine is present. Now, either dry the filter with precipitate and incinerate separately, or, better, especially if the pump was used for washing, bring the moist precipitate and filter into a platinum crucible. Heat gently at first, finally before the blast lamp energetically. Should the pyrophosphate prove to contain a little carbon, moisten with a few drops of HNO_3 , evaporate cautiously to dryness, and heat again, as above.

If the spectroscopic research proved the presence of sufficient Ba and Sr , the CaO precipitate has to be further treated. Transfer from the platinum crucible into a small thin well tempered flask of 5 to 10 c.c. capacity. Wash the residue from the crucible with HNO_3 into the flask, and add more HNO_3 to this latter, until all Ca is transformed into nitrate. The solution may be turbid from filter ash or from Ba or Sr salts. Evaporate over a small direct flame to dryness, blow out the residual HNO_3 vapour by means of a glass pipe, and add not more alcohol than is necessary to obtain, on heating, a syrupy

solution of calcium nitrate. Allow to stand for twenty-four hours, filter from barium and strontium nitrate, wash with absolute alcohol. If a sufficient quantity now remains upon the filter, dissolve this in hot water and allow the solution to run into a weighed platinum crucible. Evaporate to dryness and heat before the blast to constant weight (BaO and SrO). Now dissolve in conc. HCl , evaporate in the same little flask as previously used to dryness, separate SrCl_2 , soluble in absolute alcohol by means of this. Precipitate BaCl_2 as sulphate, and weigh. Sr is found by difference. In case no weighable amount of BaCl_2 should have remained after the SrCl_2 was dissolved in absolute alcohol, allow the syrup of SrCl_2 to be taken up by a strip of filter-paper, wind around this a thin platinum wire, incinerate in an open flame, heat until the sodium flame has disappeared, and then use the spectroscope, dipping the platinum wire frequently into HCl . Mere traces of Ba will only become visible after almost perfect evaporation of SrCl_2 .

Second Portion.

Determination of the Alkalies.

The powder is put into a platinum crucible, moistened with a few drops of conc. H_2SO_4 and then digested three or four times with conc. HF upon the water-bath. This done, the small crucible is put upright inside of and near the bottom of a large platinum crucible lying horizontally. A small flame is applied underneath the side nearest the mouth of the large crucible and the burner is gradually pushed towards the middle and near the end. The H_2SO_4 and hydrofluosilicic acid are thus expelled. This expulsion must be performed thoroughly, so that afterwards no glass vessel may be attacked by remaining HF . The small platinum crucible is not allowed to become red hot in order that alkalies may not be lost. Should the mineral not have been fully decomposed, the resulting mass must again be treated with HF on the water-bath and afterwards heated, as described. Now, while the large crucible is put vertically and the small one inserted into the same, enough conc. HCl is added to dissolve all CaSO_4 , and the large crucible containing the small one standing within is heated upon the water-bath. Generally it is found that a residue is left. The liquid must then be decanted and the residue treated as before. After perfect solution the contents of the small crucible are emptied into the large one, washing carefully. Then BaCl_2 and (without filtering) NH_4OH and $(\text{NH}_4)_2\text{CO}_3$ are added and the precipitate is filtered and washed and the united filtrates are evaporated to dryness. The ammonia salts are expelled by very cautious heating, so that no decrepitation may take place. The residue is dissolved in water, NH_4OH and $(\text{NH}_4)_2\text{CO}_3$ are again added, filtration, evaporation, and expulsion of ammonia salts is repeated again and again, until no further precipitate is formed by addition of these reagents. It is advisable to use for every new filtration a smaller platinum dish, so as not to get too much filtrate. The final solution must be absolutely free from ammonium salts.

A small quantity of pure, red HgO is added in order to transform MgCl_2 into MgO while HgO is transformed into volatile HgCl_2 . The platinum dish is covered with a watch-glass and digested (so that the mass is just kept moist) for two hours. An excess of water has to be avoided, or else the reaction does not take. After this dry for 1 to 2 hours on the water-bath, and finally drive off the HgCl_2 by heating, but not to redness. Dissolve in a minimum of water, filter into a weighed platinum crucible, add a drop of HCl , evaporate to dryness, heat so as to keep the mass just in a fused state in the covered crucible, and then weigh. In order to obtain thus the sum of the alkaline chlorides, this heating and weighing has to be repeated to constancy. After the first weighings a new addition of HCl is advisable, since (owing to organic substances from the filter) carbonates may have formed in heating.

Now dissolve in a few drops of water and add an excess of platinic chloride. (The preparation of c.p. platinic chloride will be given at the end of this chapter). Care has to be taken that all NaCl is transformed into the double salt; no white cubes must remain visible in the precipitate, since these would be insoluble in alcohol. Evaporate to dryness on the water-bath and in a *porcelain* dish. This is easily understood. In the first place the mixed chlorides of alkalis are generally dissolved and filtered after weighing, since an unavoidable residue of Fe may be present, which must be considered; secondly, the platinic chloride must not be evaporated in a platinum dish, as it would dissolve platinum as subchloride, which is insoluble in alcohol, and would result together with potassium-platinic chloride. Allow to cool, add a few drops of water in order to dissolve the sodium double salt, and throw on a filter previously washed with alcohol, dried at 105° C. and weighed. Then wash the potassium double salt first with a mixture of 1 part alcohol and 1 part water, then with 1 part water and 2 parts alcohol, finally with absolute alcohol until the filtrate runs colourless. Then wash with a mixture of 4 parts alcohol and 1 part ether. The filtrates must be preserved for the following reason: In case the determination of MgO in the filtrate should not be necessary, but that the precipitate of K_2PtCl_6 should be lost, the $PtCl_4$ would have to be reduced to metallic platinum, as described below, in order to obtain NaCl.

The precipitate is dried at 105° C. and weighed to constancy.

The filtrate is diluted with water, heated to drive off ether and alcohol, and then put into a little flask with doubly perforated stopper, which carries two rectangular bent tubes. One of these latter nearly reaches the surface of the liquid, the other ends in the neck of the flask. This second one is connected with a hydrogen apparatus. The flask is heated gently, and, while still hot, the longer rectangular tube is closed outside by means of a rubber tube with glass rod. The hydrogen apparatus is now set to work, the flask cools, and the hydrogen absorbed by reduction is thus replaced spontaneously. The liquid becomes colourless and platinum is dendritically separated, generally floating for some time upon the liquid, which is now filtered. If some FeO should still be present, a drop of HNO_3 is added and then NH_4OH . The precipitate, if any, is filtered. Then MgO is determined and deducted as $MgCl_2$ from the above found sum of the combined alkaline chlorides.

Preparation of C. P. Platinic Chloride.

The platinic chloride used in the above determination is prepared, according to Bunsen, in the following manner, which involves the separation of platinum from iridium, rhodium, and palladium:—

Dissolve platinum in aqua regia, taking 4 pts. HCl and 1 pt. HNO_3 , adding this latter very gradually while the flask stands on the water-bath. After complete solution has taken place evaporate, also on the water-bath, to a syrup, add water and evaporate again as before, repeating this process until upon renewed addition of a drop of water to the syrup no odour of nitrous acid is perceptible.

Now dissolve in water and filter into a porcelain dish. Add sodium hydrate solution, until strongly alkaline, while the liquid is kept boiling, and continue to boil after the addition for a few seconds, during which time a drop or two of alcohol are added. At first the oxides of all the metals are thus formed, but after a while the excess of NaOH transforms Ir, Rh, and Pd into the sesquioxides, while platinum remains as oxide. Sodium hypochlorite is formed at the same time, but this is destroyed by the addition of a little alcohol.

If now HCl be added and the heating continued a yellow precipitate is first formed, while the HCl and the excess of NaOH have just neutralised each other. Heating is continued, and more HCl is added until the yellow precipitate is re-dissolved.

Platinic chloride and the sesquichlorides of Ir, Pd, and Rh are formed.

All of these are soluble, but only the platinic chloride is precipitated by potassium chloride. To the clear filtrate is added a hot saturated solution of KCl, until no more precipitate is formed. After cooling, the canary yellow precipitate of K_2PtCl_6 is filtered, washed with a solution of KCl, saturated in the cold, dried very thoroughly, and reduced in a long, absolutely dry Bohemian glass tube by means of hydrogen at a very low temperature. The tube is put in an ordinary combustion furnace and the flames are kept very low.

After all of the double salt has become uniformly black, the mass is allowed to cool in the hydrogen current. The contents of the tube are then transferred to a porcelain dish, boiled with water and decanted, or filtered by decantation. This boiling is repeated until all KCl is dissolved and the wash water does not show the chlorine reaction. The pure platinum obtained is now dissolved in aqua regia, as described above for the impure metal, and the syrup is treated with water until no further escape of nitrous acid takes place.

Third Portion.

Hygroscopic Water.—Heat the substance (powdered as described), at 105° C. to constant weight. **Water of Combination.**—Heat the material for 15–20 minutes to redness in a Bohemian bulb tube and collect H_2O in a weighed $CaCl_2$ tube. Allow to cool in a current of cold dried air. In case the silicate should contain FeO, the heating has to be performed in a current of CO_2 , since it is desirable to weigh the bulb tube also for control.

Fourth Portion.

Take a well dried Bohemian glass tube, 1 foot long, closed at one end, and put into it, by means of a long weighing tube, about 1 grm. of substance. With the aid of a long capillary funnel tube moisten the mass uniformly with some drops of water. Prepare a mixture of 6 pts. conc. H_2SO_4 and 2 pts. H_2O , allow it to cool, and pour it through the same funnel tube upon the substance, until it occupies 8 to 10 times the volume of the latter. Reduce the diameter of the tube greatly at about 2 inches from its open end and replace the air above the liquid with carbon dioxide. Seal before the blast lamp. After cooling, shake the tube vigorously in order to avoid caking. Heat the sealed tube for 4 to 5 hours in a thermostat at 200° or 220° C. When quite cold open the tube, transfer its contents, without filtering, into a high beaker, wash rapidly, and titrate with permanganate solution, the titre of which has been determined immediately before use. It is evident that in presence of organic matter in the silicate this determination cannot be performed.

(To be continued).

Pyridin and its Relations to Quinoline, Isoquinoline, and the Alkaloids.—Alb. Edinger.—The author concludes that a pyridin of Dewar's formula *might* exist, but does not exist in a free state and uncontaminated with an isomer.—*Journal für Praktische Chemie*, xli., Part 7.

Behaviour of Silica and its Compounds in Microcosmic Salt.—J. Hirschwald.—Small admixtures of silica cannot be determined by means of this reagent, as it dissolves in not inconsiderable quantities in the bead of the double salt. In many cases silicates may indeed be detected in the manner in question (1) by the characteristic corrosive perforations of the sample used in the form of a splinter, and (2) by its relative insolubility in comparison with other compounds. It has, however, no decisive analytical importance, as many minerals free from silica (e.g. wavellite, monazite, apatite, diaspor, &c.), behave in the same manner as the silicates.—*Journal für Praktische Chemie*, xli., Part 7.

CORRESPONDENCE.

ELECTROLYTIC ASSAY OF COPPER.

To the Editor of the Chemical News.

SIR,—In assaying copper by the electrolytic process I frequently find the deposited copper at the beginning of the process to be of a dark brown colour, and when this is so the remainder of the copper comes down fluffly, and as I have no time to investigate the matter can you give me an explanation as to what the deposit consists of, and what will prevent its occurrence? The copper is always separated by HS_2 before precipitating as metal.—I am, &c.,

DEPOSIT.

ESTIMATION OF ALUMINA IN IRON AND STEEL.

To the Editor of the Chemical News.

SIR,—In answer to Mr. C. H. Ridsdale's letter (CHEMICAL NEWS, vol. lxii., p. 11), I beg to state that my method for the estimation of aluminium in iron and steel published in the CHEMICAL NEWS (vol. lxi., p. 313) is, in reality, a combination of other methods, carefully thought out and put together. I do not, therefore, claim originality for it; and, though Mr. Stead may have had his method in print first, I must say that the method has been worked by me in the estimation of aluminium in ferro-aluminium alloys for a number of years, and have used the same method for the determination of aluminium in steel for the past seven months, not having been called upon before to execute the same, and I certainly had no idea that Mr. Stead had been working on the same lines, as his method did not come to my hand until the receipt, in May, of the second part of vol. iv. of the *Journal of Analytical Chemistry*. I have since then tried his method, and have found that it takes nearly double the time of execution, this being a consideration; therefore I think Mr. Ridsdale cannot claim all the credit of priority for Mr. Stead.—I am, &c.,

CHARLES PHILLIPS.

Chemical and Metallurgical Laboratories,

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cx., No. 25, June 23, 1890.

The Reciprocal Action of the Alkaline and Mercurous Haloid Salts.—A. Ditté.—The decomposition of mercurous chloride by sodium chloride into soluble mercurial salt and metallic mercury is only a special case of a general action exerted by the alkaline haloid salts upon the mercurous haloid salts, and which is effected in two different manners, the action being in some cases exothermic and in others endothermic.

Certain Lithium, Glucinum, Lead, and Uranium Phosphates.—L. Ouvrard.—The author has sought to obtain simple and double phosphates by dissolving the metallic oxides or carbonates in melted alkaline phosphates. He has obtained tribasic lithium phosphate, and he remarks that lithium deviates from the other members of the alkaline group by the insolubility of its phosphate. Glucinum gives, with potassium meta-pyro- or orthophosphates only a single salt, $\text{PO}_3, 2\text{BeO}, \text{KO}$, which

forms, with sodium metaphosphate, a double salt, agreeing in composition with the mineral beryllonite. With lead the author obtains a product similar in its composition to the glucinum salt, and forming a double sodium salt. Melting potassium metaphosphate yields, with uranium sesquioxide, a pyrophosphate in which uranyl oxide plays the part of a protoxide.

Combinations of Double Phosphorus and Iridium Chlorides with Arsenic Chloride.—G. Geisenheimer.—The double iridium and phosphorus chloride described in the *Comptes Rendus* (May 12, 1890) dissolves readily in arsenic chloride. The compound dissolves in water with liberation of hydrochloric acid.

Silver Subfluoride.—M. Gunz.—This compound contains 91.86 per cent of silver and 8.14 per cent of fluorine. It is unalterable in dry air, and is only slowly decomposed in moist air.

A Contribution to the Study of the Ptomaines.—Oechsner de Koninck.—This communication relates to the ptomaine $\text{C}_{10}\text{H}_{15}\text{N}$. When in a state of purity it is a slightly yellowish viscid liquid, of a pleasant odour, slightly soluble in water, very soluble in ether, absolute alcohol, acetone, and in the light ligroines. Its sp. gr. is about = 1.18, and it boils about 230° . It is very quickly oxidised in presence of atmospheric oxygen, turning brown and depositing a thick resin, soluble in acids. It does not attract carbon dioxide from the atmosphere. The hydrochlorate, $\text{C}_{10}\text{H}_{15}\text{N} \cdot \text{HCl}$, is prepared by rapidly saturating the ptomaine with HCl and evaporating *in vacuo*. If an exceedingly minute quantity of air is allowed to enter under the bell the salt instantly takes a rose colour, and in presence of a larger quantity of air it turns red and then brown. The chloroplatinate is a deep red powder, insoluble in cold water, very soluble in hot water, but decomposed in boiling water.

Preparation of the Yeasts of Wine.—A. Rommèr.—For obtaining the wine-yeasts the author uses grapes, the seeds of which he selects, crushes, and introduces them into small flasks. Several specimens were prepared in order to have at least one exempt from bacteria and mycoderms. When fermentation has set in the flasks are gently agitated, and one or two drops of the liquid were let fall into other flasks containing grape-juice rendered clear by filtration and sterilised by heat. On microscopic examination some of the samples were at once rejected. At last only the yeast was left, known as *Saccharomyces ellipsoideus*.

Revue Universelle des Mines et de la Metallurgie.
Series 3, Vol. ix., Nos. 2 and 3.

The Production and Decomposition of Carbonic Acid in Coke-Blast Furnaces.—Felix Brabant.—The author considers that his results prove the possibility of improving the working of many furnaces, notwithstanding the persistence of a loss resulting from a reduction of CO_2 to CO .

Studies on the Processes for the Analysis of Raw Materials and Finished Products in the Metallurgy of Iron.—C. Meinecke.

Determination of Phosphorus by Molybdenum.—The question is raised whether the presence of manganese interferes with the precipitation? The author answers in the negative, and suspects that the results of M. Tamm must be due to his having operated upon spiegel and ferro-manganese without calcining the nitrates. He asks with what certainty may we conclude from the proportion of phosphorus directly precipitable by molybdate in the nitric solution of an iron as to the total phosphorus present? He admits that the proportion of phosphorus immediately precipitable by molybdate after the solution of the sample in nitric acid is liable to great variation. These may probably be made to disappear by operating always under identical conditions.

Oxidation of the Solution by Chromic Anhydride or Permanganate.—The author, Mr. Wood, has recommended oxidation by chromic acid to obtain the totality of phosphorus in a form precipitable by molybdate without evaporating down the nitric solution and calcining the residue. The author recommends the use of a sufficiency of nitric acid (avoiding excess), and by an addition of sulphuric acid. The details of this process, and of the use of nitroso- β -naphthol for the determination of iron and its separation from manganese and aluminium, are inserted in full. (See p. 19).

Vol. x., Nos. 1 and 2.

Corrosions of Steam-Boilers and the Incrustations in Marine Boilers.—The author, M. Schwarz, Inspector of Steam-Boilers in Austria, divides the corrosive agents into four groups:—(1) Gases held in solution by the feed-water; (2) insoluble matter; (3) soluble matter; and (4) volatile acids. The gases in question are chiefly oxygen and carbonic acids. The remedy is their elimination by a previous heating to 70°, or by rendering the water alkaline by a small addition of soda. The insoluble matters are animal and vegetable fats employed in lubrication. Corrosion may be prevented by the use of sodium carbonate, and the use of mineral oils in lubrication is a certain preservative. The soluble injurious matters are either such whose action increases with temperature and concentration, and comprise sodium chloride, ammonium chloride introduced by certain anti-incrustation nostrums, and caustic soda in the Honigmann boilers. The free acids are nitric acid in the waste waters of zinc works, organic acids in the waters from marshy lands, hydrochloric and sulphuric acid from the waste waters of bleach works, and sulphuric acid from the waters of mines and quarries. Corrosion by these agents is prevented by means of soda. Among the substances whose corrosive action begins at a higher temperature are the brown liquor from wood in the chemical preparation of cellulose, saccharine liquors in sugar works, and magnesium chloride. The general means for preventing the damage consists in the addition of a little soda, and sometimes in the introduction of plates of zinc.

Journal für Praktische Chemie.

New Series, Vol. xli., Nos. 4, 5, and 6.

Researches from the Laboratory of A. Weddige.—A paper on alkyl-ortho-phenyldiamines and its derivatives. Alkyl-ortho-phenyldiamines in an acid solution pass into alkylimido-benzols by the action of sodium nitrite. On the action of the same nitrite upon acetyl-orthophenyldiamine hydrochlorates, or by passing nitrous gas into the ethereal solution, there is no production of nitrosoacetylalkylorthophenyldiamines. Nitronitroso-alkylanilines are obtained by treating orthonitroalkylanilines with nitrous gas. These nitroso-compounds in acid solutions are not converted by reducing agents into the corresponding hydrazines, but into alkylortho-phenyldiamines. In alcoholic solutions they can be converted into orthoamidophenylalkylhydrazines by ammonium sulphide. Acetorthoamidophenylmethylhydrazine can be converted into α -phenyltriazine by appropriate treatment with phosphoric anhydride. On treating orthoamidophenylalkylhydrazines with sodium nitrite in an acid solution there are formed α -alkylphenyltriazines.

A New Method for the Preparation of Aromatic Mercaptans.—R. Leuckhart. Aniline and its homologues have been converted into phenylmercaptan and the homologous aromatic mercaptans. Ortho- and para-amidophenol were transformed into monothiopyrocatechin and monothiohydroquinone, &c. The conversions were in general obtained most smoothly about 70°, the diazo-compounds obtained at lower temperatures are often decomposed explosively on a rise of temperature.

The Action of Iodoform, Methyleniodide, and Iodine upon Sodium Isobutylate.—A. Gorbhoff and A. Kessler.—This memoir does not admit of useful abstraction.

Monazite from the Ural.—C. W. Blomstrand.—From the analyses it appears that we cannot, with Penfield, allot thoria exclusively to silicic acid, since, in most cases, the cerium and yttrium earths do not suffice to saturate the phosphoric acid.

Researches from the Laboratory of Prof. Saytseff at Kasan.—These consist of a paper by S. Reformatsky on the first oxide of the quadrivalent alcohols.

Researches from the Laboratory of the University of Freiburg.—These include memoirs on dichloronaphthoquinone dichloride, by Ad. Claus, and on the special arrangement of the atoms in nitrogenous compounds, by C. Willgerodt.

MISCELLANEOUS

The Diseases of Crops.—Messrs. George Bell and Sons will publish in a few days an octavo volume entitled "The Diseases of Crops and their Remedies," by Dr. A. B. Griffiths, F.R.S.E. The work is illustrated with 51 figures, and the chemical treatment of plant diseases is fully discussed.

The Behaviour of Ammonium Formiate upon Ketones.—R. Leuckart.—It results from these researches that ammonium formiate, in its behaviour with acetone, acts like free ammonia, and has, at the same time, a reducing effect. That the course of the transformation is here quite different from that in the simple aldehyds and ketones of the aromatic series depends on the peculiar nature of the ketones of the aliphatic series.—*Journal für Praktische Chemie*, xli., Part 7.

TO CORRESPONDENTS.

T. Smyth.—The annual subscription to the Chemical Society is £2 2s., with £2 2s. entrance fee. A letter to the Secretary of the Society, Burlington House, London, W., will get you all necessary information.

PATENTS, DESIGNS, & TRADE MARKS ACT, 1883.

NOTICE IS HEREBY GIVEN that the BADISCHE ANILIN AND SODA FABRIK, of Ludwigshafen-on-Rhine, in the Empire of Germany, have applied for leave to amend the Specification of Letters Patent No. 15,259 of 1888, granted to James Yate Johnson for "The manufacture of the sulpho-acids of a red basic naphthalene dye-stuff."

Particulars of the proposed amendment were set forth in the Illustrated Official Journal (Patents) issued on the 2nd July, 1890.

Any person may give notice (on Form G) at the Patent Office, 25, Southampton Buildings, London, W.C., of opposition to the amendment within one month from the date of the said Journal.

(Signed)

H. READER LACK,
Comptroller-General.

H. READER LACK,
Comptroller-General.

THE CHEMICAL NEWS.

VOL. LXII. No. 1599.

EXAMINATION OF OILS, FATS, AND ALLIED SUBSTANCES.

By THOMAS T. P. BRUCE WARREN.

THE substances alluded to in this paper may be divided into three distinct classes according to their behaviour with sulphur chloride. The solid magma which some of them yield with this reagent may be either totally soluble in carbon disulphide or only partially soluble, whilst others simply act as solvents, and apparently undergo no change. This reaction enables us to separate one class of these substances from the other two.

Assuming that we have taken every precaution to obtain a representative sample as regards purity, age, and condition of the substance operated on, we have the advantage of securing a product which can easily be kept for reference or comparison, a matter of no small importance when we consider how liable most oils are to change in a short time.

Many of the oils referred to have been prepared by myself where the sources were available, or from manufacturers of repute in cases where I have had to depend on others for the integrity of a sample.

Oils and fats obtained from animal sources, fish oils, and the concrete vegetable oils do not yield insoluble products, but are easily separated from the fluid vegetable oils, when a mixture of them is acted on by sulphur chloride. Oils obtained from pine resins behave in a similar way. The fluid vegetable oils, when deprived of a portion of their glycerin, behave in the same way, as regards their altered portion.

Hence, if a rapid stream of oxygen or ozonised oxygen (by preference) be passed through a mixture of these oils, the more easily oxidised oil can be separated from those not so readily acted on. The fatty acids of these oils do not form insoluble compounds, and are recognised by yielding dark coloured products.

Olive oil adulterated with cotton-seed oil and lard oil can easily be recognised by this treatment. Lard oil can be washed out by carbon disulphide from the solid magma; another portion well oxidised will, by the same solvent, give up both the lard oil and the fatty acids of the cotton-seed oil. The insoluble magma will be very dark, owing to the difficulty of entirely removing the oxidised oil. Treatment with a moderately strong alkaline solution will more effectually remove it. I have frequently met with a mixture of these oils having an iodine absorption closely approaching that of pure olive oil.

When pure olive oil is acted upon for some time with ozonised oxygen the colour of the insoluble product, reveals the fact that little or no absorption has taken place, pure olive oil is probably the most stable of all the vegetable oils, hence its non-suitability as a "drying oil."

Drying oils or the more easily oxidised oils, such as poppy oils, seed oil, walnut oil, linseed oil, rape, and cotton-seed oils are readily recognised. When either of these oils or a mixture containing either of them is ozonised, a reduced factor for iodine absorption is at once apparent; the extent or rapidity of oxidation is measured by the rate of diminution of iodine absorption.

A so-called "cold drawn oil" has a higher iodine absorption than when heat is used, and when the oil has been extracted from the seeds by solvents a still higher iodine absorption is noticeable. This is due in a great measure to oxidation, which reduces the iodine absorption in proportion to the extent to which it is carried.

From a consideration of this fact, it is easy to conceive that olive oil will vary according to the condition of the olive when pressed. In the plant economy the assimilation of oxygen in the ripening of the fruit would lead one to say that a reduced iodine absorption should follow. Experiment, however, does not confirm this assumption, which will be referred to hereafter.

Cotton-seed oil, as such, is rarely used for adulterations; in some cases the olein and in other cases the stearin, both more or less impure, are used.

Lard oil, which is used as a lubricant, contains, very frequently, a large proportion of cotton oil stearin, whereas oleomargarin contains principally cotton oil olein.

Machine oils containing *thickened* or *blown* oils of cotton seed or rape seed, so as to obtain an increased viscosity, are easily recognised. The viscosity of an oil before and after passing oxygen through it is an important indication in the analysis of oils; a drying oil is detected by an alteration in the iodine absorption and increased viscosity.

Iodine Absorption of Oils, &c.—Anyone who has worked on this subject must have found that comparable results involve most scrupulous care in every detail connected with its application.

Hubl's Reagent.—When a great number of samples have to be examined a litre of this reagent may be made, but, as it rapidly alters it should not be kept longer than a week or so. When only a few samples have to be dealt with, a waste from deterioration and other causes can hardly be avoided unless the samples are allowed to accumulate, which is undesirable, even if delay involves no inconvenience.

The solutions of mercuric chloride and iodine, separately, will keep tolerably well for some time, but, if mixed together, continue to change every day. This difficulty is met by making the alcoholic solutions of proper strength and mixing them as required; in this way a single sample of oil may be examined without waste or extra trouble. When little or nothing is known of a sample the test should be made in duplicate to guard against accident in the final titration with sodium thiosulphate. A blank test on the same quantity of Hubl chloroform employed should always be made, the mixture standing for the same time and in the same place as the oil under test. The reaction is allowed to go on in a dark cupboard, which is supplied with a registering thermometer so as to record the changes of temperature during the time. An accurately stoppered yellow tinted flask is used, about 6 ozs. capacity, the flasks and stoppers being marked so as to avoid being changed. The upper part of the neck is enlarged so as to admit of being luted with a little potassium iodide solution, to catch any iodine which may escape between the neck and stopper. An accurately fitting glass cap encloses the stopper and lute.

When the reaction is allowed to go on for four or six hours, as recommended, an awkward difficulty arises, due partly to the fact that it is not always possible to attend to the final titration at the precise time, and what is of more importance, an hour's extra digestion will make a very great difference in the result. To avoid the chance of this occurring, the reaction is allowed to go on for twenty to twenty-four hours, as I have found that after eighteen hours no appreciable change occurs, a matter of importance in a general laboratory. The test can be put on and finished towards the end of each day.* Volatile liquids are weighed in a stoppered flask or measured from an accurate pipette.

It is generally assumed that all oils have the same coefficient of expansion. From some recent experiments on the capacity for heat of different oils I found that oils

* A paper recently read by Messrs. Thomson and Ballantyne before the Society of Chemical Industry on the "Revision of Oil Constants" confirms the liability of absorption to alter with increased digestion.

vary considerably in their expansions, but care must be taken to conduct such experiments, so as to avoid ingress of atmospherical oxygen or loss of volatile products.

When oils are sent out by a manufacturer the casks are filled nearly to the bung; if a slight increase of temperature takes place the expansion forces the oil through any weak places in the package and into the wood itself; hence a serious loss must fall to the lot of the buyer; with olive or sperm oil the loss is more serious, as these oils become more fluid and do not dry up.

DETERMINATION OF PHOSPHORUS IN IRON.

In order to obtain the whole of the phosphorus in a state precipitable by molybdate without evaporating down the nitric solution and igniting the residue, Herr Meinecke and Mr. Wood recommend oxidation with chromic acid. They dissolve 4.375 grms. of the metal in a covered vessel in 40 to 50 c.c. of nitric acid at sp. gr. 1.3 (if the iron is very manganiferous 40 c.c. are sufficient). When the solution is completed 30 c.c. of dilute sulphuric acid are added (1 vol. acid to 1 vol. water), and the liquid is evaporated down to 15–20 c.c. From 2½ to 3 grms. chromic acid in crystals (not more) are then added, and the liquid is boiled for ten minutes to complete the oxidation of the carbon compounds and of the phosphorous acid. It is let partly cool and water is carefully added. If the evaporation has been carried too far, manganese peroxide may separate out and retain phosphorus; if this happens the peroxide must be reduced by the addition of oxygenated water. It must be remembered that all samples of oxygenated water met with in commerce contain phosphoric acid in small quantities. Hence if much of this reagent has to be used account must be taken of this impurity.

The solution contains, in an insoluble state, only a little graphite and silica; it is made up to 250 c.c., filtered through a dry filter, and 100 c.c. are taken by means of a pipette. The acid is partially neutralised by means of ammonia, heated to 85°–90°, and 50 to 100 c.c. of the molybdic reagent are added. It is convenient to precipitate in a vessel so large that it may be only half full. In this case, by leaning the beaker after the precipitate is settled we may uncover a part of the bottom. If we then cautiously bring back the beaker to its normal position that part of the bottom remains free from deposit. If, after the lapse of half an hour, we find that no fresh deposit is formed, we know that the precipitation is completed, and we then draw off the clear supernatant liquid by means of a small syphon.

The precipitate is collected on a filter as small as possible, washed at first with an acid solution of ammonium nitrate, then with pure water, and is lastly transformed into molybdenum phosphomolybdate, $P_2O_5Mo_{24}O_{68}$, by a moderate ignition. Each gm. of the product corresponds to one per cent of phosphorus.

M. von Reiss in the analysis of steels uses potassium permanganate instead of chromic acid and obtains satisfactory results.

The author has used the same process, slightly modified, with success in the analysis of cast metal rich in carbon.

He dissolves 4.375 grms. of the metal in 40 c.c. of nitric acid. If the sample is rich in manganese there is obtained on the addition of permanganate an immediate precipitate of peroxide. The results are always satisfactory on operating as follows:—To the nitric solution of the metal there are added 25 c.c. of nitric acid at sp. gr. 1.4; then 5 c.c. permanganate at 15 per thousand and the liquid is boiled. After a few minutes a fresh portion of permanganate is added, and then a third under the same conditions. There is then produced a manganic precipitate, which a new and final addition of permanganate increases. The liquid is then boiled for a few

minutes longer, cooled quickly, and the oxide is removed by oxygenated water added in small successive proportions. The liquid contains all the phosphorus in the state of a phosphate precipitable by molybdate.—*Revue des Mines*, ix., p. 239.

THE PHOTOGRAPHIC IMAGE.*

By Professor RAPHAEL MELDOLA, F.R.S.

THE history of a discovery which has been developed to such a remarkable degree of perfection as photography has naturally been a fruitful source of discussion among those who interest themselves in tracing the progress of science. It is only my presence in this lecture theatre, in which the first public discourse on photography was given by Thomas Wedgwood at the beginning of the century, that justifies my treading once again a path which has already been so thoroughly well beaten. If any further justification for trespassing upon the ground of the historian is needed, it will be found in the circumstance that in the autumn of last year there was held a celebration of what was generally regarded as the jubilee of the discovery. This celebration was considered by many to have reference to the public disclosure of the Daguerreotype process, made through the mouth of Arago to the French Academy of Sciences on August 10, 1839. There is no doubt that the introduction of this process marked a distinct epoch in the history of the art, and gave a great impetus to its subsequent development. But, while giving full recognition to the value of the discovery of Daguerre, we must not allow the work of his predecessors and contemporaries in the same field to sink into oblivion. After the lapse of half a century we are in a better position to consider fairly the influence of the work of different investigators upon modern photographic processes.

I have not the least desire on the present occasion to raise the ghosts of dead controversies. In fact, the history of the discovery of photography is one of those subjects which can be dealt with in various ways, according to the meaning assigned to the term. There is ample scope for the display of what Mr. Herbert Spencer calls the "bias of patriotism." If the word "photography" be interpreted literally as writing or inscribing by light, without any reference to the subsequent permanence of the inscription, then the person who first intentionally caused a design to be imprinted by light upon a photosensitive compound must be regarded as the first photographer. According to Dr. Eder, of Vienna, we must place this experiment to the credit of Johann Heinrich Schulze, the son of a German tailor, who was born in the Duchy of Magdeburg, in Prussia, in 1687, and who died in 1744, after a life of extraordinary activity as a linguist, theologian, physician, and philosopher. In the year 1727, when experimenting on the subject of phosphorescence, Schulze observed that by pouring nitric acid, in which some silver had previously been dissolved, on to chalk, the undissolved earthy residue had acquired the property of darkening on exposure to light. This effect was shown to be due to light, and not to heat. By pasting words cut out in paper on the side of the bottle containing his precipitate, Schulze obtained copies of the letters on the silvered chalk. The German philosopher certainly produced what might be called a temporary photogram. Whatever value is attached to this observation in the development of modern photography, it must be conceded that a considerable advance was made by spreading the sensitive compound over a surface instead of using it in mass. It is hardly necessary to remind you here that such an advance was made by Wedgwood and

* A Lecture delivered at the Royal Institution of Great Britain, May 16, 1890.

Davy in 1802.* The impressions produced by these last experimenters were, unfortunately, of no more permanence than those obtained by Schulze three quarters of a century before them.

It will, perhaps, be safer for the historian of this art to restrict the term photograph to such impressions as are possessed of permanence: I do not, of course, mean absolute permanence, but ordinary durability in the common-sense acceptance of the term. From this point of view, the first real photographs, *i.e.*, permanent impressions of the camera picture, were obtained on bitumen films by Joseph Nicéphore Niepce, of Châlons-sur-Saône, who, after about twenty years' work at the subject, had perfected his discovery by 1826. Then came the days of silver salts again, when Daguerre, who commenced work in 1824, entered into a partnership with Niepce in 1829, which was brought to a termination by the death of the latter in 1833. The partnership was renewed between Daguerre and Niepce de St. Victor, nephew of the elder Niepce. The method of fixing the camera picture on a film of silver iodide on a silvered copper plate—the process justly associated with the name of Daguerre, was ripe for disclosure by 1838, and was actually made known in 1839.

The impartial historian of photography who examines critically into the evidence will find that, quite independently of the French pioneers, experiments on the use of silver salts had been going on in this country, and photographs, in the true sense, had been produced almost simultaneously with the announcement of the Daguerreotype process, by two Englishmen whose names are as household words in the ranks of science—I refer to William Henry Fox Talbot and Sir John Herschel. Fox Talbot commenced experimenting with silver salts on paper in 1834, and the following year he succeeded in imprinting the camera picture on paper coated with the chloride. In January, 1839, some of his "photogenic drawings"—the first "silver prints" ever obtained—were exhibited in this Institution by Michael Faraday. In the same month he communicated his first paper on a photographic process to the Royal Society, and in the following month he read a second paper before the same society, giving the method of preparing the sensitive paper and of fixing the prints. The outcome of this work was the "Calotype" or Talbotype process, which was sufficiently perfected for portraiture by 1840, and which was fully described in a paper communicated to the Royal Society in 1841. The following year Fox Talbot received the Rumford Medal for his "discoveries and improvements in photography."†

Herschel's process consisted in coating a glass plate with silver chloride by subsidence. The details of the method, from Herschel's own notes, have been published by his son, Prof. Alexander Herschel.‡ By this means the old 40-foot telescope at Slough was photographed in 1839. By the kindness of Prof. Herschel, and with the sanction of the Science and Art Department, Herschel's original photographs have been sent here for your inspection. The process of coating a plate by allowing a precipitate to settle on it in a uniform film is, however, impracticable, and was not further developed by its illustrious discoverer. We must credit him, however, as being the first to use glass as a substratum. Herschel further discovered the important fact that while the chloride was very insensitive alone, its sensitiveness was greatly increased by washing it with a solution of silver nitrate. It is to Herschel, also, that we are indebted for the use of sodium thiosulphate as a fixing agent, as well as for many other discoveries in connection with photography, which are common matters of history.

* "An Account of a Method of Copying Paintings upon Glass, and making Profiles by the Agency of Light upon Nitrate of Silver. Invented by T. Wedgwood, Esq. With Observations by H. Davy," *Journ. R. I.*, 1802, p. 170.

† For these and other details relating to Fox Talbot's work, necessarily excluded for want of time, I am indebted to his son, Mr. C. H. Talbot, of Lacock Abbey.

‡ *Photog. Journ. and Trans. Photog. Soc.*, June 15, 1872.

Admitting the impracticability of the method of subsidence for producing a sensitive film, it is interesting to trace the subsequent development of the processes inaugurated about the year 1839. The first of photographic methods—the bitumen process of Niepce—survives at the present time, and is the basis of some of the most important of modern photo-mechanical printing processes. [Specimens illustrating photo-etching from Messrs. Waterlow and Sons exhibited.] The Daguerreotype process is now obsolete. As it left the hands of its inventor it was unsuited for portraiture, on account of the long exposure required. It is evident, moreover, that a picture on an opaque metallic plate is incapable of reproduction by printing through, so that in this respect the Talbotype possessed distinct advantages. This is one of the most important points in Fox Talbot's contributions to photography. He was the first to produce a transparent paper negative from which any number of positives could be obtained by printing through. The silver print of modern times is the lineal descendant of the Talbotype print. After forty years' use of glass as a substratum, we are going back to Fox Talbot's plan, and using thin flexible films—not exactly of paper, but of an allied substance, celluloid. [Specimens of Talbotypes, lent by Mr. Crookes, exhibited, with celluloid negatives by the Eastman Company.]

If I interpret this fragment of history correctly, the founders of the modern photography are the three men whose labours have been briefly sketched. The jubilee of last autumn marked a culminating point in the work of Niepce and Daguerre, and of Fox Talbot. The names of these three pioneers must go down to posterity as co-equal in the annals of scientific discovery. [Portraits by Mr. H. M. Elder shown.] The lecture theatre of the Royal Institution offers such tempting opportunities to the chronicler of the history of this wonderful art that I must close this treatment of the subject by reminding myself that in selecting the present topic I had in view a statement of the case of modern photography from its scientific side only. There is hardly any invention associated with the present century which has rendered more splendid services in every department of science. The physicist and chemist, the astronomer and geographer, the physiologist, pathologist, and anthropologist will all bear witness to the value of photography. The very first scientific application of Wedgwood's process was made here by the illustrious Thomas Young, when he impressed Newton's rings on paper moistened with silver nitrate, as described in his Bakerian Lecture to the Royal Society on November 24, 1803. Prof. Dewar has just placed in my hands the identical slide, with the Newton rings still visible, which he believes Young to have used in this classic experiment. [Shown.]

Our modern photographic processes depend upon chemical changes wrought by light on films of certain sensitive compounds. Bitumen, under this influence, becomes insoluble in hydrocarbon oils, as in the heliographic process of the elder Niepce. Gelatin mixed with potassium dichromate becomes insoluble in water on exposure to light, a property utilised in the photo-etching process introduced in 1852 by Fox Talbot, some of whose original etchings have been placed at my disposal by Mr. Crookes. [Shown.] Chromatised gelatin now plays a most important part in the autotype and many photo-mechanical processes. The salts of iron in the ferric condition undergo reduction to the ferrous state under the influence of light in contact with oxidisable organic compounds. The use of these iron salts is another of Sir John Herschel's contributions to photography (1842), the modern "blue print" and the beautiful platinotype being dependent on the photo-reducibility of these compounds. [Cyanotype print developed with ferricyanide.]

Of all the substances known to chemistry at the present time, the salts of silver are by far the most important in photography, on account of the extraordinary degree of sensitiveness to which they can be raised. The photo-

graphic image, with which it is my privilege to deal on this occasion, is that invisible impression produced by the action of light on a film of a silver haloid. Many methods of producing such films have been in practical use since the foundation of the art in 1839. All these depend on the double decomposition between a soluble chloride, bromide, or iodide, and silver nitrate, resulting in the formation of the silver haloid in a vehicle of some kind, such as albumen (Niepce de St. Victor, 1848), or collodion on glass, as made practicable by Scott Archer in 1851. For twenty years this collodion process was in universal use; its history and details of manipulation, its development into a dry plate process by Colonel Russell in 1861, and into an emulsion process by Bolton and Sayce in 1864, are facts familiar to every one.

The photographic film of the present time is a gelatino-haloid (generally bromide) emulsion. If a solution of silver nitrate is added to a solution of potassium bromide and the mixture well shaken, the silver bromide coagulates, and rapidly subsides to the bottom of the liquid as a dense curdy precipitate. [Shown.] If instead of water we use a viscid medium, such as gelatin solution, the bromide does not settle down, but forms an emulsion, which becomes quite homogeneous on agitation. [Shown.] This operation, omitting all details of ripening, washing, &c., as well known to practical photographers, is the basis of all the recent photographic methods of obtaining negatives in a camera. The use of this invaluable vehicle, gelatin, was practically introduced by R. L. Maddox in 1871, previous experiments in the same direction having been made by Gaudin (1853-61). Such a gelatino-bromide emulsion can be spread uniformly over any substratum—glass, paper, gelatin, or celluloid—and when dry, gives a highly sensitive film.

The fundamental problem which fifty years' experience with silver haloid films has left in the hands of chemists is that of the nature of the chemical change which occurs when a ray of light falls on such a silver salt. Long before the days of photography—far back in the sixteenth century—Fabricius, the alchemist, noticed that native horn silver became coloured when brought from the mine and exposed. The fact presented itself to Robert Boyle in the seventeenth century, and to Beccarius, of Turin, in the eighteenth century. The change of colour undergone by the chloride was first shown to be associated with chemical decomposition in 1777, by Scheele, who proved that chlorine was given off when this salt darkened under water. I can show you this in a form which admits of its being seen by all. [Potassium iodide and starch paper were placed in a glass cell with silver chloride, and the arrangement exposed to the electric light till the paper had become blue.] The gas which is given off under these circumstances is either the free halogen or an oxide, or acid of the halogen, according to the quantity of moisture present and the intensity of the light. I have found that the bromide affects the iodide and starch paper in the same way, but silver iodide does not give off any gas which colours the test paper. All the silver haloids become coloured on exposure to light, the change being most marked in the chloride, less in the bromide, and least of all in the iodide. The latter must be associated with some halogen absorbent to render the change visible. [Strips of paper coated with the pure haloids, the lower halves brushed over with silver nitrate solution, were exposed.] The different degrees of colouration in the three cases must not be considered as a measure of the relative sensitiveness: it simply means that the products of photo-chemical change in the three haloids are inherently possessed of different depths of colour.

From the fact that halogen in some form is given off, it follows that we are concerned with photo-chemical decomposition, and not with a physical change only. All the evidence is in favour of this view. Halogen absorbents, such as silver nitrate on the lower halves of the papers in the last experiment, organic matter, such as the gelatin in an emulsion, and reducing agents generally, all

accelerate the change of colour. Oxidising and halogenising agents, such as mercuric chloride, potassium dichromate, &c., all retard the colour change. [Silver chloride paper, painted with stripes of solutions of sodium sulphite, mercuric chloride, and potassium dichromate, was exposed.] It is impossible to account for the action of these chemical agents except on the view of chemical decomposition. The ray of light falling upon a silver haloid must be regarded as doing chemical work; the vibratory energy is partly spent in doing the work of chemical separation, and the light passes through a film of such haloid partly robbed of its power of doing similar work upon a second film. It is difficult to demonstrate this satisfactorily in the lecture-room, on account of the opacity of the silver haloids, but the work of Sir John Herschel, J. W. Draper, and others, has put it beyond doubt that there is a relationship of this kind between absorption and decomposition. It is well known, also, that the more refrangible rays are the most active in promoting the decomposition in the case of the silver haloids. This was first proved for the chloride by Scheele, and is now known to be true for the other haloids. It would be presumption on my part, in the presence of Captain Abney, to enlarge upon the effects of the different spectral colours on these haloids, as this is a subject upon which he can speak with the authority of an investigator. It only remains to add that the old idea of a special "actinic" force at the more refrangible end of the spectrum has long been abandoned. It is only because the silver haloids absorb these particular rays that the blue end of the spectrum is most active in promoting their decomposition. Many other instances of photo-chemical decomposition are known in which the less refrangible rays are the most active, and it is possible to modify the silver haloids themselves, so as to make them sensitive for the red end of the spectrum.

The chemical nature of the coloured products of photo-chemical decomposition is still enshrouded in mystery. Beyond the fact that they contain less halogen than the normal salt, we are not much in advance of the knowledge bequeathed to us by Scheele in the last century. The problem has been attacked by chemists again and again, but its solution presents extraordinary difficulties. These products are never formed—even under the most favourable conditions of division and with prolonged periods of exposure—in quantities beyond what the chemists would call "a mere trace." Their existence appears to be determined by the great excess of unaltered haloid with which they are combined. Were I to give free rein to the imagination, I might set up the hypothesis that the element silver is really a compound body invariably containing a minute percentage of some other element, which resembles the compound which we now call silver in all its chemical reactions, but alone is sensitive to light. I offer this suggestion for the consideration of the speculative chemist.* For the coloured product as a whole, i.e., the product of photo-decomposition with its combined unchanged haloid, Carey Lea has proposed the convenient term "photo-salt." It will avoid circumlocution if we adopt this name. The photo-salts have been thought at various times to contain metallic silver, allotropic silver, a sub-haloid, such as argentous chloride, &c., or an oxyhaloid. The free metal theory is disposed of by the fact that silver chloride darkens under nitric acid of sufficient strength to dissolve the metal freely. The acid certainly retards the formation of the photo-salt, but does not prevent it altogether.

* I have gone so far as to test this idea experimentally in a preliminary way, the result being, as might have been anticipated, negative. Silver chloride, well darkened by long exposure, was extracted with a hot saturated solution of potassium chloride, and the dissolved portion, after precipitation by water, compared with the ordinary chloride by exposure to light. Not the slightest difference was observable either in the rate of colouration or in the colours of the products. Perhaps it may be thought worth while to repeat the experiment, using a method analogous to the "method of fractionation" of Crookes.

When once formed the photo-chloride is but slowly attacked by boiling dilute nitric acid, and from the dry photo-salt mercury extracts no silver. The assumption of the existence of an allotropic form of silver insoluble in nitric acid cannot be seriously maintained. The subhaloid theory of the product may be true, but it has not yet been established with that precision which the chemist has a right to demand. We must have analyses giving not only the percentage of halogen, but also the percentage of silver, in order that it may be ascertained whether the photo-salt contains anything besides metal and halogen. The same may be said of the oxyhaloid theory: it may be true, but it has not been demonstrated.

The oxyhaloid theory was first suggested by Robert Hunt* for the chloride; it was taken up by Sahler, and has recently been revived by Dr. W. R. Hodgkinson. It has been thought that this theory is disposed of by the fact that the chloride darkens under liquids, such as hydrocarbons, which are free from oxygen. I have been repeating some of these experiments with various liquids, using every possible precaution to exclude oxygen and moisture; dry silver chloride, heated to incipient fusion, has been sealed up in tubes of dry benzene, petroleum, and carbon tetrachloride, and exposed since March. [Tubes shown.] In all cases the chloride has darkened. The salt darkens, moreover, in a Crookesian vacuum.† By these experiments the oxychloride theory may be scotched, but it is not yet killed; the question now presents itself, whether the composition of the photo-salt may not vary according to the medium in which it is generated. Analogy sanctions the supposition that when the haloid darkens under water or other oxygen-containing liquid, or even in contact with moist or dry air, that an oxychloride may be formed, and enter into the composition of the photo-salt. The analogy is supplied by the corresponding salt of copper, viz., cuprous chloride, which darkens rapidly on exposure. [Design printed on flat cell filled with cuprous chloride by exposure to electric light.] Wöhler conjectured that the darkened product was an oxychloride, and this view receives a certain amount of indirect support from these tubes [shown], in which dry cuprous chloride has been sealed up in benzene and carbon tetrachloride since March; and although exposed in a southern window during the whole of that time, the salt is as white as when first prepared. Some cuprous chloride sealed up in water, and exposed for the same time, is now almost black. [Shown.]

When silver is precipitated by reduction in a finely divided state in the presence of the haloid, and the product treated with acids, the excess of silver is removed and coloured products are left which are somewhat analogous to the photo-salts proper. These coloured haloids are also termed, by Carey Lea, photo salts, because they present many analogies with the coloured products of photo-chemical change. Whether they are identical in composition it is not yet possible to decide, as we have no complete analyses. The first observations in this direction were published more than thirty years ago in a report by a British Association Committee;‡ in

which the red and chocolate-coloured chlorides are distinctly described. Carey Lea has since contributed largely to our knowledge of these coloured haloids, and has at least made it appear highly probable that they are related to the products formed by the action of light. [Red photo-chloride and purple photo-bromide and iodide shown.]

The photographic image is impressed on a modern film in an inappreciable fraction of a second, whereas the photo-salt requires an appreciable time for its production. The image is invisible simply because of the extremely minute quantity of haloid decomposed. In the present state of knowledge it cannot be asserted that the material composing this image is identical in composition with the photo-salt; for we know the composition of neither the one nor the other. But they are analogous in so far as they are both the result of photo-chemical decomposition, and there is great probability that they are closely related, if not identical, chemically. It may turn out that there are various kinds of invisible images, according to the vehicle or halogen absorbent—in other words, according to the sensitiser with which the silver haloid is associated. The invisible image is revealed by the action of the developer, into the function of which I do not propose to enter. It will suffice to say that the final result of the developing solution is to magnify the deposit of photo-salt by accumulating metallic silver thereon by accretion or reduction. Owing to the circumstance that the image is impressed with such remarkable rapidity, and that it is invisible when formed, it has been maintained, and is still held by many, that the first action of light on the film is molecular or physical, and not chemical. The arguments in favour of the chemical theory appear to me to be tolerably conclusive, and I will venture to submit a few of them.

The action of reagents upon the photographic film is quite similar to the action of the same reagents upon the silver haloids when exposed to the point of visible colouration. Reducing agents and halogen absorbents increase the sensitiveness of the film; oxidising and halogenising agents destroy its sensitiveness. It is difficult to see on the physical theory why it should not be possible to impress an image on a film, say, of pure silver bromide, as readily as on a film of the same haloid embedded in gelatin. Everyone knows that this cannot be done. I have myself been surprised at the extreme insensitiveness of films of pure bromide prepared by exposing films of silver deposited on glass to the action of bromine vapour. On the chemical theory we know that gelatin is a splendid sensitiser—i.e., bromine absorbent. There is another proof which has been in our hands for nearly thirty years, but I do not think it has been viewed in this light before. It has been shown by Carey Lee, Eder, and especially by Abney—who has investigated the matter most thoroughly—that a shearing stress applied mechanically to a sensitive film leaves an impression which can be developed in just the same way as though it had been produced by the action of light. [Pressure marks on Eastman bromide paper developed by ferrous oxalate.] Now that result cannot be produced on a surface of the pure haloid, some halogen absorbent, such as gelatin, must be associated with the haloid. We are concerned here with a chemical change of that class so ably investigated by Prof. Spring, of Liège, who has shown that by mere mechanical pressure it is possible to bring about chemical reaction between mixtures of finely-divided solids.* Then, again, mild reducing agents, too feeble to

* "Researches on Light," and Ed., 1854, p. 80.

† Some dry silver chloride which Mr. Crookes has been good enough to send up for me in a high vacuum, darkens on exposure quite as rapidly as the dry salt in air. It soon regains its original colour when kept in the dark. It behaves, in fact, just as the chloride is known to behave when sealed up in chlorine, although its colour is of course much more intense after exposure than is the case with the chloride in chlorine. The tube in which the chloride had been sealed up in benzene gave off a considerable quantity of hydrogen chloride on breaking the point in June.

‡ These results were arrived at in three ways. In one case hydrogen was passed through silver citrate suspended in hot water, and the product extracted with citric acid. "The result of treating the residue with chlorhydric acid, and then dissolving the silver by dilute nitric acid, was a rose-tinted chloride of silver." In another experiment the dry citrate was heated in a stream of hydrogen at 212° F., and the product, which was partly soluble in water, gave a brown residue, which furnished "a very pale red body on being transformed by chlorhydric and nitric acids." In another experiment silver arsenite was formed, this being treated with caustic soda, and the black precipitate then treated successively with chlorhydric and

nitric acids: "Silver is dissolved, and there is left a substance . . . [of] a rich chocolate or maroon, &c." This on analysis was found to contain 24 per cent of chlorine, the normal chloride requiring 24.7, and the sub-chloride 14.08 per cent. The committee which conducted these experiments consisted of Messrs. Maskelyne, Hadow, Hardwich, and Llewellyn. "B. A. Rep." 1859, p. 103.

* The connection between the two phenomena was suggested during a course of lectures delivered by me two years ago ("Chemistry of Photography," p. 191). I have since learnt that the same conclusion had been arrived at independently by Mr. C. H. Bothamley, of the Yorkshire College, Leeds.

reduce the silver haloids directly to the metallic state, such as alkaline hypophosphites, glucose or lactose, and alkali, &c., form invisible images which can be developed in precisely the same way as the photographic image. All this looks like chemical change, and not physical modification pure and simple.

I have in this discourse stoically resisted the tempting opportunities for pictorial display which the subject affords. My aim has been to summarise the position in which we find ourselves with respect to the invisible image after fifty years' practice of the art. This image is, I venture to think, the property of the chemist, and by him must the scientific foundation of photography be laid. We may not be able to give the formula of the photo-salt, but if the solution of the problem has hitherto eluded our grasp it is because of the intrinsic difficulties of the investigation. The photographic image brings us face to face—not with an ordinary, but with an extraordinary class of chemical changes due entirely to the peculiar character of the silver salts. The material composing the image is not of that definite nature with which modern chemical methods are in the habit of dealing. The stability of the photo-salt is determined by some kind of combination between the sub-haloid or oxy-haloid, or whatever it may be, and the excess of unaltered haloid which enters into its composition. The formation of the coloured product presents certain analogies with the formation of a saturated solution; the product of photo-chemical decomposition is formed under the influence of light up to a certain percentage of the whole photo-salt, beyond which it cannot be increased—in other words, the silver haloid is saturated by a very minute percentage of its own product of photo-decomposition. The photo-salt belongs to a domain of chemistry—a no-man's land—peopled by so-called "molecular compounds," into which the pure chemist ventures but timidly. But these compounds are more and more urging their claims for consideration, and sooner or later they will have to be reckoned with, even if they lack that definiteness which the modern chemist regards as the essential criterion of chemical individuality. The investigation may lead to the recognition of a new order of chemical attraction, or of the old chemical attraction in a different degree. The chemist who discourses here upon this subject at the end of the half-century of photography into which we have now entered, will no doubt know more about this aspect of chemical affinity; and, if I may invoke the spirit of prophecy in concluding, I should say that a study of the photographic film with its invisible image will have contributed materially to its advancement.

NOTES ON QUANTITATIVE ANALYSIS.*

By L. H. FRIEDBURG, Ph.D.

(Concluded from p. 24).

Fifth Portion.

For the determination of phosphoric acid fuse with Na_2CO_3 as directed for first portion, but dissolve in HNO_3 instead of using HCl . Reduce the silicic acid to a sandy powder, filter and acidulate with nitric acid. Prepare a solution of ammonium molybdate in the following manner: 100 grms. molybdic acid suspended in 240 grms. distilled water, of a temperature of about 50°C . are mixed with 160 grms. of NH_4OH of sp. gr. 0.91. If necessary, filter and allow this solution to run gradually into 1250 c.c. HNO_3 of sp. gr. 1.20. Shake at intervals and allow the clear solution to rest for five or six days in a moderately warm, dark place. Decant or syphon, if necessary, from yellow precipitate, and add H_2O to make 2 litres. Preserve this reagent in the dark.

In case the amount of phosphoric acid in the sample does not amount to more than one decigramme, and provided the volume of the liquid to be tested does not exceed 150 c.c., add an excess of the above solution of ammonium molybdate and put the beaker into a water-bath containing boiling water. Allow the beaker to remain for ten minutes in the boiling water and all phosphoric acid will be precipitated.

If the mineral is richer in phosphoric acid it must be treated with an excess of ammonium molybdate in a warm place for fully twenty-four hours.

In either case the precipitate is filtered, washed at first with the molybdate solution used for precipitation, finally with a solution of one-third that strength, obtained by dilution with H_2O . The united filtrates are allowed to stand for a while in order to see if an additional precipitate is formed.

The yellow precipitate on the filter is quantitatively dissolved in NH_4OH .

Magnesium mixture is now prepared in the following manner:—Magnesium chloride is dissolved in conc. HCl in the proportion of 5 grms. MgCl_2 to 30 c.c. HCl . Dilute with water and supersaturate with strong NH_4OH . If the liquid should not remain clear, but precipitate magnesia, enough NH_4Cl must be added to re-dissolve this.

Of a solution thus prepared, take a certain volume and divide into halves. One half is added to the ammoniacal solution of phospho-ammonium molybdate, after this has been nearly neutralised with HCl . Finally add strong NH_4OH , amounting to one-third of the entire volume of the liquid. Allow this to stand three to four hours.

Fill up the other half of the magnesium mixture taken, with the same quantity of NH_4OH used in forming the precipitate just described, and then with H_2O to obtain the same volume. A precipitate of magnesia formed here should be deducted from the previously described one.

The filtration, washing, and heating until magnesium pyrophosphate is obtained, takes place according to the description given, I.

Sixth Portion.

Fluorine is quite frequently found in silicates containing phosphoric acid. To determine F fuse the silicate, duly prepared, with Na_2CO_3 as previously described. Boil the cake with H_2O and a little NH_4OH in order to expel CO_2 , thus preventing solution of either SiO_2 or alumina. Filter, add HCl until the liquid is almost neutral. (Avoid acidity, since HF might escape.) Digest for some time with NH_4Cl in order to separate all SiO_2 and Al_2O_3 , filter if necessary, add CaCl_2 solution, and filter the precipitate consisting of calcium fluoride, calcium phosphate, and calcium carbonate. Heat the precipitate to redness in a porcelain crucible. Now, after cooling, add acetic acid and evaporate the mass again to dryness. Continue this treatment with acetic acid, alternating with washing with water and decanting, until the weight of the residue remains constant. In this manner calcium acetate and phosphate are extracted and calcium fluoride remains.

Seventh Portion.

In order to determine titanate, the mineral is fused with potassium bisulphate, using six to eight times the quantity of this latter. Dissolve the fused mass in a little cold water, dilute strongly, and boil slowly in a round flask. From time to time add water, since titanate acid is only precipitated from very dilute solutions. In order to prevent precipitate of Fe add either sulphur dioxide, sodium hyposulphite, or H_2S to the liquid, thus reducing Fe_2O_3 or avoiding the oxidation of FeO . The precipitate of titanate acid is heated and weighed. If not quite colourless repeat the operation.

Eighth Portion.

For the determination of soluble silicic acid treat the mineral in a platinum crucible with conc. KOH solution upon the water-bath for one-quarter to one-half hour.

* From the *Journal of the American Chemical Society*, vol. xii., No. 5.

Avoid too great concentration of the liquid, as the silicic acid dissolved would be re-precipitated. If it be suspected that the mineral decomposes, heat only for a short time. The contents of the crucible are transferred to a beaker, diluted strongly, washed by decantation with boiling water until no further reaction of KOH is obtained. The residue is heated and weighed; the operation is repeated until the weight is constant.

If, upon decantation, the precipitate should not settle or should run turbid through the filter, a slight acidulation of the wash water will frequently serve. In case free quartz was present, this would become partly soluble on heating. In such case the mineral is treated several times with KOH solution, decanted each time as described, but only heated and weighed once, which weight must then suffice.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING JUNE 30TH, 1890.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;

and C. MEYMOTT TIDY, M.B., F.C.S., Barrister-at-Law,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, *Metropolis Water Act, 1871.*

London, July 5th, 1890.

SIR,—We submit herewith the results of our analyses of the 175 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from June 1st to June 30th inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 175 samples examined, the whole were found to be clear, bright, and well filtered.

The character of the water supply to the Metropolis during the month of June has not exhibited any features calling for special remark. As usual, the proportion of organic matter, inconsiderable, save on exceptional occasions, even at its highest, is somewhat higher in the case of the Thames-derived water than in the case of that derived wholly or in large part from the Lea. Taking the water furnished by the Companies deriving their supply from the Thames for comparison, the mean proportion of organic carbon was found to be 0.150 part in 100,000 parts of the water, with a maximum of 0.166 part in any single sample examined.

During the past six months of the year we have examined a total of 1455 samples of the Metropolitan water supply. Speaking generally, the water has been characterised to a more than usually noticeable degree, by its uniformity of composition from month to month. Thus, taking the Thames-derived samples for comparison, the mean proportion of organic carbon for the six months' period was found to be 0.150 part in 100,000 parts of the water, or identical with the mean proportion for the present month; while in five samples only was the proportion found to reach or exceed 0.170 part, the maximum in any

single sample examined being 0.174 part in 100,000 parts of the water.

Similar conclusions are afforded generally by a comparison of the numbers expressing the amounts of oxygen consumed, and degrees of freedom from colour-tint of the successive monthly supplies. It is to be noted, however, that while the curves representing the variations noted by the three several methods of examination, show a marked correspondence when the variations are, relatively speaking, at all considerable, their correspondence, as might be expected, is of a less strict or more general character only, in the case of such inconsiderable variations as have alone had to be recorded during the past six months.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES.

WILLIAM ODLING.

C. MEYMOTT TIDY.

ON THE ELECTRO-DEPOSITION OF PLATINUM.*

By W. H. WAHL.

THE permanence and unalterability of the metal platinum—properties which make it of such inestimable value to the chemist—have likewise suggested its application as a protective covering upon the surfaces of other metals; and, even in the early days of the art of electro-deposition, efforts to obtain a satisfactory coating of this metal were made. The failure with which these early experiments were attended served rather to stimulate than to deter subsequent investigators, and the problem has received the attention of a number of the most noted experts in the art. The results that have been accomplished cannot be said to have been entirely satisfactory—a statement which, I believe, will be fully sustained by the fact that electro-plating with platinum, on the commercial scale, is practised only to a very limited extent. When the wide field of application for platinum-plating is considered—and I need only name philosophical, engineering, surgical, dental and electrical apparatus and instruments, fire-arms, watch-cases, and jewellery, to say nothing of the host of miscellaneous articles of utility and ornament to which the metal could be advantageously applied—the conclusion is irresistible, that the processes thus far proposed for the purpose do not fully meet the requirements of practical service.

Thus far, of all the methods that have been proposed for electro-plating with platinum, three only appear to have sufficient merit to deserve special notice; these are:—

(1) Roseleur-Lanaux method, based on the electrolysis of a solution of the double phosphate of sodium and platinum.

(2) The process of the Bright Platinum Plating Company (of London), a modification of that of Roseleur, involving the introduction into the bath of certain substances, such as sodium chloride and borax, to ensure a bright deposit of the metal; and

(3) Boettger's method, founded on the electrolysis of a solution of the double chloride of ammonium and platinum in sodium citrate.

Each of these baths will yield satisfactory results for a time; but, as I shall endeavour to show, the peculiar difficulties met with in the practice of platinum-plating render it impossible to maintain the chemical integrity of these electrolytes, and, in consequence thereof, they soon become inefficient or inoperative by reason of contamination with the secondary products formed therein.

* Advance sheet. Read at the Meeting of the Chemical Section of the Franklin Institute, May 20, 1890.

I will endeavour in what follows to give the true explanation of the difficulties above referred to, and to indicate what, from a careful study of the subject, fortified by the results of numerous experiments, I conceive to be the only feasible method of overcoming them.

The first difficulty encountered is that of obtaining a bright, reguline, and adherent deposit of the metal, in which form only it will answer the demands of practice. There is no difficulty in effecting the separation of the metal from solutions of almost any of its compounds. Zinc, iron, and tin reduce it promptly by simple immersion, and this very facility of reduction is one of the reasons why, even by the method of electrolysis, the desired object is frequently accomplished only in an imperfect manner; for the electro-plater is obliged to meet and overcome its obstinate disposition to separate from many of its compounds in the condition of platinum black, lacking coherence and adherence, and therefore entirely unsuited for his purpose.

Another and no less serious difficulty arises from the insolubility of plates or sheets of this metal as anodes, when solutions containing platinum salts are submitted to electrolysis. In electro-plating with copper, silver, gold, and nickel, but little difficulty is encountered in practice on this account, since anodes of these metals are freely soluble in many solutions capable of depositing them when they are submitted to electrolysis, and the rate at which these anodes are respectively dissolved, approximates so nearly to that at which the metals are deposited upon the objects at the cathode, that the metallic strength of the electrolyte is maintained substantially uniform, and electro-plating solutions of these metals may be operated for a long time without requiring additions of metallic salts. The electro-deposition of the metals whose anodes are thus tractable is carried on industrially with success.

It results from this want of solubility of the anode that the metallic strength of the electrolyte employed is continuously being weakened, while the deposition of the metal is going on, and the conductivity of the bath is being continually modified thereby. The character of the deposited metal also is injuriously influenced by these constant alterations of condition in the bath; and, as the rate of deposition becomes slower and slower by reason of the gradual impoverishment of the metallic strength of the solution, it will be necessary to restore it by fresh additions of metallic salt. The practice in all the processes of electro-plating with platinum employed up to the present time, save that of Boettger, is to use for this purpose the tetra-chloride of platinum. With this single exception, all the solutions for the electro-deposition of platinum thus far made known, so far as I am aware, are made by treating the chloride with compounds of the alkalis, soda, potassa, or ammonia. Of these, the phosphates and oxalates of soda, or potassa, are in greatest favour, and a number of formulæ for preparing platinum-plating baths with their aid have been described. The resulting substance is commonly a double salt, such, for example, as the double phosphate of sodium and platinum; the double oxalate of potassium and platinum, &c., contaminated, however, in each case by the chloride of the alkali employed, which is formed from the decomposition of the platonic chloride. As often as it is found necessary to strengthen the bath, fresh additions are made of platonic chloride, which, by chemical interaction with the constituents of the bath, aided by the process of electrolysis, yields more alkaline chloride; and it follows that the bath, by reason of becoming surcharged with this foreign substance, and with other secondary products of electrolytic decomposition, ceases to yield bright, reguline platinum upon the articles to be plated therewith and must be discarded. It then becomes necessary to regain the platinum contained in the discarded bath, by one or another of several processes of reduction known to chemists. The platinum thus regained may be converted into chloride and utilised in the preparation of a

fresh bath, with which the same series of operations will be repeated. Boettger purposes to maintain his bath by fresh additions of his original solutions, but it must be apparent that the continued electrolysis of such a solution as he employs must be attended with the constant accumulation therein of alkaline chlorides from the same causes as those specified above. This rapid deterioration of the baths, therefore, involve their frequent renewal at the expense of time and labour, so that, in spite of the fact that there is a wide field for its application, it is principally for this reason that the art of electro-plating with platinum on the commercial scale has thus far been practised only to a very limited extent.

It occurred to me that it might be practicable to overcome the principal difficulty here set forth. Knowing the influence of extent of surface in promoting the solubility of substances, it appeared to me at least probable that if the platinum were exhibited at the anode in the form of platinum-black, or sponge, exposing thus an enormously greater number of points of attack to the electro-negative element or acid radical there set free, the result might be the solution of the platinum, and the problem of maintaining the metallic strength of the electrolyte would thus be solved. The correctness of this conjecture was verified by experiment. For this purpose a plate of porous battery carbon, previously treated with boiling hydrochloric and nitric acids, was saturated repeatedly with a solution of platonic chloride and dried. It was then introduced into a graphite crucible, finely divided carbon was packed about it, and the crucible and contents heated for about half an hour to bright redness. The carbon plate then contained within its pores platinum in a state of eminently fine division. Treatment with water, and with hydrochloric acid at boiling temperature, failed to leach out any platinum salt, showing that the previous treatment has sufficed to reduce all the platinum salt to the metallic state. The carbon plate was then suspended as the anode in moderately diluted hydrochloric acid, a platinum plate serving as the cathode. The acid bath was gently heated and a current of moderate strength was allowed to flow through it. There was a liberal evolution of hydrogen from the cathode, but little perceptible evolution from the anode. The acid solution gradually became coloured from the formation of platonic chloride, and after some time the bright surface of the cathode began to blacken and ultimately became covered with a thick coating of platinum black. It was thus demonstrated that an anode of platinum in a fine state of division is readily soluble in an electrolyte which yields chlorine at the anode when the same is electrolysed. This observation, so far as I am aware, is new. It proved, however, to have no practical value, since the solution of the anode demanded the presence of a large proportion of free acid in the plating-bath and the use of currents of such strength as to produce invariably the deposition on the surfaces to be plated, of black and non-adherent metal. Furthermore, it was found, as was to have been anticipated, that the physical condition of the anode exerted no influence whatever in the electrolysis of baths formed of the oxy-salts of platinum, from which the best results in electro-plating are obtained—since, in electrolysis such compounds, the acid radical separated upon the surface of the platinum black failed to exert any perceptible solvent action.

It was therefore necessary to devise some other plan for overcoming the difficulties herein described, and, after making a number of fruitless experiments, I was so fortunate as to find a plan which appears to offer a solution of the troublesome problem of electro-plating with the group of metals, whose anodes are insoluble, in a more satisfactory manner than any other that has hitherto been suggested.

The plan here referred to consists in employing platinum hydroxide for the purpose of maintaining the metallic strength of the plating-bath. For this purpose, the hydroxide, which is readily soluble in alkalis and in

many of the acids, may be introduced into the plating-bath from time to time and dissolved therein by stirring, or it may be permitted to remain in the bath in excess, the undissolved portion remaining at the bottom of the containing vessel, or it may be suspended in a canvas bag adjacent to or surrounding the anode of carbon, according as the nature of the electrolyte may indicate one or the other method to be the preferable one. As the solutions which yield the best results in plating are those of the oxygen salts, I have found it advantageous also to prepare these directly from the hydroxide. This method, I have found, is capable of yielding a number of electrolytic baths of platinum that will maintain their metallic strength approximately unimpaired during electrolysis, and without the objectionable features of introducing into them substances that will cause them to deteriorate by the accumulation therein of injurious secondary products of decomposition, as is the case where such baths are maintained by additions of platinic chloride or alkaline chloroplatinates, as has hitherto been the invariable practice. Referring now specifically to the properties that render the platinic hydrate useful for the purposes above indicated, the following points appear to be deserving of mention.

It is readily soluble in aqueous solutions of the alkaline hydrates, and in a number of acids, mineral and vegetable. In the treatment of the platinic hydrate with aqueous solutions of the alkaline hydrates, the former plays the part of a weak acid, forming compounds known as platinate, which are very soluble, and from which the platinum is not precipitated on the addition of an excess of alkali. A weak aqueous solution of sodic or potassic hydrate (but especially the last named) will dissolve a large quantity of platinic hydrate, at the ordinary temperature, though solution takes place more freely when heat is applied. These solutions have the advantageous features of being freely conductive of electricity, and of yielding bright, reguline, and adherent electro-deposits of platinum on metallic surfaces previously prepared to accept the same. Furthermore, with a current of moderate strength the platinic hydrate only is affected, as is shown by the pronounced evolution of oxygen at the anode, and by the total absence of gas at the cathode. Also, it is manifest from the free solubility of platinic hydrate in alkaline hydrate, even in the cold, that if free platinic hydrate be present in a bath of alkaline platinate, the alkali set free in the process of electrolysis will combine with this platinic hydrate to form fresh platinate. For this purpose it will be necessary either to have present in the bath at all times a small excess of platinic hydrate, which may remain upon the bottom of the containing vessel without interference with the plating, and which may be replenished from time to time, or to introduce at the end of the day's work a quantity of the platinic hydrate sufficient to restore the metallic strength of the bath to normal, assisting the solution of the metallic hydrate by stirring, and if necessary by the application of gentle heat. As I have found that the platinate solutions act best when they contain a considerable excess of free alkaline hydrate, being more conductive of the current and yielding the platinum more freely and in the best condition, the addition of the proper quantity of platinic hydrate at the close of the day's work in the case of a bath of considerable volume, or the addition of small quantities at intervals, in the case of a small bath, will be found to answer the desired purpose of maintaining the metallic strength of the bath approximately normal for an indefinite period. In a bath where considerable free alkali is present, the platinic hydrate added, as just indicated, dissolves very freely even in the cold. The important fact is to be noticed that the alkaline platinate solutions may be maintained and operated for a long time in the manner described, since no deleterious secondary products are formed by electrolysis to vitiate and render them inoperative, as will speedily be the case where the platinic chloride is used for this purpose. The

mineral acids (hydrochloric, nitric, sulphuric, and phosphoric acids) dissolved the hydroxide freely, as likewise do certain of the vegetable acids, notably oxalic acid, and form with corresponding salts of the alkalies double salts, many of which are soluble in water. Of the salts thus capable of being formed, however, so far as I have been able to determine by experiment, only a limited number appear to be adapted to yield a deposit of bright, reguline, and adherent platinum. The halogen compounds may obviously be prepared more conveniently by the direct solution of the metal in aqua-regia than by the method I have described, but as I have found the oxygen compounds of platinum to yield much more satisfactory results, I therefore exclude them from consideration.

Of the salts that may be formed from platinic hydrate by solution in acids (and in part by suitable combination with the corresponding alkaline compounds to form double salts) three only may be named as sufficiently useful to yield practically valuable results in plating. These are the phosphates, oxalates, and acetates, of which also it is practicable to form double salts with the alkalies, soda, potassa, and ammonia, which yield bright, reguline, and adherent platinum.

Oxalic acid, so far as I have been able to determine, of all the oxygen acids, is the best solvent of platinic hydrate, dissolving it even in the cold, but with great energy when aided by heat, and forming platinous oxalate, with evolution of carbonic anhydride. From this brownish black or deep blue solution (according to concentration) brilliant reddish brown scales of the salt separate abundantly and readily from the hot saturated solution. A saturated aqueous solution of the simple oxalate prepared from the hydrate, as above described, will yield bright, reguline, adherent platinum when electrolysed with a comparatively weak current, with evolution of carbonic anhydride at the anode. With a stronger current hydrogen also appears at the cathode. This bath may be maintained indefinitely at normal metallic strength by observing the precaution to add oxalic acid and platinic hydrate in small quantities from time to time; or by keeping constantly at the bottom of the bath some platinic hydrate, and adding oxalic acid in crystals or powder from time to time as may be required to keep the bath saturated; or, what is much to be preferred, making a supply of platinous oxalate from platinic hydrate in the manner previously described, and keeping an excess of this present in the bath at all times. This bath has the same advantages as are possessed by the above-described alkaline platinate baths, of being capable of indefinite maintenance at normal metallic strength, and of introducing no substances that will cause its deterioration by the formation of secondary decomposition products.

(To be continued).

NOTICES OF BOOKS.

The Law and Practice of Letters Patent for Inventions, with the Patents Acts and Rules Annotated and the International Convention; a Full Collection of Statutes, Forms, and Precedents, and an Outline of Foreign and Colonial Patent Laws, &c. By LEWIS EDMUNDS, D.Sc., F.C.S., F.G.S., Barrister-at-Law; assisted by A. WOOD RENTON, M.A., LL.B., Barrister-at-Law. London: Stevens and Sons, Limited.

IT has been the object of the author to produce a "comprehensive treatise upon the law and practice of patents for inventions," similar to that of Hindmarch, which, having been written as early as 1846, prior to the Acts of 1852 and 1883, is now to a great extent obsolete. In this attempt, as far as a non-legal reader can judge, he has been very successful.

With an admirable expenditure of research and labour he has collated all the principal judicial decisions bearing upon the subject, and from these materials, taken in conjunction with the existing statutes and rules, he has deduced a general survey of Patent Law. That this task has not been easy any reader may easily satisfy himself. The more gratitude is consequently due to the author, not merely from his own profession and from patent-agents, but from patentees, actual or prospective, and from patentees who may possibly be aggrieved by some existing patent.

The work is divided into three parts. The first deals generally with Patent Law and practice, with an account of the procedure for obtaining a patent—the application, specification, amendments, and oppositions, assignments, and licenses.

Part II. gives the Patents, Designs, and Trade Marks Acts of 1883—1888, so far as they bear upon patents.

Part III. gives an Appendix of Statutes, Forms, Foreign and Colonial Patent Laws—or, as we should prefer to put it, Colonial and Foreign.

On reading over this work with anything like the care which it fairly demands we cannot fail to be struck with the vast amount of litigation which our patent system involves. This is in part due to the circumstance that a patent is granted to every applicant, provided only he pays the fees and observes certain very simple regulations. Now, it is plain that no preliminary examination can prevent subsequent appeals to the Courts. In the United States and in Germany, where examination is very stringent, litigation on the validity of patents is by no means unknown. But we cannot help regretting the effrontery with which certain persons, especially aliens, will come forward and obtain patents for processes which have been in common use, and which have become public property. Thus, as recently as 1877, an agent patented as a "communication from abroad" the manufacture of aluminium sulphate by the action of sulphuric acid upon dried or powdered shales, and used the sulphate obtained in treating sewage!

In speaking of the publications of the Patent Office the author mentions with evident and most justifiable regret the discontinuance of the *Commissioner's Journal*, which not only gave information regarding every British patent, from the first application to its final expiry, but also the patent lists of foreign countries.

As a rule it has been the author's object simply to set forth the law as it now is, and not to suggest what it might, could, or would be. He writes, however:—"Patentees still suffer an anomalous and heavy taxation in the form of renewal fees, which begin to be payable before the end of the fourth year." Unless these are duly paid the patent lapses. To our certain knowledge this fact renders it much more difficult to dispose of a patent, since capitalists hold back in the hope that the patentee may fail to pay the fee. In the United States, on the contrary, when once the initial fee of 20 dollars has been paid the patent is safe for the full term of seventeen years.

The author mentions the complexity of the law prior to 1852, by which three separate patents were required for England, Scotland, and Ireland, and the heavy expenses thrown upon patentees, and adds that, "under the Patent Law Amendment Act the cost of obtaining a patent was greatly lessened, and there was a further reduction in 1883."

The expense of obtaining protection throughout the British Empire is, we believe, about £1400! We know of one invention which is lying dormant on this very account. What should have been done in 1852 was to devise an Imperial patent, obtainable either in London, Calcutta, Sydney, Cape Town, &c., or such other centres as might be agreed on.

It was very generally hoped when the Patent Act of 1883 was passed and the fees were made easier that a new vein of inventions would be tapped. This hope

does not seem to have been fully realised. The number of patents has indeed been largely increased, but a very large proportion are frivolous, whilst another proportion are held by aliens who formerly did not think it worth while patenting their ideas in Britain. We fear the British workman too generally seeks to rise in the world by strikes and agitations rather than by inventions.

It was originally held that the very meaning of the patent system was to introduce new arts and manufactures into the realm, but the law is now actually made the means of keeping them out. This is to a great extent effected by the "International Convention." Dr. Edmunds says that its "first principle was to ask only from each country the same treatment from subjects of each of the other countries as was accorded to their own subjects. The Convention was in no way based upon the principle of strict reciprocity." In fact it is based upon the principle of a completely "one-sided reciprocity," to the disadvantage of British subjects. Thus, suppose an Englishman wishes to obtain protection for an invention, say in the German Empire. His application will, in the preliminary examination, be "winnowed with so rough a wind," that to prove the novelty and utility of his ideas will be a hard task. We know an instance where the German Patent Office raised two objections to a desired patent. After prolonged negotiation it withdrew these objections as untenable, and immediately raised a fresh one of which no mention had been made in the first unfavourable report. Nor are the examiners of the American Patent Office any better to deal with. We remember a case in which they insisted that a terhydrate and a tersilicate were one and the same thing.

To return to Germany. Suppose the examiners report favourably, the patent is granted, subject, however, to the condition that the patent must be worked in Germany within three years.

In France there is no preliminary investigation, but the invention must be worked in France within two years, and the importation into France of articles patented in that country is forbidden under penalty of forfeiture.

The manner in which aliens are treated under the British law is in full contrast. Protection is granted without examination, and they are under no compulsion to work their inventions upon British ground at all. In fact numbers of them have evidently not the least intention of so doing, their object being simply to prevent anyone else from working such inventions in this country, though they go to work at once abroad. The remedy would be to enact that if any person, native or alien, holds a British patent for an invention and works it abroad, but does not work it in this country on a commercial scale within two years the patent shall become *ipso facto* void. The present state of things is a powerful argument in favour of Mr. Macfie and others, who are opposed to patent-right altogether.

We find it stated in a note that the Patent Commission, constituted under the Act of 1852, was to include, in addition to the Law officers of the Crown, certain other persons. "Application was in fact made to the Royal Society, the Chemical Society, and Institute (of Chemistry?) to advise on the selection of one member from each society to act as examiners." But as it appeared that these gentlemen were expected to give their services gratuitously the proposal fell through.

It is stated—and it has been repeatedly ruled by the Courts—that no patent can be granted for an invention which is in itself illegal or immoral. Yet we believe a patent was once granted for a machine to mould chicory into the shape of coffee berries. As the sole conceivable use for such a machine was fraudulent, this invention was surely immoral.

A vast amount of fraud, imposition, quackery, and sophistication would at once be rooted out if articles of food, drink, or substitutes for such articles, pharmaceutical products, and processes for their preparation, were deprived of protection by patent or trade-mark.

We regret that we cannot devote any further space to the consideration of this work and the questions which it raises. We must pronounce it indispensable to all who in any way come into contact with patents.

Bech Book for Test-tube Work in Chemistry, By H. T. LILLEY, M.A. London: Simpkin, Marshall, and Co. We have seen and heard "test-tube chemistry" spoken of with unsparing contempt, and here we find instructions for its performance! Who is in the right? It seems to us that a great number of preliminary examinations—especially if the substance in question is to be had in small quantities only—are best performed in test-tubes. If this is the case, instructions for the accurate performance of such operations are exceedingly useful.

The work is carefully written, the tests laid down are correct, and there are not a few remarks which will be of value to the student.

A Treatise on Practical Chemistry and Qualitative Analysis. Adapted for Use in the Laboratories of Colleges and Schools. By FRANK CLOWES, D.Sc., F.C.S. (London and Berlin), F.I.C., &c., Fifth Edition. London: J. and A. Churchill.

WHEN an elementary work on chemistry has undergone the ordeal of five successive editions it is evident that the task of the critic must be light indeed. We are bound at the same time to recognise that the book is admirably compiled, and that it presents a happy medium between the obscure conciseness of some text-books and the prolixity—often irrelevant—of others. Intelligibility and simplicity have been successfully aimed at. Directions for working and for the right use of apparatus are given more fully than is done in many manuals, and, what is of great importance, the whole has been carefully checked over by the author and his students. We must highly approve of the omission of speculative and descriptive matter, which, however interesting *per se*, is, in a treatise of this kind, "matter out of place."

The only drawback we can perceive is, perhaps, less the author's fault than his misfortune. The work is distinctly examinational, as will at once be seen from p. v. of the preface. We fear it must be admitted that the temporary awakening caused by the protest against examinationism set on foot by Mr. Auberon Herbert, though supported by thinkers who, perhaps, would agree on no other subject, has died away. It has been lost amidst the din of contending factions, and borne down by the mute unreasoning opposition of those interested in "passing," and in getting others to pass. Hence, if anyone takes an unexpected place in a competitive examination, the feat is greeted with jubilant cheering, as if the student had decomposed an element, discovered a new form of energy, or a biological generalisation wider than that of Darwin. So long as such a spirit prevails we shall never be released from those correlative enemies of research—the crammer and the examiner.

CORRESPONDENCE.

COMPLEX MINERAL ACIDS.

To the Editor of the Chemical News.

SIR,—In the "Notes on Valency, Basicity, Complex Acids, and Chemical Notation," which you were so good as to print from my MS. in the CHEMICAL NEWS (vol. lxi., p. 267), it should have been explained that the discussion of these subjects was there undertaken with reference to the question of mineralogical classification, as will be more fully set forth in a forthcoming treatise on

"Systematic Mineralogy." The conception of complex acids is not to be limited to oxygenised compounds, but, as will be seen, is also applicable to complex metalline species in which sulphur and selenium, arsenic, antimony, and bismuth are associated. The careful reader of these "Notes" will, moreover, perceive that where, in two places, the symbol Tl immediately precedes La, it is a mistake for Y (yttrium); and, moreover, that FeO₂ should be TeO₂ (tellurium dioxynid).—I am, &c.,

T. STERRY HUNT.

New York, June 30, 1890.

QUASSIA BITTER *versus* HOP BITTER.

To the Editor of the Chemical News.

SIR,—Mr. Adams, of Maidstone, some few weeks ago, in giving evidence before the Select Committee of the House of Commons appointed to enquire into the decline of the hop industry, described before that body a process which he stated would enable him to state whether foreign bitters had been used in place of hops in brewing, and a few days later read a paper before the Society of Public Analysts in which he stated that "boiling a 2½ per cent decoction of hops with 2½ per cent of sulphuric acid under a reflux condenser for two or three hours every trace of bitter is removed; but quassia and its allies are not at all affected by this treatment."

The statement that quassia and its allies are not at all affected by this treatment I repudiate strongly.

To substantiate my repudiation of Mr. Adams's process the following experiments were made:—

A 100 c.c. solution of quassia (B.P.) was taken and 50 c.c. of normal solution of sulphuric acid added, the flask was then attached to a reflux condenser, and boiled for three hours. Barium hydrate solution was then added to faint alkaline reaction, heated, and filtered. The filtrate was then freed from excess of barium hydrate by sulphuric acid, and filtered; the filtrate just exhibiting a faint acid reaction, which was then evaporated on a water-bath to about 200 c.c. Basic acetate of lead solution was next added until the point of saturation was reached, then boiled, and the precipitate filtered off, the excess of lead in the filtrate being very carefully precipitated by sulphuric acid. The slightly acid filtrate was then evaporated to its original bulk (100 c.c.), chalk added to neutralise any free acid, boiled, and then filtered. The solution thus obtained was compared with the original solution of quassia, with the result that the bitter was completely changed (to use Mr. Adams's expression) from that of a fixed bitter to that of a fugitive bitter.

Such being the case, I decided to boil some of the quassia solution for five hours, following the same treatment exactly, except that the last filtrate was evaporated to 50 c.c., and, when compared with the original, the bitter was found to be of a different character to that of the original; at least two-thirds of the original bitterness having disappeared.

Under these circumstances, the process is, in my opinion, worthless, and I have no doubt that if Mr. Adams will repeat the above experiment, and boil the solution of quassia with 2½ per cent of sulphuric acid for ten hours instead of five hours, at the end of that time he will most likely find that all traces of bitterness have vanished, even if taken up with chloroform.—I am, &c.,

WILLIAM JOHNSTON.

City Central Laboratory,
13, Fish Street Hill, E.C., July 14, 1890.

Parkes Museum.—In order to make the Parkes Museum, which is supported by the Sanitary Institute, available to all classes for the purpose of obtaining information on matters relating to hygiene and sanitary appliances, the Council have resolved to throw the Museum open free at all times except when meetings are being held.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cx., No. 26, June 30, 1890.

Partial Eclipse of the Sun of June 17.—J. Janssen.—The author communicates a letter from M. A. de la Baume Pluvinel, in which the latter remarks that so far he has not been able to detect any difference between the spectrum of the ring and the ordinary spectrum of the sun.

Photographic Spectrum of Sirius.—Dr. W. Huggins.—The author has for some time suspected the presence of a group of obscure rays in the most refrangible part of the spectrum of this star. In a photograph of Sirius taken on April 4 this group came out distinctly, and the author was able to make approximate measurements of the positions of six rays of this group. These obscure rays are as strong and broad as the rays of the ultra-violet series of hydrogen, and they probably belong to one and the same substance, at present unknown.

Researches on the Application of the Measurement of the Rotatory Power to the Determination of the Compounds Resulting from the Action of Malic Acid upon the Neutral Sodium and Potassium Tungstates.—D. Gernez.—Like the alkaline molybdates, the tungstates exert upon the rotatory power of malic acid a very well-marked action, the measurements of which show the compounds produced among simple numbers of equivalents of these bodies. The author's results are given in the form of a table.

The Action of Titanium Chloride upon Metals.—Lucien Lévy.—Titanium chloride being passed over silicon at white redness yields very hard cubic crystals of a steely whiteness. To obtain them it is necessary to operate in an atmosphere of pure dry hydrogen. Boron and various metals (excepting iron and antimony) may be substituted for silicon in this experiment. The crystals obtained are not readily attacked by reagents. Melting potassa alone dissolves them and produces an inflammable gas.

The Decomposition of Rocks and the Formation of Arable Soils.—A. Muntz.—The author has found the microbia of nitrification present on rocks, especially on parts which are in process of disintegration, and he ascribes to these organisms a considerable share in the formation of soils.

Identity in Composition of Certain Sedimentary Phosphates with Apatite.—Henri Lasne.—The author states that in the natural phosphates of sedimentary origin which he has examined fluorine is present in much larger proportions than it is commonly supposed. This is due to the defective analytical methods employed. The minerals in question contain 1 equiv. of fluorine to 3 of phosphorus.

Journal für Praktische Chemie.
New Series, Vol. xli., Part 7.

Certain Syntheses by means of Phenylcyanate.—R. Leuckart.—The author has examined the action of phenylcyanate upon aromatic hydrocarbons, upon the alkyl ethers of the phenols, upon the phenols, and upon the nitro-substituted aromatic amines and the amido-phenols.

Nitro- and Chloro-Derivatives of β -Methyl- δ -Oxyquinazoline.—H. Dehoff.—The author has examined the action of nitric acid and phosphorus pentachloride upon anhydro-acetyl-ortho-amido-benzamide. The results will shortly be made known.

MISCELLANEOUS.

Elizabeth Thompson Science Fund.—This fund, which has been established by Mrs. Elizabeth Thompson, of Stamford, Connecticut, "for the advancement and prosecution of scientific research in its broadest sense," now amounts to \$26,000. As accumulated income will be available December next, the trustees desire to receive applications for appropriations in aid of scientific work. This endowment is not for the benefit of any one department of science, but it is the intention of the trustees to give the preference to those investigations which cannot otherwise be provided for, which have for their object the advancement of human knowledge or the benefit of mankind in general, rather than to researches directed to the solution of questions of merely local importance. Applications for assistance from this fund, in order to receive consideration, must be accompanied by full information, especially in regard to the following points:—1. Precise amount required. (Applicants are reminded that one dollar (\$1.00 or £1) is approximately equivalent to four English shillings, four German marks, five French francs, or five Italian lire. 2. Exact nature of the investigation proposed. 3. Conditions under which the research is to be prosecuted. 4. Manner in which the appropriation asked for is to be expended. All applications should reach before December, 1890, the Secretary of the Board of Trustees, Dr. C. S. Minot, Harvard Medical School, Boston, Mass., U.S.A. It is intended to make new grants at the end of 1890. (The trustees are disinclined, for the present, to make any grant exceeding three hundred dollars; decided preference will be given to applications for smaller amounts.—(Signed) Henry P. Bowditch, President; William Minot, jun., Treasurer; Edward C. Pickering; Francis A. Walker; Charles-Sedgwick Minot, Secretary.

NOTES AND QUERIES.

* * Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertisement columns.

Tempering Brass.—Can any of your readers give me a recipe for effectually hardening or tempering small brass articles; the elasticity of the brass must not be disturbed, and whatever is used should not corrode the brass in any way? If the surface only of the wire is hardened this may be sufficient.—C.

PRINCIPLES OF
GENERAL ORGANIC CHEMISTRY.

By Prof. E. HJELT,
of Helsingfors.

Translated from the German by J. BISHOP TINGLE,
Ph.D., Assistant in the Laboratory of the Heriot
Watt College, Edinburgh.

LONDON: LONGMANS, GREEN, AND CO.

PATENTS, DESIGNS, & TRADE MARKS ACT, 1883.

NOTICE IS HEREBY GIVEN that SIGISMUND PICK, of Szczakowa, Galicia, Austria, has applied for leave to amend the Specification of Letters Patent No. 5124 of 1887, granted to George Isaac James Wells, for "Improvements in the evaporating of liquors containing salts and in the separation of those salts."

Particulars of the proposed amendment are set forth in the Illustrated Official Journal (Patents) issued on the 25th June, 1890.

Any person may give notice (on Form G) at the Patent Office, 25, Southampton Buildings, London, W.C., of opposition to the amendment within one month from the date of the said Journal.

(Signed)

H. READER LACK,
Comptroller-General.

W. LLOYD WISE,

Agent for the Applicant.

THE CHEMICAL NEWS.

VOL. LXII. No. 1600.

THE PHOSPHORESCENCE PRODUCED UPON THE FIRST CONTACT OF OZONE WITH CERTAIN FLUIDS.

By ERNST FAHRIG.

SOME years since, in experimenting with some new liquid preparations of ozone, I accidentally observed a phenomenon which immediately attracted my attention, and led me to make many more experiments upon the subject. But these further tests, instead of clearing up the matter by affording a definite explanation of the peculiar action produced, only mystified me the more; for they merely served to upset the various theories and explanations which have from time to time suggested themselves not only to me, but to scientific friends to whom I have mentioned the matter; and in my own view, they render no less untenable a theory which has been publicly advanced by some others who have independently discovered and worked in the same field, and to which I shall presently refer. Thus perplexed, I have resolved, with the Editor's kind permission, to publish an account of these experiments in this journal, in the hope that some among its wide circle of readers may be able to throw some fresh light upon the question.

My first observation of the phenomena was in the following manner:—I was in a dark room, and having in my hand a sealed bottle about three-quarters full of a preparation of ozone (in this instance a solution of ozone in water containing a small percentage of other substances, which I have found in the course of my experience are necessary to retain the ozone in solution), I, with no particular purpose in view, gave the bottle a vigorous shaking up; instantly I saw a soft phosphorescent glow of light floating above the surface of the liquid and permeating the space in the upper part of the bottle. Its appearance was only momentary; but on shaking the liquid up again immediately afterwards it was observed again, but in much diminished intensity. Further repetition failed to produce any results, but after an interval of ten days the liquid had apparently regenerated its power, and the same effects could be observed, though weaker. I observed the phenomena in another way, and obtained some especially remarkable results, by pouring a small quantity of an ozone solution into a glass beaker containing ordinary water. At first the cone-like projection of the solution where it falls into the water becomes luminous, and then the light suffuses the whole mass as the liquids become thoroughly mingled, and finally disappears. Similar experiments to this have since been successfully carried out by the gentlemen above mentioned as having worked in this direction; and it is doubtless upon consideration of this particular variation of the phenomena that they have based their theory.

Now, it does not seem possible that the luminosity can be due to a purely chemical action among the various inorganic constituents brought together, for a careful consideration of the properties and chemical reactions of these does not indicate the likelihood of any such action taking place. I have found, indeed, that it is essentially dependent upon some peculiar property of the ozone, and that it is in no wise influenced by the medium, solvent, or condition in which this is presented to the water. That is to say, the appearance of the phosphorescence is not thereby interfered with in entirety, although there is some difference of degree in the intensity produced. Thus, with preparations of ozonised oil the same effects occur, and also with ozonised air or the pure gas itself.

The latter is applied by means of a glass tube immersed in the water, and with this method there is a marked increase in the duration and intensity of the phosphorescence. Or an easy way, very similar to my first experiments, of observing the effect is to take a bottle partly full of ordinary water and confine ozone gas or ozonised air in the remaining space. When shaken up in the dark, the upper part of the bottle is seen to become permeated with the light.

Trying the experiment with other substances in place of ozone, I each time failed to produce the least appearance of the phenomena. Thus, chlorine, an element which in the striking similarity of its reactions to those of ozone exhibits a remarkable analogy to that gas—so much so, that it is extremely difficult to test or distinguish between the two—absolutely would not afford the slightest glimmer of light; although it, of all other substances, should be the most likely to produce analogous effects to those of ozone. To be quite certain upon this point, I applied the chlorine in a great many different ways and conditions, but always with the same negative results. Thus, free chlorine - gas, chlorine - water, chlorinated soda hypochlorides, chloride of lime, and ordinary bleaching liquors were all subjected to experiment, and in every case, as with numerous other substances, peroxide of hydrogen included, the already strongly established conclusion was confirmed, that the phenomenon is wholly and solely due to some remarkable action of the ozone, and to electrically produced ozone alone.

Having satisfied myself of this in a sufficiently exhaustive manner, I turned my attention to water into which the ozone preparations are introduced, and endeavoured to determine how variations in its quality and source might influence the effects. In this direction I met with a series of most strangely conflicting results. I found that some samples of water would duly give off the momentary glow of light, upon the application of the ozone, while others would not, but the most curious fact was that examination or analysis failed to discover any cause to which these and negative results might be assigned, or any explanation by which they might be reconciled. In river water the light was very good; in some from a deep well there was none whatever. In sea water there was none, and altogether there is a great and inexplicable uncertainty about the probable behaviour of any particular specimen of water, which makes it practically impossible to foretell the result when first trying the experiments with a new sample, although the characteristic impurities and conditions of the same may be well known and understood beforehand. It was owing to this same uncertainty that I was much vexed a short time since by failure in an attempt to exhibit the phenomena to a party of scientific gentlemen; while on the very next day I was able to succeed with almost identical materials and conditions. Hence, also, the great difficulty of arriving at any plausible explanation.

The theory before referred to, and which is apparently the most probable of any that has yet been suggested, is that the light is generated during the destruction or oxidation of the organic matter of the water, or in killing the bacteria or micro-organisms which it may contain. But I think this cannot be sustained in view of the tests made with different samples of water; for it is evident that were this the case, the appearance and intensity of the effects would depend upon the presence and proportional amount of organic matter in the water, which, however, does not seem to be at all agreeable with experience. In fact, I have found that water previously boiled and filtered, to free it from bacteria and other organic life, does not thereby become indifferent to the experiment, thus furnishing what would seem to be a very strong and direct negative to the aforesaid theory. But, in justice to its exponents, I should add that they deny it is possible to destroy bacteria by boiling, in which statement I understand they are supported by the great

bacteriologist, Dr. Koch, and they further affirm that this important office can only be effectually performed by means of ozone. If they are right in this contention their theory must be allowed to stand; but to prove it thoroughly it will be necessary to show a closer connection between the intensity of the phosphorescence and the observed proportions of micro-organic life than can at present be said to exist.

As to the light itself, I can only describe it as a soft phosphorescent glow, which quickly spreads through the mass of fluid or gas, as the case may be, and as quickly disappears. It is very similar in appearance to that of another phenomenon which I believe I was the first to observe some ten or twelve years ago, and of which also I have been unable to find any satisfactory explanation. It is that when the globe or bulb of an old incandescent lamp is lightly rubbed with the hand and then immersed in water, slightly warm, or simply breathed upon, a distinct light is observed to be diffused through the globe—in the dark, of course. I have laid especial emphasis upon the fact that the lamp must be an old one, because herein lies the peculiar interest of the experiment. For at first sight one naturally supposes that the same results can be obtained with an ordinary piece of glass; but this is not so; neither can any response to the experiment be excited in a new or unworked lamp. Of this I fully assured myself by making lamps specially for the purpose and subjecting them to tests to see if it was not some hitherto unobserved property of an exhausted bulb of glass. Therefore, as the vacuum, pure and simple, is not the cause, it would seem that the light is in some way dependent upon some sort of chemical change in the minute quantities of gases remaining in the bulb, produced by long contact with the incandescent filament. Gaseous compounds may be thus formed, which under the condition of extreme rarification, may have the property of phosphorescence when subjected to electric strain. Still this does not leave the reason for moistening the bulb at all clearly defined; though the function of this process is doubtless to accomplish a rapid discharge of the electricity generated by the friction of rubbing.

In conclusion, I may throw out a suggestion that the luminosity in the first case is due to a release of the energy stored up in the ozone at its creation, but I will say nothing as to its plausibility, or as to how it appears to meet the case.

ON THE ELECTRO-DEPOSITION OF PLATINUM.*

By W. H. WAHL.

(Concluded from p. 35).

PHOSPHORIC acid also is a solvent of platonic hydrate. A dilute aqueous solution of this acid will dissolve a small quantity of the metallic hydrate in the cold, and a much larger quantity when aided by heat. With increasing concentration the solvent power of this acid for platonic hydrate is correspondingly increased. The resulting solution of phosphate of platinum, according to the degree of concentration, will be wine-yellow to cherry-red in colour, and, with a comparatively weak current, will yield bright, reguline, and adherent platinum on metallic surfaces properly prepared to accept the same. The electrolysis of this compound also does not involve the formation of deleterious secondary products, the result of the operation being the separation of the metal at the cathode and of the acid radical at the anode—and of the elements of water which are evolved as gases respectively from anode and cathode. In the operation of the bath, therefore, it will become more and more acid

as the metal is withdrawn by the accumulation therein of the phosphoric acid set free at the anode. The maintenance of the metallic strength of the bath, therefore, may be effected as in the foregoing cases by having present therein at all times a small quantity of platonic hydrate, or by the addition at the end of each day's work of the quantity of the metallic hydrate which will be required to restore the amount of metal withdrawn. This bath must be worked very acid, and the solution of the platonic hydrate, to maintain the strength of the bath; must be facilitated by heating, as the solvent power of phosphoric acid for platonic hydrate is much inferior to that of oxalic acid. The double phosphates of platinum with certain of the alkalis may be formed, which will be capable of yielding a deposit of bright, reguline, and adherent metal, and of being maintained approximately at normal metallic strength in the same manner as I have set forth above. The best results I have obtained with the ammonio-platonic phosphate prepared by adding to the solution of platonic hydrate in phosphoric acid sufficient *aqua ammonia* to cause the same to give an alkaline reaction, which point will be indicated by the formation of a greyish precipitate that will not disappear on stirring; then restoring the acidity of the solution by adding free phosphoric acid in excess, upon which the precipitate readily dissolves. The resulting solution is yellowish or brownish, and yields superb plating; though, on account of the greater difficulty of maintaining its metallic strength by the solution of the hydroxide, it is not so well adapted as the oxalate for the work of electro-deposition on the large scale. The sodio-platonic phosphate, formed in a manner precisely analogous to the ammonia compound just described, will also yield bright, reguline, and adherent plating; but I have observed that the soda salt is less freely soluble than the corresponding ammonia compound, and consequently more difficult than the latter to maintain of normal metallic strength.

Platonic hydrate is only very sparingly soluble in strong acetic acid, and it is impracticable to facilitate the solution by boiling, since by persisting in this for a very short time the hydrate is decomposed and black platonic oxide is formed, which is quite insoluble in this menstruum. I have found, however, that an alkaline acetate bath may be prepared by the addition to the alkaline platimates above described of as much acetic acid as may be introduced without causing the formation of a permanent precipitate. But although the appearance and quality of the plating obtained with this bath leave nothing to be desired, the bath does not meet the requirements in respect of indefinite maintenance in normal metallic strength and uniform composition. This difficulty, however, as I have observed, becomes less and less pronounced as the bath is made more strongly alkaline, when it approximates more and more closely to the alkaline platimates; for it is obvious that in the presence of a large amount of free alkali this would unite with the acetic acid to form a simple acetate. The resulting solution would no longer contain sodio- (potassio-) platonic acetate, but sodic (potassic) acetate, sodic (potassic) platinate, and free alkali. Nevertheless the presence of acetic acid in such alkaline bath appears favourably to influence the quality of the plating yielded, giving the deposited metal a whiteness approaching that of silver; and since, furthermore, acetic acid yields only the elements of water and volatile compounds when electrolysed, and therefore does not contaminate the electrolytic bath by forming deleterious secondary products, I find its judicious addition to the above-described alkaline platinate baths to present some advantages.

The foregoing comprise the compounds that I have found to yield the most satisfactory results in platinum plating, and I will not tax your patience at this time by an enumeration of the results, either partially successful, or wholly unsuccessful, that I have obtained with a number of differently constituted compounds of this metal.

* Advance sheet. Read at the Meeting of the Chemical Section of the Franklin Institute, May 20, 1890.

I append directions for the preparation of the several electrolytic baths above described, and indicate what I have found to be the most favourable conditions for working them.

In conclusion, I desire to make known the fact, which was brought to my knowledge only within the past week, that my friend Prof. Wm. L. Dudley, of Vanderbilt University, Nashville, Tenn., has independently worked out the problem of electro-plating with iridium in a manner precisely analogous to that which I have herein described with platinum. Prof. Dudley has made no publication of his research, but, in a letter, informs me that he employed, as long ago as 1886, the following procedure, which I quote:—"A bath of the metal may be composed of either the chloride (IrCl_3), the double chloride of iridium and sodium, a double sulphate of iridium-ammonium. The latter was preferred. The bath was kept saturated with metal by suspending canvas bags in the solution (either near to or around the anodes) containing the hydroxide of iridium."

Directions for Preparing the Electro-Plating Baths.

For the alkaline platinate bath the following directions may suffice:—

Platinic hydrate	2 ozs.
Caustic potassa (or soda)	8 ozs.
Distilled water	1 gallon.

Dissolve one-half of the caustic potassa in a quart of distilled water; add to this the platinic hydrate in small quantity at a time, facilitating solution by stirring with a glass rod. When solution is effected, stir in the other half of alkali dissolved in a quart of water; then dilute with enough distilled water to form one gallon of solution. To hasten solution, the caustic alkali may be gently heated, but this is not necessary, as the platinic hydrate dissolves very freely. This solution should be worked with a current of about 2 volts, and will yield metal of an almost silvery whiteness upon polished surfaces of copper and brass, and quite freely. There should be slight, if any, perceptible evolution of hydrogen at the cathode, but a liberal evolution of oxygen at the anode. I have observed that the addition of a small proportion of acetic acid to this bath improves its operation where a heavy deposit is desired. The anode may be of platinum or carbon, and owing to the readiness with which the metal is deposited an excess of anode surface is to be avoided. Articles of steel, nickel, tin, zinc, or german-silver will be coated with black and more or less non-adherent platinum; but by giving objects of these metals a preliminary thin electro-deposit of copper in the hot cyanide bath, they may be electro-platinised in the alkaline platinate bath equally as well as copper. The bath may be worked hot or cold, but it is recommended to work it at a temperature not exceeding 100° F. It may be diluted to one-half the strength indicated in the formula, and still yield excellent results. The surface of the objects should be highly polished by buffing, or otherwise, prior to their introduction in the bath, if the resulting deposit is designed to be brilliant.

The deposition of platinum takes place promptly. In five minutes a sufficiently heavy coating will be obtained for most purposes. The deposited metal is so soft, however, that it requires to be buffed very lightly. A heavier deposit will appear grey in colour, but will accept the characteristic lustre of platinum beneath the burnisher.

The oxalate solution is prepared by dissolving 1 ounce of platinic hydrate in 4 ounces of oxalic acid and diluting the solution to the volume of one gallon with distilled water. The solution should be kept acidified by the occasional addition of some oxalic acid. The simplest plan of using this bath, and which requires no attention to proportions, is simply to work with a saturated solution of the oxalate, keeping an undissolved excess always present at the bottom of the vessel. An addition of a small quantity of oxalic acid now and again will be found

advantageous. The double salts of oxalic acid with platinum and the alkalies may be formed by saturating the binoxalate of the desired alkali with platinic hydrate and maintaining the bath in normal metallic strength by the presence of an undissolved residuum of platinous oxalate.

The double oxalates are not so soluble in water as the simple salt. The oxalate baths, both of single and double salts, may be worked cold or hot (though not to exceed 150° F.) with a current of comparatively low pressure. The metal will deposit bright, reguline, and adherent on copper and brass. Other metallic objects must receive a preliminary coppering as above. The deposited metal is dense, with a steely appearance, and can be obtained of any desired thickness.

The deposit obtained in the oxalate baths is sensibly harder than that from the alkaline platinate bath, and will bear buffing tolerably well.

The phosphate bath may be prepared by the following formula:—

Phosphoric acid, syrupy (sp. gr. 1.7) ..	8 ozs.
Platinic hydrate	1—1½ oz.
Distilled water	1 gallon.

The acid should be moderately diluted with distilled water and the solution of the hydrate effected at the boiling temperature. Water should be added cautiously from time to time to supply that lost by evaporation. When solution has taken place, the same should be diluted with sufficient water to make the volume one gallon. The solution may be worked cold or warm to 100° F., and with a current much stronger than that required for the platinites and oxalates. The ammonio- (and sodio-) platinic phosphates may be formed from the simple phosphate by carefully neutralising the solution of the phosphate with ammonia (or soda); then adding an excess of phosphoric acid, or enough to dissolve the precipitate formed, and an additional quantity to ensure a moderate amount of free phosphoric acid in the bath. The phosphate baths will be maintained of normal strength by additions of platinic hydrate, the solutions of which will have to be assisted by heating the bath, preferably at the close of each day's work. The metal yielded by the electrolysis of these phosphate solutions is brilliant and adherent. It has the same steely appearance as that exhibited by the oxalate solutions, but to a less pronounced degree. The physical properties of the deposited metal are in other respects like those described in connection with that obtained from the oxalate baths.

BLOWPIPE TEST FOR MERCURY.

By T. CHARLTON.

HAVING of late been engaged in testing a number of minerals for mercury qualitatively, I had occasion to employ the method recommended by Alexander Johnstone, F.G.S. (CHEM. NEWS, vol. lxxix., p. 221), and was highly pleased with the simplicity and delicacy of the method. In fact, I think that no blowpipe test has been devised equal to it for value for many years. There is, however, one small drawback to the method as given by Mr. Johnstone, and that consists in the likelihood of washing much of the sublimate formed on the cooler part of the tube down on the addition of the two drops of nitric acid and the one drop of potassic iodide, prior to obtaining the reaction. And it also happens at times that the effervescence caused by this addition of acid to the fusion mixture ($\text{K}_2\text{CO}_3 + \text{Na}_2\text{CO}_3$) is so violent as to cause loss of the sublimate by washing it down the tube into the acid below.

To avoid these difficulties I have devised the following modified form of the test, which I can thoroughly recommend:—

First obtain the sublimate either by heat alone or by anhydrous fusion mixture, as recommended by Mr. Johnstone, and then, instead of adding nitric acid and solution of potassic iodide, simply drop into the tube a small grain of iodine (not an iodide). If this is quickly done the tube will still be warm enough to volatilise the iodine. If the tube has been allowed to cool before adding the iodine, then it will be necessary to apply a gentle heat, to cause the iodine to volatilise. As soon as the iodine comes into contact with the sublimate of mercury a bright scarlet mass is formed which is very characteristic of mercury.

Rocky Mountain Smelting Co.,
West Cliff, Colo., July 1, 1890.

ELECTROLYSIS OF DIFFERENT SUBSTANCES.

By P. L. ASLANOGLU.

1. *Water*.—On passing a current of electricity from six Fuller's mercury bichromate elements through ordinary London tap-water for about twelve hours, the hydrogen pole (platinum) became coated with a white residue, which, from time to time, fell to the bottom of the electrolysis tube. This white residue having been analysed, it was found to be calcium carbonate, which is contained in small quantities in ordinary drinking water.

The oxygen pole (platinum) was free from any residue whatever.

During electrolysis hydrogen and oxygen were given off as usual.

2. *Magnesium Carbonate* was suspended in distilled water and CO_2 was passed through the solution, and, after filtering, the clear solution was tested for magnesium, which it contained in considerable amount. The results obtained were the following:—

Hydrogen and oxygen given off as usual.

The hydrogen pole became coated with white residue, which fell to the bottom of the tube as in the previous experiment.

The oxygen pole was free from any solid matter.

3. *Silver Chloride* dissolved in sodium thiosulphate ($\text{Na}_2\text{S}_2\text{O}_3$), filtered, and electrolysed. The following results obtained:—

Only hydrogen given off, and a thick grey precipitate, turning at once to black, deposits on the hydrogen pole, which shakes off to the bottom of the tube. The smell

given off was that of sulphuretted hydrogen. The black precipitate was tested and found to be very fine metallic silver.

4. *Lead Sulphate* dissolved in a solution of tartaric acid, neutralised by ammonia (ammonia tartrate), and filtered. Hydrogen and oxygen were given off.

The hydrogen pole was coated with black residue, which smelt of ammonia, while the oxygen pole was coloured a golden yellow, and in the course of a few hours the solution was of the same colour, but gradually became darker.

5. *Barium Carbonate* and *Strontium Carbonate* were suspended in distilled water, and CO_2 was passed through the solution and filtered.

Hydrogen and oxygen were given off, whilst a fine white precipitate coated the hydrogen pole and fell off to the bottom of the tube.

6. *Zinc Carbonate* was suspended in distilled water, and, after passing CO_2 through it, was filtered.

Hydrogen and oxygen were given off with effervescence and bubbles of the two gases collected on the surface of the liquid.

The hydrogen pole was coated with a greyish black residue of zinc carbonate. The liquid became turbid, and a gelatinous precipitate floated on the surface, and by shaking the tube the precipitate fell to the bottom.

7. A mixture of *Ferrous Sulphate* and *Carbonate of Soda* was placed in a flask, which was then filled with

distilled warm water and CO_2 was passed through for half an hour. It was left to settle and the liquid was poured, leaving the precipitate at the bottom of the flask, and fresh hot distilled water was poured over it, and CO_2 was then passed for half an hour; this process was repeated six times, during which time CO_2 was passing through the flask so as to prevent the iron from oxidising. The last time it was left to settle for a few hours, and was then poured as quickly as possible through a filter, the clear liquid running into the electrolysis tube. The ferrous sulphate was thus converted into ferrous carbonate by carbonate of soda, and part of it was dissolved by passing CO_2 through. The liquid in the electrolysis tube was quite clear, free from signs of oxidation, &c. When it was subjected to a continuous current hydrogen and oxygen were given off. Both platinum poles were free from any residue from the beginning to the end of the experiment. The result is shown by the above diagram.

UPON THE CARBOHYDRATES OF PEACH GUM.*

By W. E. STONE.

A CERTAIN class of vegetable products, known as "gums," or "mucous," or mucilage, yield, as the result of hydrolytic action, glucose-like bodies. These, whenever carefully studied, have, almost without exception, been identified as either *galactose* or *arabinose*. When heated with a dilute solution of sulphuric acid, gum arabic yields sometimes *galactose* and sometimes *arabinose*,† although it is not quite clear whether this is a specific characteristic of a distinct gum, or whether there may not be gums of different origins sold under the one name. The gum exuding from the bark of the cherry tree produces, by hydrolytic action, *arabinose*.‡ Tragacanth gum yields the same product.§ The mucilage occurring in the seed-coats of linseed, quince seeds, &c., yields also glucoses, which, however, have not been satisfactorily isolated or identified. A gum-like substance which can be extracted from lignified tissues, by alkalies yields, by hydrolysis, *xylose*.|| A gum exudes from the bark of the peach tree (*Persica vulgaris*) following injury, or from the fruit of the same when punctured by insects, which, with one exception, has not been studied. The wild peach tree, escaped from cultivation in the middle southern United States, produces this gum in considerable quantities, and from this source I obtained 200–300 grms., in air-dried weight, of gum as collected from the bark, and a somewhat less quantity from the fruit. The former was of a dark brown colour and contained many impurities, such as bits of bark, leaves, &c.; that from the fruit exuded in clear drops, which soon hardened on exposure to the air to transparent or semi-opaque tears, and was, of course, of a higher grade of purity than that from the bark.

This gum was soluble in water, by which it first became swollen to a marked degree, and in solution showed a slightly acid reaction, and a distinct, although not strong, *lævo*-rotation.

After my investigation had been in progress some time I learned of R. W. Bauer's results obtained from peach gum which was probably of European origin. By treating the same with a dilute solution of sulphuric acid he secured a crystalline sugar-like substance which possessed the specific rotation $(\alpha)_D = 76.02^\circ$, and which he regarded

as identical with *galactose*, although lack of material had evidently prevented confirmatory tests. From this he concluded that the peach gum contained the carbohydrate from which *galactose* is derived by hydrolysis. A preliminary examination of the gum in my possession indicated, however, that it also contained the substance from which *arabinose* is derived, as well as that mentioned by Bauer, and this was confirmed by further investigation.

The two portions of gum were examined separately, although all stages of the examination showed them to be of practically the same nature. As preliminary to a close study, portions of both gums were subjected to the furfural test for the presence of an *arabinose*-producing substance,* and to the mucic acid test for a similar source of *galactose*.†

By distillation at $125-130^\circ \text{C}$. with sulphuric acid kept at a constant density of 1.254, concentration of the distillate, and precipitation with dilute ammonia, the following data were obtained:—

Gum from Bark.—2.5 grms. yielded 0.1181 gm. of furfuramide, or 4.72 per cent.

Gum from Fruit.—2.5 grms. yielded 0.1214 gm. of furfuramide, or 4.84 per cent.

By oxidation with nitric acid of 1.15 specific gravity, mucic acid was produced as follows:—

Gum from Bark.—5 grms. yielded 0.618 gm. of mucic acid, or 12.36 per cent.

Gum from Fruit.—2.5 grms. yielded 0.423 gm. of mucic acid, or 16.92 per cent.

These results indicated the presence in the gum of those substances which yield *arabinose* and *galactose* upon hydrolysis, and the course of the investigation was directed towards isolating and identifying the same. 110 grms. of the gum from the bark of the peach tree were dissolved in 880 c.c. of dilute sulphuric acid of 1.03 specific gravity, and the solution heated on the water-bath for ten hours. At the end of this time, the liquid was of a dark amber colour, much humin-like substance had been separated, and the vapours gave an intense red colour upon paper moistened with aniline acetate, indicating the formation of furfural. The liquid was neutralised with barium carbonate, filtered, and evaporated, yielding a thick dark-coloured syrup which reduced Fehling's solution strongly. In the same way, 50 grms. of the gum from the peach fruit were dissolved in 400 c.c. of dilute sulphuric acid of 1.03 specific gravity, and heated during nine hours, with the same results as in the previous case.

The dark-coloured impure syrups thus obtained were boiled with strong alcohol for about an hour, whereby a dark gummy substance was precipitated. From this the clear alcoholic solution was decanted and again evaporated, after which crystallisation soon followed. In this way 21.3 grms. of a white crystalline product were obtained from the bark gum, or nearly 20 per cent of the material taken. From the fruit gum a proportionally smaller quantity was obtained. Both products were sweet, and reduced Fehling's solution strongly. After recrystallisation, the specific rotations of each were determined as follows:—

From Bark Gum.—3 grms. in a solution of 30 c.c. showed an average dextro-rotation of 19.16° , or $(\alpha)_D = 98.4^\circ$.

From Fruit Gum.—3 grms. in a solution of 30 c.c. showed an average dextro-rotation of 19.04° , or $(\alpha)_D = 95.2^\circ$.

These numbers indicated the identity of the two products, but did not correspond to the specific rotations of any of the known glucoses or sugar-like bodies, although that of the product from bark gum approximated the specific rotation of *arabinose*. They differed also decidedly from Bauer's result $(\alpha)_D = 76.02^\circ$. A mixture

of two substances like arabinose and galactose, however, would give a polarising number like that obtained. Moreover, the preliminary tests for mucic acid and furfural had indicated the formation of both of these compounds. The next step therefore was an attempt to separate these products by means of fractional crystallisation into their constituents. By crystallisation from absolute alcohol each of the two original products was separated into several portions, the specific rotations of which showed a curious relation to that of the original substance.

From the sugar from bark gum, which showed the specific rotation of 98.4 , five fractions were obtained, which, in the order of their separation, showed the following polarising numbers:—

I. $(\alpha)_D = 97.5$	IV. $(\alpha)_D = 94.3$
II. „ $= 73.5$	V. „ $= 95.3$
III. „ $= 93.0$	

The sugar from fruit gum, which had the specific rotation 95.2 , was separated into two portions, which gave the following polarising numbers:—

I. $(\alpha)_D = 75.0$	II. $(\alpha)_D = 94.8$
------------------------	-------------------------

In both cases it is to be noted that a fraction was separated with a much lower specific rotation than the original without increasing the specific rotation of the other fractions. These fractions ultimately included all of the mother-liquor; hence it may not be assumed that a higher polarising sugar remained in solution. In the sugar from fruit-gum it is certainly remarkable that the original portion polarising 95.2° should have been resolved into one polarising 75.0° and another polarising at 94.8° , which latter number is practically the same as the original. There was no marked disproportion in the quantity of the fractions. The separations were made from alcohol at the ordinary laboratory temperature, which conditions could scarcely affect or change the specific rotations of the bodies in solution.

Of the fractions from the sugar from bark-gum, numbers I., II., and III., while not agreeing exactly with the polarisation constants for arabinose and galactose, still approached them. They were therefore re-crystallised and gave respectively the following numbers:—

I. $\alpha, (\alpha)_D = 98.8^\circ$
II. $\alpha, „ = 82.09^\circ$
III. $\alpha, „ = 98.9^\circ$

In like manner also the fractions from the sugar of the fruit gum were re-crystallised. I. was unfortunately lost by an accident, but its specific rotation, as already observed (75.0°), leaves little doubt that it would also have given a result similar to that of II. of the bark-gum product. II. showed after re-crystallisation the specific rotation 101.6° .

Nos. I. and III. of the product from the bark-gum were again re-crystallised and yielded a product with the specific rotation $(\alpha)_D = 102.3^\circ$. As results, therefore, of these repeated and tedious fractional separations, there were obtained, from the bark-gum, two products; one with the specific rotation 102.3° , which approximated very closely that of arabinose (104°), and a second with the specific rotation 82.09° , which is practically that of galactose. From the fruit-gum also we obtained two products which were undoubtedly identical with those from the bark-gum, and which, according to their specific rotations, were also respectively arabinose and galactose.

These comparatively pure products were now subjected to some confirmatory tests in order to leave no doubt as to their nature.

Arabinose being a pentaglucof, $C_5H_{10}O_5$, has, in common with xylose, the only other known member of the class, the characteristic reaction of producing furfural in large quantities when distilled with sulphuric acid.* Xylose, however, has the specific rotation $(\alpha)_D = 18^\circ - 19^\circ$,†

* *Loc. cit.*

† Wheeler and Tollens, *Ber. de Chem. Gesell.*, xxii., 1046.

and was therefore quite out of the question in connection with the body already described with the specific rotation 102.3° . 0.9246 grm. of the latter was distilled with sulphuric acid of 1.254 sp. gr. (the loss by distillation being replaced by a regular constant addition of water to the distilling flask), until the distillate no longer gave a distinct colouration on paper moistened with aniline acetate. The distillate being then concentrated by fractional distillation and treated with dilute ammonia gave a precipitate of furfuramide, which, on being dried, weighed 0.1843 grm., or 19.93 per cent of the weight of sugar taken. This result, taken with the specific rotation, leaves no doubt as to the identity of this product with arabinose. From a very small quantity a phenylhydrazine compound was prepared, which was, however, insufficient for re-crystallisation, and, in the impure state, showed the melting-point of 145° .

A well-known specific reaction for galactose is the formation of mucic acid when subjected to the action of nitric acid. The other portion of sugar from bark-gum, polarising at 82.09° , was heated on a water-bath with nitric acid of 1.15 sp. gr. 0.5025 grm. received 20 c.c. of nitric acid, and the whole was heated until two-thirds of the original volume was evaporated. 0.288 grm. of mucic acid was thus produced, or 57.3 per cent of the weight of sugar taken. A phenylhydrazine compound was also formed which melted at 154° . These reactions, coupled with the specific rotation, identifies the second product as galactose.

The gummy substance secreted from the tissues of the peach tree, as above described, contains, therefore, those bodies which, by hydrolysis, yield arabinose and galactose. The occurrence of these bodies together under these circumstances is the more noteworthy from the fact that arabinose and galactose represent two distinct classes of carbohydrates, the true glucoses and the pentaglucof, and are not usually found in such intimate connection with each other. The gum arabic is, I believe, the only other instance where such occurrence has been recognised, and in no previous case has the isolation and recognition of both these carbohydrates from a single homogeneous substance been accomplished.—*American Chemical Journal*, xii., No. 6.

ON A PHYSIOLOGICAL ACTION OF THE THALLIUM SALTS.

By Dr. J. BLAKE.

In a memoir presented to the Academy in 1887 (*Comptes Rendus*, cv., p. 1250) the author has demonstrated that on injecting the electro-positive elements into the circulation the number of the nerve centres upon which they react increases as does the atomicity of the elements.

In a communication recently made to the Academy by M. Rydberg it is demonstrated that the molecules of the electro-positive elements are the seat of one or of several systems of harmonic vibrations, which, in the mono-valent elements, are confined to a single system, but which, in the elements with stronger valencies, may be extended to two or even to more systems of harmonic vibrations in the same mol. This is a very important fact for biological reactions. The author has already published experiments demonstrating the great difference presented by the biological action of the salts of the same element when the valence of the mol. is increased, but as M. Rydberg's observations enable us to consider the question from a novel point of view, he recites the most important phenomena presented on injecting thallous or thallic salts into the blood.

Here we have two classes of salts of one and the same element. In the one class, the thallous salts, the mol. is found with a single system of molecular vibrations,

whilst in the thallic salts the mol. is the seat of several systems of harmonious vibrations. He merely reproduces here the most important facts presented by these experiments. He injected into the jugular vein of a rabbit 0.090 (grm. ?) of thallous sulphate. The result was an arrest of the passage of the blood through the lungs by the action of the thallous salt upon the pulmonary ganglia. After a few seconds the right side of the heart overcomes the obstruction, and the salt circulates through the entire body without giving rise to any symptom. The animal appears to be in a normal state. A second injection of the same quantity arrests the pulmonary circulation and the animal dies. The right side of the heart is found engorged with venous blood, and a few drops of arterial blood in the left cavities. By venous injection the salt only comes in contact with the most important nerve centres in a state of great dilution. To examine its action upon these centres it must be injected into the aorta. It was accordingly injected into the right carotid artery of a rabbit, the point of the syringe being directed towards the heart. There was injected 0.040 of thallous sulphate, then, at different intervals, 0.080, 0.200, 0.280, 0.350, without any apparent reaction on the nerve centres. There was then injected 0.770, and only then the salt came into contact with the pulmonary ganglia in a state sufficiently concentrated to arrest the passage of the blood through the lungs. Ten times as much of the salt was required to cause death by arterial injection as by venous injection. It seems that the reagent with a single system of vibrations did not meet in the most important nerve centres any system of vibrations which its own vibrations might either strengthen or enfeeble. It is only in the pulmonary ganglia that it finds vibrations with which those of the thallous salts are in relation, and the case is the same with all the mono-valent elements.

With the thallic salts the phenomena are very different. Here we make use of a salt the molecular weight and volume of which are much higher, and where the mol. is the seat of several systems of vibrations. We inject 0.007 of thallic nitrate into the jugular vein of a rabbit. After thirty seconds there was want of power in the limbs, the respiration slackened, and the animal is stupefied. After another injection of 0.007 the animal falls upon its side and struggles. Four minutes after the injection the respiration ceases. The right cavities of the heart were found engorged and the left empty (pulmonary obstruction); the ventricles still contract twenty-three minutes after the auricles are arrested (action upon the cardiac ganglia).

In this experiment the same action was observed upon the pulmonary ganglia as with the thallous salts, but when the salt had traversed the lungs and circulated in the whole body other nerve centres were found to be affected by the salt, even in its greatly diluted state (twelve times more diluted than the thallous salts), but these reactions upon the other nerve-centres show themselves more plainly in arterial injection. We inject 0.007 thallic nitrate into the aorta of a rabbit; after thirty seconds there was an increase of arterial tension from 100—180 m.m. (vasomotor centre); respiration slackened; after one minute, arterial tension from 170—190 m.m. with great oscillations; two minutes after injection respiration ceased without convulsions (direct action upon the respiratory centre). After death the contractions of the heart continue, and the arterial tension undergoes variation, as during life; three minutes after respiration has ceased the arterial tension increases from 40 m.m. to 100 m.m., and the same phenomenon was repeated three times before the heart stopped (action upon the vasomotor centre); the contractions of the heart continue for more than an hour after death; the ventricles and the auricles with a quite different rhythm (131 and 134) (action upon the cardiac ganglia) the lungs were hepatised (action upon the pulmonary ganglia). The contrast between the biological action of the two classes of salts of a single element could not be more striking. With the

thallous salts having only one system of molecular vibration there is only a single nerve system in which the action is shown; whilst with the thallic salts with mols. having several systems of vibrations there is not a single nerve-centre which does not experience their action, even when present in the blood in quantities less by 200 times than the thallous salts. The author believes that the spectroscopic will play as important a part in physiological research as it does in chemistry,—*Comptes Rendus*, cxi., p. 57.

CHEMISTRY AND MINERALOGY.*

By Professor E. H. RENNIE, M.A., D.Sc., University of Adelaide.

IN assuming the presidency of Section B of the Australasian Association for the Advancement of Science, it is my first duty to thank those who have done me the honour to elect me to the office, and to say that it will be my earnest desire to deserve the distinction by doing all in my power to forward the interest of the sciences which this section represents. While thoroughly appreciating the honour conferred upon me, I feel also a grave sense of responsibility—a responsibility to say something which may help to further the interests, not only of this section, but also of the Association, and, therefore, of Australasia.

The benefits to be derived from a meeting of this kind are doubtless, in a large measure, those which arise from conversation and social intercourse between men of like pursuits, and, in fact, we are often twitted with the preponderance of the social element. It will, however, be a great pity if those portions of the proceedings devoted to pleasure and relaxation are allowed to entirely eclipse the scientific objects of the gathering—if, in fact, by means of papers and discussions, we do not get some stimulus to more earnest work in the future.

In common with many others occupying somewhat similar positions, I have felt considerable difficulty in choosing a subject on which to address you. It has been customary in past years in the British Association for sectional presidents to give a general *resumé* of the more important researches and discoveries of the year immediately preceding; but, latterly, men in such positions have found themselves obliged by the ever-increasing rapidity of scientific discovery, and the consequent massing together of material, either to choose some educational theme, or to discourse on those aspects of the science to which they have themselves devoted special attention.

It will, I think, be granted that to the members of our Association any aspects or results of our science which have special reference to Australasia should be of peculiar interest, and I propose, therefore, to-day, in the course of a very brief address, first to inquire into some of the more important results which have been obtained by examination of Australasian products, and then shortly to touch upon some of those great chemical questions which are being more and more forced upon our notice by the far-reaching generalisations to which they point.

There are, of course, two lines on which an inquiry as regards Australasian products might proceed, viz., the purely utilitarian and the purely scientific. If, in this address, preference is given to the latter, it is not from any desire to undervalue the former, but partly because I have elsewhere given prominence to the importance of the application of science to practice, and because, as I believe, the greatest discoveries in chemical science in recent years, which have also been of great practical importance, have not been the result of accident, but the outcome of long and patient investigation in realms of work at one time most unpromising as regards useful issues, and, moreover, because one object of this Association, as

* Australasian Association for the Advancement of Science, Melbourne Meeting, 1890. Presidential Address in Section B.

I understand it, is the prosecution of scientific knowledge for its own sake, quite irrespective of the question whether it will immediately yield payable results or not. The perpetual cry, "*Cui bono?*" which would never be uttered by those who make use of it had any real idea of the history of the discoveries of the past, is most discouraging to those of us who are endeavouring to prosecute scientific work in these colonies, where it is exceedingly difficult to rouse interest in anything which does not immediately lead to material profit in one shape or another. May I not, in this connection, take the opportunity of urging upon all scientific teachers to use every endeavour to impress upon their students the historical developments of such discoveries as I have referred to?

Entering now upon the consideration of the chemistry of plant products, I am sure you will, in the first place, join with me in paying a hearty tribute of praise to the very valuable preliminary work which has been accomplished in the region of plant chemistry by our President and his collaborators, and to that more recent and most valuable bibliography of the subject contained in the "*Useful Native Plants of Australia*," lately compiled by Mr. Maiden, curator of the Technological Museum of New South Wales.

Among the more important products, those obtained from the "everlasting gum-tree" first claim our attention. In a remarkable series of researches carried out in the laboratory of the University of Bonn, Wallach has succeeded in reducing to something like order and system the confusion which has hitherto existed in our knowledge of that class of hydrocarbons known as the terpenes, and has revealed some most interesting facts about the relationships of these substances to one another, especially with reference to their optical properties. He has shown that some of these substances exist in what may be termed pairs, one of each pair dextro-rotatory, the other lævotatory, in its effect on polarised light. Thus he has found two pinenes, two phellandrenes, and two limonenes, the only difference between the two members of each pair being the effect on polarised light just referred to; but each set of two is characterised by the formation of derivatives distinct from those of any other two, and also from those of other hydrocarbons belonging to the terpene group. In the case of the two limonenes, however, there is a special and most peculiar characteristic. When simply mixed in equal proportions these two hydrocarbons unite directly to form another hydrocarbon, called dipentene, which is very different from either of the originals. This reminds one, of course, of the relationships between dextro- and lævo-tartaric and racemic acids. There is, however, this distinction, that dipentene differs much more widely from the limonenes than does racemic acid from the tartaric acids, and, moreover, there seems to be at present no known means of regenerating the original hydrocarbons from the product. My object in referring to these researches, however, is to point out that the oil of *Eucalyptus amygdalina* has supplied one of the missing links in the chain of discovery, Wallach having found that it contains lævo-rotatory phellandrene (this is at present the only source of this hydrocarbon), the dextro-rotatory variety occurring in the oil of *Phellandrium aquaticum*, and also in the oil of the bitter fennel in the south of France. The oil of *Eucalyptus globulus*, on the other hand, contains no phellandrene, but dextro-rotatory pinene, the two varieties of which are found in turpentines from different sources. The common constituent of both these oils is an oxygen-containing liquid called cineol, of formula $C_{10}H_{18}O$, and boiling-point about $176^{\circ}C$, which is the chief constituent of oil of wormseed, oil of cajuput, and is also found in oil of rosemary and other essential oils. This substance is identical with the so-called "Eucalyptol," about the presence or absence of which in oils produced by different firms there has, I understand, been a good deal of dispute. Wallach himself had at first some difficulty in isolating this substance from the oil of one of these (*Eucalyptus amygdalina*), ap-

parently owing to the presence of some disturbing impurity. The fact that it appears to be more easily isolated from the oil of one variety than from that of the other may probably have caused the dispute referred to; at any rate there can be no doubt whatever of its presence in considerable quantities in the oils from both the varieties of eucalyptus I have named, and probably it exists in the oils from other species also. It is a very interesting fact, however, that there should be a considerable difference between the constituents of the oils from these two trees, and there are indications of still wider differences between the oils from other species. The oil from *Eucalyptus Staigeriana*, for example, according to a report by Messrs. Schimmel and Co., of Dresden, contains an oxygenated substance (a ketone, $C_{10}H_{16}O$?) which imparts to it its pleasant lemon-like odour, and several other species of eucalyptus yield oils of a similar odour, probably due to the presence of similar substances. References to these will be found in Mr. Maiden's book, to which I have already referred. It is obvious that there is still abundant room for investigation in the direction indicated, an investigation too which has the additional merit of possibly leading to important practical results, some of the substances obtained having been highly spoken of as perfumes, while some, we know, possess considerable disinfecting power.

There are many other Australasian plants, besides the eucalyptus, the leaves of which yield essential oils, but scarcely any of these have received more than an imperfect examination, and here again is a wide field for work.

I may mention also here that some years ago I succeeded in getting a hydrocarbon, apparently a terpene of boiling-point $156^{\circ}C$, from New Zealand Kauri gum by passing steam over the roughly-powdered gum heated in a copper vessel. It would be interesting, perhaps, to re-examine this in the light of Wallach's researches, but up to the present time I have had no opportunity.

Leaving the essential oils, and passing to other classes of products, we find that *Eucalyptus viminalis* yields the well-known "manna." This has been lately shown by Tollens to contain over 50 per cent of raffinose, or melitose, one of the more recently investigated, and from a scientific point of view more interesting sugars, containing as it does at least eighteen atoms of carbon, and yielding a mixture of lévulose and galactose on treatment with dilute acids. I believe, though on this point I am not quite certain, that "manna" has also been found on other species of eucalyptus; if so, it would be well worth examining.

The alkaloids afford us a field almost untouched, so far as exact chemical investigation is concerned. So far as I know the only substances belonging to this class which have been at all carefully examined are those to be found in the bark of *Alstonia constricta* and the "*pituri*." Of the former several have been isolated and partially described by different observers, but especially by Hesse, who describes at least four; but all of them need further examination, especially as some, at any rate, possess very marked physiological activity. The alkaloid to which the peculiar effects of "*pituri*" are due has been isolated by Professor Liversidge, who describes it as a volatile liquid possessing characteristics closely allied to but distinct from those of nicotine, and having the formula C_8H_7N . This also needs further examination, but sufficient quantities of material are very difficult to obtain, and I understand Professor Liversidge has not had an opportunity to continue the investigation. There are numbers of plants which seem to contain principles of more or less poisonous nature, notably two natives of New Zealand, the *Coriaria ruscifolia* and *Corynocarpus levigata*. The former is said to be excessively poisonous to sheep feeding upon it, and extraordinary stories are told of the powerful physiological effects produced by eating the nuts of the latter unless they are first pounded and washed with water, a practice always observed by the natives. Mr. Skey, who examined these nuts, states that he suc-

ceeded in isolating a crystalline poisonous substance, which, however, appeared to him to be more closely related to the glucosides than to the alkaloids.

It is scarcely necessary to say that the complete isolation and thorough chemical investigation of physiologically active principles, whether of the nature of alkaloids or not, is of the greatest importance, if such principles are to be usefully applied to medicinal purposes. The scientific world owes a debt of gratitude to Dr. Bancroft, of Brisbane, for the valuable results he has obtained by physiological experiments with a variety of Australian plants, but the statement will bear repetition that from a chemical point of view a great deal still remains to be done.

As an instance of a glucoside, we have the active principle of *Smilax glycyphylla*, which is asserted by some to have considerable medicinal value, but which has not yet, so far as I am aware, been tried medicinally in the pure state, and in larger doses than can be conveniently administered in the state of infusion. It is a crystalline substance closely allied to phlorizin. By the action of dilute acids it yields phloretin and isodulcite, the latter, I need scarcely tell you, a substance of considerable interest and importance in connection with the question of the constitution of the sugars, and hitherto obtainable with difficulty from a few rare sources.

Colouring matters are not wanting as products of the Australasian flora, and many of these would, without doubt, yield results of great interest, if not always of great practical importance, were they subjected to close examination. You may be interested in examining these specimens of colouring matters from *Drosera whittakeri*, a South Australian species. These materials are capable of being used as dyes, and appear to bear much the same relationship to one of the methyl-naphthalenes as alizarin and its congeners do to anthracene.

My attention has been recently drawn to the fluorescent infusion yielded by the leaves of *Bursaria spinosa*; the fluorescence proves, on examination, to be due to the presence of considerable quantities of *asculin*, which, you will remember, is found in the horse-chestnut, and, as is stated, in the root of one other plant, the wild jasmine. This may prove to be an important source of this substance, should it ever prove to be of practical value.

Many of our gums and resins would doubtless repay close examination, and Mr. Maiden has done a great deal in collecting, classifying, and partially examining a large number of them, especially with reference to the quantities of tannin which they contain. One of the most closely examined of the resins is that obtained from the various species of *Xanthorrhoea*, which was at one time largely used as a source of picric acid. Its products of distillation, under different conditions, have not been thoroughly investigated, and might yield results of importance; and besides, the resin, originally examined by Stenhouse, appears to have been the product of one species only.

A great deal more might be said on this part of my subject, but I think I have said enough to show that there is still a wide field open if we can only find workers, but herein lies the difficulty. It has often occurred to me that outsiders may wonder why, in this land of great advantages, and with such an extensive field, there is not more original investigation. Why is there not an abundance of scientific papers, on all sorts of subjects, to be found in the proceedings of our scientific societies? It is true there are plenty of papers dealing with matters of Natural History, Geology, and kindred subjects, but very few involving long, accurate, and painstaking investigation in other branches of science. The reason is plain enough, viz., that those who have the will have either not the time or the means. Those of us who are most favourably situated as regards appliances have our hands full with the teaching, organising, and all sorts of outside work which is inevitable in colonies in a state of growth, and we have not, as yet, numbers of advanced students, such

as we find in older countries, who are only too glad to be entrusted with new lines of research. May we not hope that one effect of this Association will be to so interest young and old alike in the cause of scientific investigation, that such of the younger members as have time and means will come to our aid, and such of the older members as have sons, and can afford, will endeavour to give us a chance of showing what Australians can do in this direction by sending us their sons to be trained in some branch of scientific work.

Besides this difficulty of obtaining hands to work, there is often difficulty in obtaining material to work with; and here I have a suggestion to make, which may, perhaps, commend itself to you, and which, in case it is approved, will, I hope, be taken up by this section at a later stage in our proceedings. It is the custom in these colonies to apply to a paternal Government for assistance in almost everything, and this meeting owes its hearty thanks to the Government of Victoria for very valuable assistance rendered. Now, there are in most of the colonies, government organisations which specially deal with matters bordering upon purely scientific territory—geological, mineralogical, entomological, agricultural, and sanitary departments—not to mention others; and these departments have at their command men who could in many cases, at very slight expense, collect from time to time valuable material. Could it not be so managed that an individual, or individuals, thoroughly capable of dealing with some special investigation, and desirous of following it up, should apply to this Association, or to a specially appointed committee, for assistance; and might not such assistance take the form of accrediting such individual or individuals to the government of that colony from which he wishes to obtain material in such a way that the authorities would be induced to take steps for obtaining a supply of such material? In most cases the cost involved would be very small. The plan seems to me to be feasible, and it might, to some extent, prevent duplication of work, for it would become generally known that certain persons were carrying out such and such investigations. Of course, such applications would need to be governed by regulations; but should the suggestion meet with your approval, it will be easy to discuss the details at a later period.

(To be continued).

NOTICES OF BOOKS.

The Diseases of Crops and their Remedies. A Handbook of Economic Biology for Farmers and Students. By A. B. GRIFFITHS, Ph.D., F.R.S.E., F.C.S. London: G. Bell and Sons.

THIS work scarcely falls within the ordinary purview of the CHEMICAL NEWS; but we should neglect our duty did we not pronounce it a most serviceable publication. The majority of farmers, not to speak of the general public, have not the faintest conception of the extent to which we are robbed by tiny pests, of the very existence of which only specialists are often aware. The author tells us with perfect truth, that at least one-sixth part of the entire yield of farms is consumed by insects and fungi. Yet too many people, overlooking this definite demonstrable evil and its remedies, seek to remedy "bad times" by political or social agitation, and even sneer at the entomologist and the fungologist as triflers! Alas, in comparison, this name belongs with more propriety to the devotees of classical, historical, and ethical study.

A very remarkable fact is that the plants most useful to man, such as wheat, the potato, the turnip, the coffee tree, the vine, the sugar cane, &c., seem most open to the attacks of enemies, animal and vegetable, and to have the

least power of resistance. The vine, we read, "is liable to be attacked by some 350 parasitic fungi, in addition to the *phyllorera* and other animal pests."

The author's remarks on nomenclature are certainly not orthodox, though they are not without an element of truth. But the reason why the first describer's name is attached to a species—a practice condemned by no less an authority than Charles Darwin—is that sometimes a "reformer" takes a name already bestowed upon some plant or animal and gives it to another. Hence has arisen dire confusion.

Dr. Griffiths takes in succession the different crops produced in Britain, and describes under each the parasites by which it is attacked, and the remedies, so far as they have been ascertained. Here, however, there is room for a vast amount of research, much of which comes within the sphere of the chemist.

We must put on record our surprise at finding so scarce an insect as the swallow-tail butterfly (*Papilio machaon*) placed among destructive insects. It is far too rare to be of any importance in this respect. As regards the Death's Head moth, we must agree with Miss Ormerod, F.E.S., that its larvae seldom cause any serious amount of damage.

In his concluding remarks Dr. Griffiths emphasizes the importance of the microscope in the study of destructive fungi and insects, and especially recommends the instruments of Zeiss (of Jena). But many farmers and gardeners commit mistakes which a careful use of the naked eye might have prevented. We have known, *e.g.*, the useful lady-birds destroyed on suspicion of being identical with the potato-beetle.

Accidents with Mineral Oil Lamps. Report from Colonel MAJENDIE, C.B., H.M., Chief Inspector of Explosives to the Right Hon. the Secretary of State for the Home Department, covering a Joint Report from Sir F. ABEL, C.B., F.R.S., &c., and Mr. BOVERTON REDWOOD, F.R.S.E., F.C.S., &c.

These reports contain matter calculated to make the users of such lamps thoughtful. Minute particulars have been obtained concerning 29 lamp accidents. Here it appears that in 11 cases the lamp exploded spontaneously while burning normally. Hence the fault cannot always be traced to carelessness, to moving the lamp, attempting to replenish it whilst burning, or to extinguish it in some careless manner. Indeed, the death of Prof. Wroblewski—one of the most skilful and delicate experimentalists in Europe—shows that ignorance and awkwardness are not always to be blamed as the cause of the mischief.

Again we read that:—"In one-half of the cases in which it was possible to determine the flashing-point of the oil, this was about 10° and upwards above the legal standard." Sir F. Abel and Dr. Redwood even add that in some of these instances the explosion was of a more than ordinarily violent character.

It would be indeed deplorable if mineral oil lamps had to be abandoned or their use restricted on account of danger. Not only are they the cheapest known source of artificial light, but the steadiness of the flame recommends them to the student, and to the microscopist they are simply indispensable.

It is, therefore, fortunate that means are indicated in the Reports before us by which the dangers may be minimised. The reservoirs should be of metal, a suitable extinguishing apparatus should be provided so that persons present may not be tempted to blow down the chimney, and "all channels of communication between the burner and the oil-holder should be protected with wire gauze of 28 meshes to the inch." Lamps in which oil is supplied to the burner on the "bird-fountain" principle are considered free from danger if the tube through which the oil passes remains sealed by the

liquid. The wicks should be soft and not tightly plaited; they should be rendered quite dry before being put into the lamp, and should be only just long enough to reach the bottom of the oil reservoir. They should be so wide as to quite fill the wick-holder without squeezing. The reservoir should be quite filled before using the lamp; all charred wick and dirt should be removed before lighting, and the oil should be stored for use in vessels closely stoppered.

The subject is obviously of great importance, and we can only hope that the suggestions of Sir F. Abel and Dr. Boverton Redwood may be carried into practice by lamp-manufacturers and the public.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 1, July 7, 1890.

Oxidation of the Sulphur in Organic Bodies.—MM. Berthelot, André, and Matignon.—The authors, after criticising known methods, propose to burn the sulphuretted organic matter in oxygen at the pressure of 25 atmospheres in the calorimetric bomb, along with 10 c.c. of water. The combustion is instantaneous, and gives rise merely to dilute sulphuric acid whenever the organic compound is sufficiently rich in hydrogen. If it is not sufficient it is merely requisite to add to the body in question its own weight of camphor, or even a smaller dose. After the combustion the bomb is opened, the liquid which it contains is collected, and the interior is repeatedly washed out. The liquid contains in general nothing but sulphuric acid and some traces of nitric acid. It is precipitated with barium chloride and the barium sulphate is collected and weighed with the ordinary precautions. In some cases, in bodies sparingly hydrogenous, the combustion may be incomplete. This is indicated by the smell of sulphurous acid in the gases which escape when the cock of the bomb is loosened. The combustion in such cases is repeated, adding to the substance its own weight or half its weight of camphor. The author has obtained satisfactory results with such bodies as albumen, gluten, vegetable fibrin, and again with taurine and carbon disulphide. Free sulphur, however, even with the addition of naphthalene, evolved some sulphurous acid in its combustion.

Combustion-Heat of Certain Sulphur Compounds.—MM. Berthelot and Matignon.—The authors used the method mentioned in the foregoing paper in determining the combustion-heats of thiophene, taurine, and carbon disulphide.

Researches on Certain Saccharine Principles.—MM. Berthelot and Matignon.—Thermo-chemical determinations concerning erythrite, arabinose, xylose, raffinose, and the inosites.

New Researches on the Effluve.—P. Schützenberger.—The author describes his experiments on carbon monoxide. In a blank experiment a current of this gas, obtained by the decomposition of sodium formate by monohydrated sulphuric acid, freed from every trace of free oxygen, of carbon dioxide, and watery vapour, was allowed to pass in bubbles for six hours, and it was found that the weight of the tubes had not appreciably varied. In experiments when the gaseous current was kept at the same speed, but with the action of the coil, there was obtained a solid acid product which, when the gas was renewed only every three hours, gave carbon 42.1 per cent, hydrogen 1.4, and oxygen 56.5 per cent. On pro-

longing the duration of the action of the effluve upon one and the same portion of gas, the proportions of oxygen and hydrogen increase. The excess of these gases condensed is not in the proportions of water, the oxygen being in excess. On prolonging the action of the effluve upon one and the same portion of gas the proportion between the carbon dioxide formed and the total condensed product diminishes up to a certain limit. The elements of water do not penetrate the tube in their combined state, but separately, in consequence of a kind of electrolytic transference.

Action of the Various Alkaline Arseniates, in the Dry Way, upon Certain Metallic Sesquioxides.—C. Lefèvre.—The aluminium, chromium, and iron sesquioxides always yield an arseniate of the composition $2MO, KO, AsO_5$, as do those of the alkaline earths and of the magnesian series.

New Method of Preparing Basic Copper Nitrate and Crystalline Metallic Subnitrates.—G. Rousseau.—The author submits the two hydrates of neutral copper nitrate, along with an alkaline earthy carbonate, to the action of heat in sealed tubes. He rejects the formula proposed by Berzelius and Graham, and accepts that of Gerhardt, $3CuO, CuO, NO_5, HO$.

Double Phosphorus and Indium Bromides.—G. Geisenheimer.—The author has obtained $Ir_2Br_3, 3PBr_3$ in red crystalline needles. He has failed in producing a bromide corresponding to the double chloride, $Ir_2P_3Cl_{12}$. The double bromides differ from the corresponding chlorides in as far as the most stable of the former is $Ir_2P_3Br_9$, whilst the most stable of the chlorides is $Ir_2P_3Cl_{12}$.

On Certain Chromo-Iodates.—A. Berg.—M. Berg has obtained and described the magnesium, cobalt, nickel, and silver chromo-iodates, and subsequently that of copper.

On the Nitroprussiates.—M. Prud'homme.—The author gives three processes for obtaining nitroprussides. He recommends a mixture of sodium nitrite, 34.5 grms., and sodium hyposulphite, 15.5 grms., in 150 c.c. of water boiled with 41 grms. ferricyanide in 250 grms. water. If this liquid, when cold, is mixed with 108 grms. solution sodium bisulphite at 37° B. it becomes of a very deep red.

The Cause of the Alterations which Certain Compounds of the Aromatic Series undergo under the Action of Air and Light.—André Bidot.—The changes of colour in question are not due to any inherent properties of the compounds in question, but are occasioned by the intervention of foreign matters in infinitesimal proportions.

Transformation of Glucose into Sorbite.—J. Meunier.—The author hydrogenises glucose by the action of sodium amalgam, and obtains from 25 grms. 21 grms. of benzoic acetal, which corresponds to 35–40 per cent of sorbite.

The Hydrogenation of Sorbine and the Oxidation of Sorbite.—Camille Vincent and M. Delachanal.—The authors find that by hydrogenising sorbine they obtain sorbite. In attempting to produce sorbine by oxidising sorbite they have obtained glucose.

Synthesis by Means of Cyanacetic Ether.—A. Haller.—If the cyanacetic ethers are treated with sodium alcoholate they yield sodium derivatives, very susceptible of double decomposition. If these sodium compounds, dissolved or suspended in absolute alcohols, are treated with a current of cyanogen chloride, dicyanacetic ethers are produced.

Preparation of Certain Ethers by Means of Fermentation.—G. Jacquemin.—The author finds it possible to obtain ethers by sowing, e.g., the wort of malt with organised ferments.

Physiological Action of the Salts of Thallium.—J. Blake.—(See p. 44).

Bulletin de la Société Chimique de Paris.
Series 3, Vol. iii., No. 8.

The Preparation of the Crystalline Basic Copper Nitrate and its Identification with Gerhardtite.—L. Bourgeois.—On heating copper nitrate with urea in a sealed tube the author obtains very slender tablets of a pale greenish blue, which prove to be a basic copper nitrate. This substance occurs, along with malachite and cuprite, in specimens from Arizona, and has received the name Gerhardtite.

The Nitration of Propylbenzene.—R. Lespieau.—On causing a mixture of sulphuric and nitric acids to act upon propylbenzene the author has obtained a white crystalline body fusible at 238°. In the liquid separated from the crystals there appear oily products, which cannot be distilled, even in a vacuum. One of them is a yellowish liquid, having the odour of nitrobenzene.

Action of Ethyl Iodide upon Certain Acid Amides.—E. Duvillier.—The author examines the action of ethyl iodide in excess upon amidobutyric acid in presence of potassa. There is no production of betaine, but an abundant yield of diethylamidobutyric acid. If ethyl iodide in large excess (4 mols. and upwards) is allowed to act upon 1 mol. alanine dissolved in an alcoholic solution of potassa at 100° in a closed vessel there is not production of ethyl betaine, but of diethylamidopropionic acid.

Action of Trimethylamine upon Bromoisovaleric Acid.—E. Duvillier.—This reaction produces only a very small quantity of betaine, but an abundance of tetramethylammonium, and much dimethylacrylic acid. No iso-oxyvaleric acid is formed.

Combination of Ammonia with Metallic Permanganates.—T. Klobb.—According to the text-books, ammonia decomposes permanganic acid and its salts with liberation of nitrogen and separation of manganese dioxide or sesquioxide. This takes place on prolonged contact or at high temperatures, but it is possible to obtain crystalline compounds of certain permanganates with ammonia. The author has obtained such salts with copper, zinc, nickel, and cadmium. All these compounds dissolve without decomposition in dilute sulphuric acid, but their aqueous solutions, which are at first of a fine violet, soon deposit manganese oxide. The salts of zinc and copper are the most permanent. All of them detonate if struck with a hammer.

On Certain Products of the Distillation of Wood.—M. Vladesco.—In all the examples examined there were found, along with ordinary acetone, certain other higher acetones. It is probable that on operating upon larger quantities of material, propione or methylisopropylacetone might be recognised.

The Wines of Dried Grapes and their Total Proportion of Nitrogen.—P. Cazeneuve and L. Ducher.—The authors propose a determination of nitrogen, which is more abundant in raisin-wines than in wines made from fresh grapes.

On the Chloronitroanisols.—Louis Hugouneq.—An examination of dichloromononitroanisole, of the corresponding dinitro-compound, and of the trichloromono- and dinitroanisols.

Vol. iii., No. 10.

Vapour Density of the Selenium Chlorides.—C. Chabré.—It appears that the chloride $SeCl_4$ is dissociated into free chlorine and sub-chloride, and that Se_2Cl_2 , which is only decomposed partially if not in presence of an atmosphere of chlorine, is not decomposed at all if in contact with an atmosphere of this gas in the nascent state.

Sulphoconjugated Phenols Derived from Ordinary Camphor.—P. Cazeneuve.—Concentrated sulphuric acid yields in the cold, with monochloro-camphor, a total of sulphoconjugated compounds possessing the phenolic function. This formation proves that the terebenic series contains the benzene nucleus, and is a branch of the aromatic series.

Journal de Pharmacie et de Chimie.

Series 5, Vol. xxi., No. 3.

On a New Inosite.—MM. Maquenne and Tanret.—The authors have obtained racemo-inosite, which has the same relations to the dextro-rotatory and the levo-rotatory inosites as the paratartronic acid has to dextro- and levo-tartaric acids.

Presence of Magnesia in Acid Calcium Phosphate and Sodium Phosphate.—M. Schlagdenhauffen.—Acid calcium phosphate, if prepared in the ordinary manner from calcined bones, must of necessity contain magnesium phosphate to the extent of 1.02 per cent, and which is not fully eliminated. Solutions of sodium phosphate contain calcium and magnesium phosphates. In determining magnesia there should be used, instead of common sodium phosphate, a mixture of this phosphate, of magnesium chloride, and of ammonia, letting it stand for twenty-four hours, and using the clear liquid as precipitant.

On Quebrachite.—M. Tanret.—Quebrachite is not a hexatomic but a pentatomic alcohol.

Determination of Cantharidine in Insects.—J. B. Nagelvoort.—10 grms. of cantharides are moistened with a solution of soda at 10 per cent and let steep for six hours. The mixture is then acidulated with hydrochloric acid, placed in a Soxhlet apparatus, and exhausted with boiling chloroform (about 50 c.c.). When the chloroform is evaporated the remainder is washed with carbon disulphide, thrown upon a filter, and again exhausted with boiling chloroform. The solution is received in a small tared capsule, evaporated, and weighed.

Vol. xxi., No. 4.

Boric Acid in Articles of Food.—Contractors supplying preserved meats for the German navy have been officially forbidden to make use of substances containing boric acid. All persons who have experimentally consumed meat preserved with the aid of a powder composed of borax and soda have experienced derangements of digestion.

Sophistications in Russia.—According to *Le Caucase* the tea grown in Trans-Caucasia consists in large part of the leaves of a shrub named *Vaccinium arcto-staphylos* (?) which yield a decoction having some resemblance in taste to tea, but acrid and nauseating. These leaves are mixed up with inferior tea and with tea-leaves which have been already used. The *Nouvelles de St. Pétersbourg* adds that groceries, such as mustard, pepper, coffee, &c., often contain only from 1-20th to 1-10th of the substance which they professedly represent.

Vol. xxi., No. 5.

Assay of Commercial Tin Plate by Potassium Iodide.—Dr. Perron.—It is usually supposed that tin mixed with lead may be detected if we treat a spot of the surface with nitric acid, evaporate the white stannic stain produced, and then apply potassium iodide. In this operation there is a great risk of error if the nitric spot is either heated too little or too much in the process of drying. The author announces that he will indicate a novel reaction.

New Process for the Carbonisation of Wood in the Manufacture of Gunpowder.—H. Güttler.—The author injects hot carbon dioxide into the retorts during charring, and allows the product to cool in a cold atmosphere of the same gas.

Process for Rendering Thermometers more Sensitive.—C. Sache.—The author uses, instead of pure mercury, an amalgam containing 1 per cent of silver, which is a better conductor.

Vol. xxi., No. 6

Digestibility of Boiled Milk.—W. Raudnitz.—The use of milk boiled or even heated slightly above 100°

having been generally recommended in order to destroy morbid germs, the author has made comparative experiments with raw and boiled milk upon a young dog. He finds that the nutritive value of the raw milk is not appreciably less than that of boiled milk.

Action of Organic Acids upon Utensils of Nickel.—A. Rohder.—The author thinks that the use of such articles may be tolerated. Surfaces of 290 centimetres, after being exposed for twenty-four hours to the action of acetic acid at 2 per cent, only lost 24 to 29 milligrammes.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale. Series 4, Vol. v., No. 52.

This number contains no chemical matter.

MISCELLANEOUS.

Institute of Chemistry.—The following are the names of the 43 candidates who passed the Institute Examination in Practical Chemistry held July 14 to 17 at Birmingham, Glasgow, Leeds, Liverpool, London, and Manchester:—J. Anderson, F. Boyce, H. Broadbent, F. Brownswort, A. Carey, G. C. Clayton, J. T. Conroy, A. W. Crossley, L. Crossley, H. E. Davies, E. V. Ellis, P. A. Estcourt, C. H. Field, A. W. Gilbody, W. Goodall, W. Greaves, A. Hall, G. Hefford, H. Ingle, S. Jackson, B. W. Jones, W. H. Joseland, Dr. J. W. Leather, J. H. Lester, J. G. Lord, H. S. Marsh, W. MacDonald, T. Newsome, S. Pickford, R. W. Prideaux, J. R. Paterson, W. Ramsay, G. H. Robertson, C. Smith, J. Spilsbury, J. H. Stansbie, J. A. Storey, J. J. Sudborough, M. Taylor, E. A. Wagstaffe, H. Watson, J. Wild, and J. H. Wilson.

Photographic Convention of the United Kingdom.—At this Convention there was presented a Report from the Committee on "Weights, Measures, and Formulae," drawn up by Mr. C. H. Bothamley. The Committee fully recognise the value of a decimal system, and also of a definite relation between the measures of weight and the measures of capacity. These features are possessed by the French or metric system, but also by a system of units in common use in England, the grain-weight and the grain-measure or fluid grain. It is merely necessary to reject the drachm, the scruple, and the minim, and express all weights in grains and decimal fractions of a grain, and all measures in fluid grains and their decimal multiples and sub-multiples. They remind their constituents that an exact equivalence between weights and measures exists only at one fixed temperature, and as concerns liquids of the same sp. gr. as water. Hence all solutions should be made up at 15° C. or else at 62° F. They recommend that formulæ should state the quantities of the ingredients to be contained in x parts of the finished solution and not the quantities to be added to x parts of the solvent. Hence they very properly advise photographers in making up a solution first to dissolve the ingredients in a quantity of the liquid smaller than the required volume of the finished mixture, making it up after cooling (if necessary) to the volume specified. These proposals, if acted upon, will prevent much confusion and error.

On Phenyl-Dithienyl.—Adolphe Renard.—Phenyl-dithienyl is formed along with phenyl-thiophene by the action of sulphur upon toluene at dull redness. It appears in colourless plates, fusible at 209°, and capable of subliming. It is very little soluble in alcohol, ether, petroleum essence, slightly soluble in chloroform and acetic acid, very soluble in boiling benzene and toluene. Its composition is $C_6H_5-(C_6H_4S-C_6H_4S)_2$. The author has examined its tribromo-, dinitro-, and disulphonic compounds.—*Comptes Rendus*, vol. cxi., No. 1.

THE CHEMICAL NEWS.

VOL. LXII. No. 1601.

EXAMINATION OF OILS, FATS, AND ALLIED SUBSTANCES.

By THOMAS T. P. BRUCE WARREN.

WHEN two oils are mixed together which separately yield insoluble products with sulphur chloride it is found that this reagent exerts a *selective* action, so that one of the oils is, relatively, more affected than the other, and I have no doubt a fractional separation may be made by adjusting the amount of chloride required for the quantity present of the more active oil. The quantity of soluble matter yielded by a magma to carbon disulphide, or removable by boiling in a solution of caustic soda, will depend on the amount of chloride used and also on the nature of the oils themselves.

Castor oil yields a small proportion of soluble matter and is so energetic in its action that we are obliged to dilute the chloride so as to moderate its effect. Rape oil or any similar oil, if used to dilute the castor oil, will only slightly modify its action; the effect of this oil is to deprive the rape oil of its allotted proportion of chloride and to become itself more firmly solidified; hence, when the magma is treated with CS_2 , the soluble portion will be proportionately richer in rape oil products as the quantity of castor oil is increased.

When the *yellow* chloride of sulphur acts upon an oil the chlorine is chiefly evolved as HCl , whilst the sulphur combines simultaneously with the dehydrogenised portion of the oil. I cannot speak definitely of what happens with those oils which do not yield insoluble products. The estimation of sulphur and chlorine retained in these purified insoluble products will assist us in many ways, so that I hope to supplement this part of the subject at an early date.

The total weight of the *dried* solid magma formed by sulphur chloride should always be noted, as it not unfrequently gives us an important insight into the nature of the substances we are dealing with; but a far more important clue is to be gained from the subsequent treatment with solvents—5 grms. lard gave 5.80 grms. solid magma, which was entirely soluble in CS_2 . This lard was prepared from the "flare" of the pig, under my own supervision. The iodine absorption was 52.6 per cent. I hope to obtain some purified lard oil from the same source at some future time, but the significant fact proved here is that lard oil should yield no insoluble product if pure.

The same quantities of lard and lard oil and chloride were used. Cocoa-nut oil is added to show the differences in weight yielded by fats giving no insoluble products and adulterated oils containing an oil which gives an insoluble product.

	SULPHUR CHLORIDE.		IODINE ABS., P.C.		REMARKS.
	Total weight, grms.		Original	Extract.	
	Magma.	Soluble.	oil.	from magma.	
Lard ..	5.80	5.80	52.6	47.40	Own rendg.
Lard oil ..	6.25	0.75	93.2	48.58	American.
" ..	6.19	0.48	89.9	52.06	English.
Cocoa-nut oil	5.14	5.14	—	14.70	

These results are very instructive. The iodine absorptions show that the oils or fats which yield no insoluble products are but little altered by chloride of sulphur, whereas a mixture of such an oil or fat will yield a soluble portion totally different in its iodine absorption and more closely approaching that of pure lard similarly treated.

Again, an oil or fat which is not solidified by chloride of sulphur gives an increase in weight very different from

oils yielding insoluble products, and the portion thus removed gives an iodine absorption quite unlike the original oils or mixtures. A mixture of cocoa-nut oil and cotton-seed oil may be put together having a low iodine absorption, but this treatment would at once reveal the nature of the mixture, as the cocoa-nut oil would be removed by CS_2 .

Lard oil, as used for lubricating, may be put together in two ways; animal fatty matter may either be added to cotton-seed oil, or the stearin from cotton oil may be in excess of what the oil naturally contains, and this may be added to animal fat, but by refrigeration and pressure we may recover the olein, when the iodine absorption of the substance left on the filter, as well as that of the olein, will help us to a solution of the problem. Animal fats or oil do not blend so intimately with vegetable fluid oils.

As regards lubrication, I do not suppose that there is much to complain of in this mixture, but when we pay £40 per ton for an article consisting mainly of an oil which can be bought for £20 per ton, the financial aspect is at least discouraging.

Bearing more directly on the chemistry of fatty bodies, and more particularly on the oleic and stearic glycerides, I may say that I am driven to the conclusion that chloride of sulphur shows us that we cannot regard these compounds in animal and vegetable oils and fats as having an identity of composition. Oleic and stearic acids from animal fats and concrete oils, when separated and purified, and subsequently converted into glycerides, behave as the original oils and fats, but if stearic or oleic acids be separated from cotton oil, or any similar oil, and subsequently converted into their corresponding glycerides, they behave with chloride of sulphur as before separation.

I was inclined to believe that this difference was due to the presence of some modifying constituent in certain oils or fats, or to a deficiency of glycerin; for the presence of this latter body is essential to the reaction. The probable expulsion of the glycerin will not account for the apparent anomaly in the behaviour of these acids.

This portion of the subject seems so important that I propose to re-examine the whole matter more minutely, so as to include the details in these papers.

The experimental case is briefly this:—A mixture of cotton-seed oil and lard was saponified, the fatty acids separated and re-converted into their corresponding glycerides, and purified by recovery from CS_2 solution. This mixture showed no difference when treated with chloride of sulphur, the cotton-seed oil and the lard had each recovered their own individuality as before.

The practical deduction is, that a mixture of oils may be so completely altered by time, exposure, or other accidental causes, that identity of its original composition seems hopeless. The mere loss of glycerin need introduce no embarrassment.

A BRIEF SUMMARY OF THE VARIOUS METHODS TRIED FOR THE PRODUCTION OF ALUMINIUM FROM 1886 TO 1890.

By H. N. WARREN, Research Analyst.

THE failures to procure several of the leading commercial articles at a less price, such as the caustic soda of the alkali manufacturers, the synthesis of alcohol for the distiller, the replacement of cane-sugar by saccharine, besides other compounds too numerous to mention, have of late led to the production of several eminent works, in which these experiments are clearly brought to the front, greatly aiding, no doubt, others working in the same direction. Still there are, in each of these works, gaps remaining to be filled, and it is therefore the author's intent to bring before those interested in the production

of aluminium at least a few of the more important experiments that have been undertaken both by himself and in conjunction with others, with the hope of obtaining further light upon this metal of the nineteenth century.

In the first instance I will confine myself as closely as possible to the mineral cryolite or its derivatives as the direct source or storehouse for the metal. One of the earliest experiments was the action of amorphous silicon upon that substance, which, although it yielded a negative result, being afterwards readily observed on account of the stability of that substance and its neutral reaction, nevertheless pointed to the direction of some allied substance presenting an acid reaction and less stable, and for it was substituted aluminium fluoride itself. Amorphous silicon thrown into melted fluoride of aluminium when at a high temperature reacts according to the following equation, yielding aluminium and silicon fluoride—

but aluminium being once formed and in contact with silicon fluoride at once decomposes it, yielding an alloy of silicon with aluminium containing about 70 per cent of the former substance.

The second lot of experiments comprise chiefly the injecting of the vapour of ammonia, ammonia oxalate, and the more volatile metals into the melted cryolite.

Experiments with the fluorides in contact with metallic copper, using as a reducing agent the hydrides of antimony, arsenic, sulphur, selenium, &c., have also been tried for the production of Al bronze.

For the production of ferro-aluminium metallic manganese in presence of iron has been made use of, also ferro-manganese, spiegeleisen, &c.

To manufacture the anhydrous chloride the incineration of a mixture of barium chloride and soda-alum has been made use of, and the introduction of magnesium for the replacement of the aluminium. The phosphides and sulphides have also been largely dealt with. With respect to arsenic the reaction afforded with this substance is more than striking. Absolutely pure aluminium was taken, melted at a red-heat, and metallic arsenic thrown on to its surface and impregnated with the same by stirring. A brittle arsenide of aluminium may be formed, but strange to say this compound is completely decomposed again on raising the temperature, even when out of contact with air, inasmuch that no arsenic hydride is produced when acted upon by dilute acids.

This reaction was at one time considered to be of value for the separation of aluminium from alloys containing the same. But quite a different phenomenon is observed in the case of alloys, an arsenical regulus being in every case readily formed. Aluminium in this respect may be compared to the action of metallic copper when in contact with sulphide of that element, and the marked difference observed when foreign impurities present themselves.

Bromides, iodides, and the subjecting of the oxide to all grades of temperatures when in contact with reducible gases have also been thoroughly experimented with. Various methods have been of late patented for the production of aluminium. Among a few of the most famous may be mentioned the action of common salt upon clay when in presence of zinc, and also that of heating to an enormous temperature a mixture of alumina, petroleum, and sulphuric acid, after which is introduced some fabulous metal which is stated reduces the aluminium; but the most curious part of these patents is the present price of aluminium when it can, according to the minds of several, be manufactured so readily. As regards the electroplating of aluminium the same difficulties present themselves. A cyanide of the metal would undoubtedly sound the most feasible, but to procure this compound is as difficult as the preparation of the metal itself. The cyanide, although stated by the various handbooks of chemistry to be unknown, is by no means so; for when a

rod of metallic aluminium is connected to the positive pole of a compact battery, a platinum plate furnishing the negative, and the extremities of each are brought into contact with a strong solution of hydrocyanic acid, aluminium cyanide is formed in the solution, which is entirely decomposed below the boiling temperature. Sulphocyanides, ferrocyanides, and all the compounds of aluminium, both organic and inorganic, have in short been thoroughly experimented with.

Everton Research Laboratory,
18, Albion Street, Everton, Liverpool.

ON THE COLOURING REAGENTS OF THE FUNDAMENTAL SUBSTANCES OF VEGETABLE MEMBRANE.

By M. L. MANGIN.

THE use of colouring matters in vegetable anatomy has not formed hitherto the subject of methodic investigations. Although the list of reagents used in microscopical studies grows daily, the absence of precise data on their composition, their chemical properties, and the conditions of their action renders the verifications of the results announced very much a matter of chance.

In the researches which the author has undertaken he has proposed to compare the action of the colouring matters with their composition, and to verify analytically the results obtained with colouring-reagents. He believes that by defining strictly the nature and the *modus operandi* of these reagents, it will be possible to arrive at a method for the qualitative micro-analysis of the tissues capable of superseding the empirical processes of colouration now used.

In this memoir he concerns himself merely with the fixation of the colouring reagents on the fundamental substances recognised in the so-called cellulosic membrane of plants, this fixation taking place without mordants in a neutral, alkaline, or acid medium.

The various colouring matters of the aromatic series may be divided into two categories: the one is formed of compounds in which a basic colouring-matter is united to various acids, mineral or organic; the other is formed of acid colours employed in the state of alkaline salts.

The substances of the first class fix themselves with a variable energy upon the pectic compounds, and thus manifest the acid function of the compounds. They colour neither callose nor cellulose. The author mentions the *azo-group*, e.g., Vesuvian brown and chrysoidine; the *diphenylmethane group*, e.g., auramine; the *triphenylmethane group*, such as Victoria blue, night-blue, magenta, Paris violet; then all the colours of the *oxazines group*, as naphthylene blue, Nile blue; of the *thiosins group*, methylene blue; of the *eurodins group*, neutral red; of the *saffranins group*, neutral blue, phenosafranine, magdala red, &c. The affinity of these colours for the pectic compounds is very unequal and feeble, as the presence of an excess of acid or glycerin is sufficient to decolourise the tissues more or less quickly.

The second class, formed of the alkaline salts, contains a number of substances which never colour the pectic compounds, but many of them fix upon cellulose and callose, proving the basic nature of these bodies. In this class we have an interest only in two groups, the *azo-group* and the *triphenylmethane group*.

The *azo-group*, if we set on one side chrysoidine and Vesuvian brown, is chiefly formed of alkaline salts, among which we distinguish three important types.

The first type comprises the colouring-matters which only contain one *azo-group*, such as xyldine ponceau, the composition of which is—

To this type belong aniline and toluidine ponceau, naphthorubine, &c., and the tropecolines. These substances colour the protoplasm yellow, but they have no action upon cellulose or callose.

The second type is formed of substances containing two azo-groups, such as orchil red A.

Here belong orselline BB., azorubine, naphthol black, the croceines, &c. The substances colour cellulose in a neutral or faintly acid bath, and have no action upon callose.

The third type contains colouring-matters of the benzidic series, such as Congo red—

To this type belong Bordeaux extra, Congo G R, Congo-corinth, delta-purpurine G, brilliant Congo G, resulting from the action of the sulphur compounds of naphthol upon benzidine; azo-blue, the Congo-corinth B, the benzo-purpurines, the rosazurines, where toluidine is substituted for benzidine, azo-violet, benzo-azurine, heliotrope, where dianisidine is substituted for benzidine, &c. These colouring matters, which are ordinarily precipitated by acids, dye cellulose and callose directly in a neutral or feebly alkaline bath.

The triphenylmethane group does not offer such definite relations between the colouring power and the chemical compositions. We distinguish here first a great number of bodies formed of hydrochlorates, sulphate, &c., which dye the peptic compound directly, and then a series of alkaline salts which we divide into three groups. The first group includes acid magenta, acid violet, Bayer's blue, Nicholson blue, &c., resulting from the respective action of sulphuric acid upon magenta, Paris violet C B, diphenylamine blue, or aniline blue. These substances do not colour cellulose, but some of them, as the soluble blues, and especially Bayer's blue, colour callose. The colourisation is the more active as the sulphurisation is more complete; thus 6 B blue, a mixture in which trisulphonated triphenylrosaniline predominates, is the most active of the soluble blues.

The second triphenylmethane group is formed of the alkaline salts of rosolic acid, which dye callose and cellulose directly.

The third group is formed of eosines, a salt of fluoresceine, such as eosine, erythrosine, phloxine, which colour nitrogenous matters strongly, but do not attach themselves to callose or cellulose.

The manipulative details will be described in a future communication.—*Comptes Rendus*, cxi., p. 120.

CHEMISTRY AND MINERALOGY.*

By Professor E. H. RENNIE, M.A., D.Sc., University of Adelaide.
(Concluded from p. 47).

If we inquire now what has been done in the region of mineral chemistry (I am speaking, remember, chiefly from a purely scientific point of view), we shall find, I think, that in this department even less has been accomplished. It is true we have a large number of analyses in official reports of one kind and another, but these have, for the most part, been undertaken and published purely from a commercial point of view, and there has been very little

careful and systematic analysis of the less common and less useful minerals, of which many varieties are to be found. So far as I have been able to ascertain there is scarcely any record of the discovery of the rarer elements. The only instance I have come across is the analysis of a sample of *monasite*, which was examined by Mr. Dixon, of the Technical College, N.S.W., and which he found to contain Cerium, Lanthanum, Thorium, and Didymium. In one or two instances some of the less rare elements have been discovered; for example, Mr. Mingaye, at the first meeting of this Association, proved the presence of considerable quantities of tellurium in some bismuth ores from Captain's Flat, N.S.W., and some years ago I showed that the appearance of brilliant yellow, reddish, and green colourations on white bricks made in the neighbourhood of Sydney were due to the presence of vanadium. I have found small quantities of vanadium widely distributed in many clays in the neighbourhood of Sydney. But is it not, to say the least of it, highly probable that in the large areas of mineral country which exist in so many parts of Australasia there are waiting to be found many minerals, possibly many new ones, containing either considerable quantities of rare but already known substances, or perhaps even new elements? That they have not been found I attribute to the fact that the search for minerals has been almost entirely directed to the finding of gold or other payable metals. We have heard a good deal of Broken Hill, perhaps there are some listening to me who are fortunate enough or unfortunate enough to know more about it than by mere hearsay, but it is scarcely to be doubted that a scientific search for and examination of minerals from the great silver field would yield results of great interest. Professor Masson and Mr. Kirkland have, I understand, examined a considerable number of zinc ores from that district for gallium, but so far without success. I have roughly examined the flue dust from the Dry Creek Smelting Works for germanium, but so far without finding any, but these negative results need not discourage us. You may be reminded in this connection that the Government assayer of N.S.W. reports the discovery of platinum, and probably therefore some of the associated metals, in some minerals from somewhere in the Broken Hill region.

This department of chemical science—I mean the search for new or imperfectly known elements—has acquired great interest and importance in view of the great impulse recently given to the study of the periodic law of Newlands and Mendeleëff by various chemists in Europe and the brilliant researches of Crookes on the nature of several of these so-called elements. It may not be out of place before bringing this address to a conclusion to review very briefly the more important results obtained in this direction during the past few years, the questions involved being of all absorbing interest to both chemists and physicists. It is evident that, whether justified by facts or not, there is a growing disbelief in the elementary character of the so-called elements, and this disbelief has arisen from results obtained in two different lines of research, namely, a more thorough study of the periodic law, and the spectroscopic investigations of Crookes and others.

One of the most important papers on the periodic law was that read before the British Association at Aberdeen, in 1886, by Carnelley. He brought out very clearly the analogies between the elements so called when arranged according to the periodic law and series of hydrocarbon radicles and their derivatives, and showed that it is possible to build up a series of compounds of two primary elements corresponding in many respects to the known series of elements, and he advances the speculation that all of the latter, except hydrogen, may be compounds of two substances, one with atomic weight 20, and the other with atomic weight -2, the latter being identical with the *ether* which exists all through space and matter as the medium of transmission of heat and light. Dr. Carnelley

* Australasian Association for the Advancement of Science, Melbourne Meeting, 1890. Presidential Address in Section B.

puts this forward merely as a speculation, and though the idea of a substance with negative atomic weight may be to others, as to myself, very difficult to grasp, there can be no doubt that his paper is a very valuable contribution to the study of the causes underlying the periodic law.

By the adoption of a form of zigzag curve Emerson Reynolds succeeded in indicating much more clearly than by the ordinary tabular system, the relations and contrasts between the various members of the different periods, bringing into prominence especially the following noteworthy points:—(1) The possibility that hydrogen is not the first member of Mendeléeff's first period, but the last—in other words, that there is still room for elements of lighter atomic weight than hydrogen. (2) The possible non-existence of Mendeléeff's ninth period, which includes at present only the metal *Erbium*; and (3) the inter-periodic character of the triplet group Fe. Ni. Co., Rh. Ru. Pd., and Ir. Os. Pt.

Crookes, in his lecture on the "Genesis of the Elements," adopted a slightly modified form of the curve proposed by Reynolds, and of it he says, "The more I ponder over the arrangement of this zigzag curve the more I become convinced that he who fully grasps its meaning holds the key to unlock some of the deepest mysteries of creation." Using it as an illustration, he sketches out a possible evolution of the substances known to us as elements from an original or primordial matter, which he calls *pyrolyte*, and in this sketch he explains the possible formation of such groups as the three triplets already referred to, and that of the Cerium metals, the characteristics of which he has done so much to elucidate. While on this subject of the graphic representation of the periodic law, attention should be drawn to a curious paper by the Rev. Dr. Haughton, read before the Royal Irish Academy in 1888, in which, by a geometrical representation of the law, he brings out some interesting and hitherto unnoticed points, and indicates in a very graphic manner the isolation of hydrogen and the points at which, in his opinion, there are still to be found missing elements.

The other line of investigation, which has led to serious doubt as to the accuracy of the hitherto generally accepted notions of the nature of the so-called elements, is the purely experimental, as developed by Crookes and others in researches on the rare-earth metals. By long and tedious experiments Crookes has succeeded in splitting up *yttrium*, for example, into several substances, which are, at any rate, spectroscopically distinct, but which are so closely related chemically that they are indistinguishable by ordinary methods. He believes it will be possible to obtain similar results with other substances, if only the right methods can be found; in fact, he has actually found indications of the commencement of a like separation in other cases than that of *yttrium*. Reasoning on these facts he has modified his views as to the character of the elements, and is now inclined to regard them, not as made up of a number of atoms of rigorously the same weight, but as consisting of groups of atoms of which the mean atomic weight is practically constant, but which differ in weight among themselves to a small but finite extent. This, in his view, would be the natural consequence of the generation of the elements from a primordial matter, and if I understand him aright, he believes that in such groups as that of the cerium metals, and others of which the members closely resemble one another, we have traces remaining of an imperfect differentiation into the distinct substances we have been accustomed to call elements.

In his Faraday lecture, delivered last year before the Chemical Society of London, Mendeléeff criticises somewhat severely these views as to the character and origin of the elements. He objects to the representation of the periodic law in the form of curves, as used by Reynolds, Crookes, and Haughton, on the ground that a curve as ordinarily used indicates a continuous and unbroken series of points, and that, therefore, at any and every point of such a curve, there should be a corresponding

element—in other words, this method of representation implies an infinite number of elements—so, at least, I understand his objection. It would appear, however, that this criticism is based upon a misconception of the real object of these so-called curves, which, I take it, are not intended to be understood in a purely mathematical sense, but simply as graphic representations of the periodic law, which enable us to see more clearly its prominent features. He points out further that the analogy between the series of elements and hydrocarbon radicles, worked out by Carnelley (thought previously indicated by Pelopidas) is weak in this respect, that whereas the series of natural elements involves an increase of mass as we pass from one member to another, the series of hydrocarbon radicles involves a decrease, and that therefore there is no true identity of periodicity in the two cases. This statement is, of course, involved in Carnelley's assumption of a negative atomic weight. As regards the existence of *helium*, an element supposed by Lockyer to exist in the sun, he points out that no attention is paid to the fact that the helium line is seen only in the spectrum of the solar protuberances, nor to the fact that the same line is wanting among the Fraunhofer lines of the solar spectrum, and therefore does not answer to the fundamental conception of spectrum analysis, and he further criticises other statements regarding the alleged spectroscopic indications of the decomposition of the elements. He does not, however, attempt to controvert Crookes's results, but says:—"From the foregoing as well as from the failures of so many attempts at finding in experiment and speculation a proof of the compound character of the elements and of the existence of primordial matter, it is evident, in my opinion, that this theory must be classed among mere utopias."

The supposition of Carnelley that the ether may be one of the forms of the primordial matter has been already alluded to. Recent physical investigations have thrown a wonderful light on the nature and functions of the ether, for a simple account of which I refer you to that fascinating book by Professor Lodge, entitled "Modern Views of Electricity." In his preface to the work he says "the evidence for (the existence of) ether is as strong and direct as the evidence for (the existence of) air," and he regards it as "a perfectly continuous, subtle, incompressible substance pervading all space, and penetrating between the molecules of all ordinary matter, which are embedded in it and connected with one another by its means." If there be such an all-permeating form of matter, does it not seem improbable that this substance should exist separate, distinct, and different from all other forms of matter, and having no share in their composition? Is it not more likely that it forms an essential part of all forms of matter known to us, and is it not possible that the known effects of heat, light, and electricity, for all of which this ether is undoubtedly the means of transmission, are either due to, or at least would be greatly aided by, its presence as a constituent part of the matter upon which the effects are produced? You are doubtless well aware that Sir W. Thompson has elaborated what is known as the vortex theory of matter, which represents the atoms as vortex rings formed of the substance of the ether, he having demonstrated that vortex motion is capable of conferring upon a fluid such as the ether the necessary rigidity. In speaking of this, Professor Lodge says:—"The atoms of matter are not so much foreign particles imbedded in the all-pervading ether, as portions of it differentiated off from the rest by reason of their vortex motion, thus becoming virtually solid particles, yet with no transition of substance: atoms indestructible and not able to be manufactured, not mere hard rigid specks, but each composed of whirling ether—elastic, capable of definite vibration, of free movement, of collision."

Whatever opinions we may hold on these subjects, there is not one of us but must feel, I think, that the scientific atmosphere is pregnant with coming discoveries, though the boldest prophet may well hesitate to predict

what they will be. In a few years chemistry, perhaps, will be reduced to a mere branch of the all-embracing science of physics, to be studied by differential equations and other mathematical processes yet to be invented. Already it is becoming more and more necessary for scientific chemists to be, not mere chemists, but also physicists and mathematicians. Let those of us who are not able to plunge into the more abstruse reasonings upon which some of the recently obtained results depend, content ourselves with doing our utmost to discover such new facts as lie within our reach, to aim at generalising these facts as far as possible, and so add to that storehouse of knowledge by means of which those possessed of greater powers of analytical investigation than ourselves may be able to elucidate the greater problems of nature: and let all of us who are members of this Association strive to make it such an influence in these colonies that Australasia may not be behind the rest of the world in its eagerness for scientific investigation and ambition to produce men who may rank among the great discoverers of future years.

A METHOD FOR THE REDUCTION OF ARSENIC ACID IN ANALYSIS.*

By F. A. GOOCH and P. E. BROWNING.

HOLTHOFF's development of Mohr's suggestion relative to the reduction of arsenic acid to the lower condition of oxidation by the action of sulphurous acid,† with the demonstration that arsenic acid can be evaporated even to dryness in presence of hydrochloric acid without danger of significant volatilisation, has placed the analysis of ordinary compounds of arsenic, both natural and artificial, within the scope of Mohr's classical and exact method of determination by titration with iodine. As Holthoff left the method, it is satisfactory so far as regards accuracy, and as modified by McCay,‡ who substitutes for the four hours' digestion heating for one hour in a pressure bottle, is eminently successful. In the account of the experiments about to be described we detail our experience in an attempt to shorten still further the process of reduction of arsenic acid by making use of hydriodic acid as the active agent instead of sulphurous acid.

In a recent paper§ we have described a method for the determination of iodine in haloid salts, based upon the action of arsenic acid, in the presence of sulphuric acid, according to the equation—

the iodine being completely volatilised, but leaving behind in the arsenious acid produced by the action the record of the amount of hydriodic acid originally present. This reaction we propose to utilise conversely, and to employ potassium iodide in excess, in presence of sulphuric acid, to bring about the reduction of the arsenic acid to arsenious acid, which may be determined, after neutralisation, by the iodine method. The conditions of the method are different than, in the former the hydriodic acid is entirely broken up by the action of the arsenic acid, and the iodine volatilises easily; while in the latter some hydriodic acid must remain in solution until a very low degree of concentration is reached, and remaining must exhibit its characteristic proneness to retain free iodine.

We find in practice that when a solution made up to contain sulphuric acid, an arseniate, and potassium iodide to an amount somewhat in excess of that theoretically demanded to effect the conversion of the arsenic acid to

arsenious acid, is boiled, iodine is evolved and the colour of the liquid passes from the dark red when the iodine is abundant through the various gradations of tint to a canary yellow, and then, as the sulphuric acid reaches a degree of concentration sufficient to determine by its own specific action the liberation of iodine, the colour again darkens, and if the process of concentration is continued, and much arsenic is present, crystals of arsenious iodide separate and form more abundantly on cooling. If evaporation is pushed still further the arsenious iodide begins to volatilise, and at the point where the sulphuric acid fumes the liquid loses all colour and the arsenic has vanished more or less completely. In one experiment conducted in this manner it was found, by the method to be described later, that of 0.3861 grm. of arsenic pentoxide originally present with 1 grm. of potassium iodide and 10 c.m.³ of sulphuric acid [1:1] the equivalent of 0.1524 grm. remained. In another similar experiment, in which, however, only a few m-grms. of arsenic oxide were involved, not a trace of arsenic remained at the end.

It is obvious that two points in this course of action demand examination at the outset. First, means must be found for removing the remnant of free iodine which is withheld by the hydriodic acid; or of rendering it harmless in the titration process to follow; and, secondly, the degree to which the solution may be concentrated without loss of arsenic must be fixed. In our work upon the converse of this process, we noted particularly the marked influence of the amount of sulphuric acid present upon the degree of concentration necessary to expel the iodine. We turned attention, therefore, at once to this point in the present case and investigated the effect of varying the proportion of sulphuric acid in solutions containing definite amounts of potassium iodide and potassium arseniate. The volume of the solution was made up to about 100 c.m.³ and concentrated by boiling until the colour was faintest. Then, to determine provisionally, and for preliminary purposes, the point at which volatilisation of arsenic was likely to occur, the concentration was continued until the arsenious iodide began to separate. The results are tabulated as follows:—

KI.	As ₂ O ₃ .	H ₂ SO ₄ [1:1].	Volume when colour was lightest.	Volume when AsI ₃ appeared.
Grm.	Grm.	C.m. ³ .	C.m. ³ .	C.m. ³ .
1	0.1900	20	80	33
1	0.1900	15	65	25
1	0.1900	10	40	19
1	0.1900	5	30	11

The amount of sulphuric acid which, considering rapidly in concentrating to the proper point, ease in neutralising the acid previous to titration, and general convenience in manipulation, seemed to be best was 10 c.m.³ of the mixture made by diluting the acid with an equal volume of water. This we fixed upon for use in future experiments, and set the limit of concentration at 40 c.m.³.

It is manifest from the phenomena described that when much hydriodic acid remains in the solution the last portions of free iodine cannot be completely removed by heat without volatilisation of the arsenic. We experimented, therefore, upon the effect of very dilute sulphurous acid upon the remnant of iodine in liquids constituted as described and concentrated to 40 c.m.³, the point of minimum colour, the solution of sulphurous acid which we employed corresponding approximately to centinormal iodine. We found that upon adding the sulphurous acid drop by drop to the hot concentrated solution the point at which the colour vanished could be determined without difficulty, but that if the solution was permitted to stand a single minute the colour of iodine returned, doubtless developed by the action of air upon the hot hydriodic acid. We adopted, therefore, the plan of at once diluting the solution with cold water as soon as the sulphurous acid had done its work and immediately neu-

§ *American Journal of Science*, vol. xxxix., p. 188.

tralisating with potassium carbonate. When this mode of proceeding was followed we were unable to find evidence of reversion of arsenious acid to arsenic acid, magnesia mixture producing in the solution no precipitate of the ammonium magnesium arseniate.

Following out the same general lines, therefore, we proceeded to the quantitative examination of the process. Portions of a standard solution of the dihydrogen potassium arseniate were measured from a burette into counterpoised Erlenmeyer flasks of 250 c.m.³ capacity, and the increase in weight was taken as the measure of the actual amount of the solution employed. Potassium iodide in solution, and 10 c.m.³ of sulphuric acid [1:1] were added, and the liquid was diluted with water to a volume of about 100 c.m.³. A trap made as described in this paper upon the reverse of this process, by cutting down a two-bulbed drying tube, was hung in the neck of the flask to prevent mechanical loss, and the liquid was rapidly concentrated by boiling until the volume of 40 c.m.³, the point at which the colour of iodine had faded to a pale yellow, was reached. At this point the flask was removed from the flame, its sides and the trap were quickly washed down, the weak sulphurous acid was added drop by drop from a burette until the colour of the free iodine had just vanished, the liquid was immediately diluted with cold water, the free acid was nearly neutralised with potassium carbonate, and the point of neutralisation was reached and passed a little by the addition of the acid potassium carbonate. After cooling completely a definite amount of starch solution was added and the titration of the arsenious acid was proceeded with as usual, due correction being made for the amount of iodine necessary to produce the end colour into the volume of liquid and starch solution employed.

The value of the standard solution of the arseniate was fixed by two series of determinations. One series was made according to Levot's method of precipitating the ammonium magnesium arseniate and weighing as the pyroarsenate, modified, however, in that the precipitate was collected on asbestos in a perforated crucible and ignited after moistening with ammonium nitrate. In the second series McCay's modification* of Reich's method was followed, excepting that the silver arseniate was collected, dried, and weighed on asbestos in a perforated crucible. The mean of several closely agreeing determinations gave for the contents of 50 grms. of the solution in arsenic pentoxide as 0.3824 grm. by Levot's method and 0.3830 grm. by McCay's modification of Reich's process. We took the mean of these figures 0.3827 grm. as the standard of the solution.

The details of the experiments with this solution are recorded in the following table:—

KI taken. Grm.	H ₂ SO ₄ [1:1] taken. C.m. ³ .	As ₂ O ₃ taken. Grm.	As ₂ O ₃ found. Grm.	Error. Grm.
1.5	10	0.3861	0.3862	0.0001+
1.5	10	0.3862	0.3856	0.0006-
1.5	10	0.3861	0.3862	0.0001+
1.5	10	0.3860	0.3862	0.0002+
1.5	10	0.3863	0.3862	0.0001-
1.5	10	0.3862	0.3862	0.0000
1	10	0.1927	0.1922	0.0005-
1	10	0.1928	0.1922	0.0006-
1	10	0.1930	0.1925	0.0005-
1	10	0.1930	0.1927	0.0003-
1	10	0.1936	0.1929	0.0007-
1	10	0.1929	0.1928	0.0001-

Experiments in which smaller quantities of arsenic were handled were made similarly, excepting that the standard solution from which portions for the tests were measured was made by diluting the former standard ten times, and centinormal iodine was used in the titration.

KI taken. Grm.	H ₂ SO ₄ [1:1] taken. C.m. ³ .	As ₂ O ₃ taken. Grm.	As ₂ O ₃ found. Grm.	Error. Grm.
1	10	0.0383	0.0380	0.0003-
1	10	0.0383	0.0385	0.0002+
0.5	10	0.0383	0.0384	0.0001+
0.4	10	0.0383	0.0385	0.0002+
0.3	10	0.0383	0.0386	0.0003+
0.2	10	0.0383	0.0384	0.0001+
0.2	10	0.0076	0.0074	0.0002-
0.2	10	0.0076	0.0074	0.0002-
0.2	10	0.0038	0.0034	0.0004-
0.2	10	0.0038	0.0034	0.0004-

When the amount of hydriodic acid in solution is small, correspondingly small amounts of iodine are retained after concentration. In the following experiments colourless solutions were obtained, and, for the sake of comparison with the previous results, these solutions were neutralised and titrated without treatment with sulphurous acid, there being no apparent need for adding it in these cases.

KI taken. Grm.	H ₂ SO ₄ [1:1] taken. C.m. ³ .	As ₂ O ₃ taken. Grm.	As ₂ O ₃ found. Grm.	Error. Grm.
0.2	10	0.0038	0.0035	0.0003-
0.2	10	0.0038	0.0035	0.0003-

It appears, therefore, that the average error of the whole number of determinations (twenty-four) made by this process amounts to rather less than 0.0002 grm. —, falling between extremes of 0.0003 grm. + and 0.0007 grm. —. The entire amount of arsenic pentoxide handled in the twenty-four determinations was 3.7352 grms., and of this 3.7309 grms. were indicated in the titration as reduced to the arsenious condition. The loss 0.0047 grm. — the entire error of the process—amounts to 0.13 per cent of the amount taken.

Certain experiments were made to see whether the period of evaporation might not be dispensed with by so modifying the process that the entire amount of iodine set free in the action of the sulphuric acid, the arseniate, and the iodide might be re-converted at once by sulphurous acid to the condition of hydriodic acid. The conversion was apparently successful, but the results of the modification were several per cent below the truth, indicating that the digestion during evaporation, or the removal of the free iodine, or the combined effect of the two, is essential to the completion of the reduction of the arsenic.

The process as we recommend it may be summarised briefly as follows:—To the arseniate in solution are to be added potassium iodide in excess of the amount needed according to the equation to complete the reduction, and 10 c.m.³ of half and half sulphuric acid. The liquid is to be diluted to about 100 c.m.³ and boiled rapidly (with the precaution of trapping as described) until the volume is decreased to 40 c.m.³. The colour of free iodine is to be bleached by cautious additions of sulphurous acid (corresponding roughly to centinormal iodine) and instantly diluted with water and neutralised with potassium carbonate, the neutral carbonate at the first and afterward the acid carbonate. The whole is to be cooled and titrated as usual with iodine, using starch as an indicator. Its advantage is in the rapidity with which it may be executed, the whole operation being easily completed in a half-hour.

On Mannite Hexachlorhydrine.—Louis Mourgues.—The hexachlorhydrine of mannite, C₆H₃Cl₆, melts at 137.5°, boils at 180—185° under a pressure of 0.03 metre, and has the sp. gr. 2.060. It has a rotatory power at 20° of [α]_D = +18.32°. It is insoluble in water, very soluble in ether, benzene, chloroform, ligroine, &c., sparingly soluble in alcohol. Boiling concentrated alkalis do not attack it. It is dissolved by hot sulphuric acid, but reprecipitated on cooling.—*Comptes Rendus*, cxii., No.2.

THE DRY ASSAY OF TIN ORES.*

PART I.

By HEINRICH O. HOFFMANN,
Assistant Professor of Mining and Metallurgy.

THE tin deposits of the Black Hills, discovered some ten years since, are beginning to attract very general attention, and the question how to treat the ores to the best advantage has become a pressing one. No systematic investigation of this subject has been made until quite recently, when it was taken up by the Dakota School of Mines, and the ores tested as to their tenour and proper mode of treatment. In the assay laboratory numerous determinations were made of the percentage of black tin in the ore bodies, and of the metallic tin contained in it. The occurrence of tin in the Black Hills being different from that in other parts of the world, the usual mode of procedure had to be somewhat modified.

The object of this paper is to give the results of the writer's effort to discover the best method of assaying the tin ores in the dry way. His task divided itself under three heads, in the following order:—

1. To test the different methods of assaying purified black tin in the dry way.
2. To study the influence upon the assay of the different minerals associated with the black tin.
3. To find by what simple and rapid means the cassiterite could most effectually be freed from its gangue.

The apparatus used was that to be found in any ordinary assay laboratory (the pulp-balance being sensitive to 1 m.grm.), as it was the aim to furnish quick and reliable methods with simple appliances. That dry assays of black tin have not the same degree of accuracy as wet assays is well known, but they suffice for the determinations necessary in metallurgical work. If great exactness is required, recourse must be had to one of the two wet methods,—that of Rose (fusing with sulphur and sodium carbonate, and converting the insoluble stannic oxide into soluble stannic sulphide), or that of Rivot (reducing the stannic oxide in a current of hydrogen to metallic tin, which is then readily soluble).

The cassiterite occurring in the Black Hills tin ores is quite pure, as is shown by the following analyses† of lode tin and stream tin:—

Lode tin:—

Occidental Mine	96.42	SnO ₂ .
Tin Mountain	97.50	"
First Find	94.70	"

Stream tin:—

Nigger Hill	92.60	"
Nigger Hill	93.00	"
Southern Hills	92.80	"

Stannite has lately been found in one locality. The cassiterite has an adamantine lustre, and its colour varies from brown to black, the light varieties being rare. The minerals associated with the cassiterite that are of interest to the assayer are iron pyrites, arseno-pyrites, in a very few instances galena and blende, quartz, feldspar, mica, tourmaline, garnet, and columbite (tantalite). The sulphides occur rarely, and then always in small quantities; quartz and silicates form the gangue; columbite (tantalite), although sometimes found in the same veins, can always be separated by hand-sorting. When it has accumulated in the stream tin deposits, which occasionally happens, it remains with the purified black tin. Bismuth, copper, and tungsten, which occur frequently in the deposits of other countries, are found very sparingly.

* Read at the Colorado Meeting of the American Institute of Mining Engineers, June, 1889. From the *Technology Quarterly*, Vol. iii., No. 2.

† *Transactions of the American Institute of Mining Engineers*, xvii., pp. 595, 596.

I. The Assay in General.

Tin that is to be assayed in the dry way must be present in the form of oxide. The assay proper consists of applying in a crucible at a high temperature reducing and fluxing reagents, which bring the stannic oxide to the metallic state and convert the gangue into a liquid slag. The behaviour of stannic oxide and of metallic tin at an elevated temperature causes, however, certain difficulties, which make the results often less accurate than could be desired. These difficulties are:—

First. That some of the resulting metallic tin is liable to be volatilised.

Second. That metallic tin decomposes the alkali carbonates used as fluxes, forming stannates, which enter the slag.

Third. That at the temperature required to reduce the stannic oxide, other metallic oxides become also reduced to the metallic state and alloy with the resulting tin button, and vitiate the assay.

Fourth. That sulphates are reduced, or, if sulphides are present, they combine directly with the metallic tin and carry it into the slag.

Fifth. That the gangue in the ore is always siliceous. This causes loss, as the stannic oxide, while passing through the intermediate state of stannous oxide, combines with silica and silicates.

Sixth. That stannic oxide is liable, before its reduction has begun, to combine with the basic fluxes used in assaying and form stannates. This liability increases as the quantity of the flux is increased.

Thus it will be seen that the results can be too high (as when iron enters the tin button) or too low (as when tin is carried off in the slag as stannate, sulphide, or silicate), and that all impurities should be removed, if possible, before the actual dry assay takes place. The making up of the charge must also be regulated to counteract as much as possible the bad influences of the basic fluxes.

The crucibles used in assaying tin ores are the ordinary clay crucibles, the plumbago crucible, and the porcelain crucible. The naked clay crucible has the disadvantage that the basic fluxes attack the clay and form silicates, which are liable to slag some of the tin. From the results obtained by the writer it would seem that the material of the Battersea crucibles used by him must have been much better than that of the crucibles referred to by Berthier,* as no appreciable loss resulted from their use. P. Ricketts† recommends the lining of the crucible with chalk. This is probably to avoid the action of the basic fluxes on the acid material of the crucible, as the calcium oxide, being a strong base, protects the clay of the crucible from the corrosive action of the alkali, and thus hinders the formation of an alkali silicate. An outline of his method having been obtained from Dr. Ricketts, the lining was made from the so-called "prepared chalk" of the druggist in the following manner:—The prepared chalk was mixed with water in an enamelled iron dish to the consistency of cream. It was then allowed to stand, that the coarse gritty particles might settle and collect at the bottom. The chalk emulsion, now freed from impurities, was poured off and was ready for use. To line the crucible, it was half filled with the chalk mixture, the upper half being coated by giving the crucible a rotary motion, after which the excess of the liquid was poured off. The crucible was then placed bottom up for five minutes to drain, after which it stood for two hours to dry, and was then ready for use. The coating obtained was thin, uniform, and smooth. If the crucible be filled entirely with the mixture, and this be allowed to remain a little while before being poured off, the coating will be less uniform on the sides, part of the naked crucible will be exposed, and the lining at the bottom, being too thick,

* "Traité des Essais par la Voie Sèche," Liege, 1847, vol. ii., p. 485.

† "Notes on Assaying," 8th Ed., New York, 1886, pp. 88, 89.

will crack when it dries. If a greater thickness is wanted than can be obtained by one coat, it can only be properly put on, a layer at a time, as above, until the desired thickness is reached. The effect of the lining was disappointing; it did not, as will appear later, prove useful, but rather the reverse.

Another highly recommended lining is one of charcoal. The fluxes do not act chemically upon it, and its reducing power makes it unnecessary to add any charcoal to the assay; a reducing atmosphere is kept up during the entire operation. Berthier* states that he obtained 4 per cent more tin in a brasqued crucible than in a naked one, although even then he recovered 2 per cent less tin than was present.

The following method of brasquing, which differs somewhat from any of those described and recommended in the books, proved the most satisfactory. Pine charcoal is pulverised and screened through a 40-mesh sieve; the fine powder is then mixed with molasses and water in a suitable flat dish, and kneaded with the fingers until a homogeneous mass is obtained, which, when squeezed in the hand, coheres into a lump, and has not sufficient moisture to adhere to the hand.

Different proportions of molasses—the ordinary New Orleans molasses being used—and water were tried. Molasses alone with charcoal gave a sticky shiny mass, which cracked on the sides and the bottom of the crucible as it dried; two parts by volume of molasses and one of water behaved better, only the bottom cracking; three parts of molasses and one of water gave the desired mixture.

The crucible is moistened by dipping into water and quickly removing it. It is then partly filled with the charcoal paste, and this is pressed with the fingers against the sides and the bottom, a slight excess of material being used. Then a conical wooden plug, which has been dipped in water, is forced by hand into the charcoal paste and turned round and round, the excess escaping over the edge of the crucible. A few light taps with a mallet help to make the lining more compact. The wooden plug has a mark, and when this reaches the upper rim of the crucible the plug is withdrawn with the same rotary motion with which it was forced in. It has the form of a long cone, the point being slightly flattened. Its size is such that when forced into the crucible down to the mark, the lining at the bottom will be $\frac{1}{8}$ inch thick. This thickness decreases until near the upper edge of the crucible, where it is only $\frac{1}{16}$ inch. It is then rounded off until even with the inner edge of the crucible, and the sides are polished with a strong test-tube to prevent any particles of tin from adhering, and to obstruct the filtering of fluxes through it. In drying, it is best to place the crucible upside down; otherwise the lining is liable to separate from the wall, especially if it dries too rapidly. When a little skill has been acquired it takes four-and-a-half hours, including the preparation of the mixture, to line fifty Battersea crucibles, half of size F and half of size C.

It will be seen that this lining is quickly made; it dries quickly without cracking, and is hard when dry. After being in the fire, it is rapidly removed from the crucible, which can be used again, and is so compact and hard that it is difficult to break the thin upper edge with the fingers, while the thick lower part has to be broken with the hammer.

In summing up the subject of brasqued crucibles, it may be said that, although charcoal linings are perfect from a chemical point of view, their use has practical objections because of the separating of fine tin from fine slag in the pan. The results to be described will show that crucible linings are, in fact, unnecessary.

The plumbago crucible stands between the naked and the brasqued crucibles, for while the action of the fluxes on the clay is weakened by the plumbago, the neutral character of the latter is slightly modified by the clay

that binds it together. Plumbago crucibles are frequently used in the Cornish assay, but we shall see that this method is unreliable, and, as the plumbago crucible is expensive, more need not be said about it.

Finally, the porcelain crucible used by Levol has the same disadvantages as the naked clay crucible, although in a less marked degree.

II. Preparation of the Ore for the Experiments.

The more representative lode tin not being available in sufficient quantities to be made the basis of the following experiments, stream tin from the Nigger Hill district had to be resorted to. The cassiterite of the Bismarck district would have been the most desirable of all, as it is the purest. It is found in quartz, and has comparatively no deleterious minerals occurring with it. This makes the separation of the black tin from the gangue simple and perfect. The other lode tins, as well as all the stream tins of the Black Hills, have a number of minerals occurring with them which are difficult of removal; for instance, garnets.

The first pulverising of the ore was performed with the distance of $\frac{1}{4}$ inch between the faces of the sample-grinder. The crushed ore was then screened through a 40-mesh sieve. At the second grinding the faces of the machine were brought somewhat nearer together, and the sifting afterwards repeated. The operation was continued until the ore had all become fine enough to pass through the sieve, with the exception of some mica, which was thrown out. This gradual method was used in order to prevent the cassiterite from becoming too fine, as a large amount might thus have been lost in the washing of the ore. The pulp obtained was then roasted in a muffle to decompose any sulphides and arsenides that might be present. After roasting, and while still hot, it was thrown into cold water, to make silicates, not otherwise attacked by acids, decomposable. It was also hoped that the cassiterite might thus be made more readily reducible, an expectation which the event fulfilled. The ore was now boiled with nitro-hydrochloric acid, to remove all soluble metallic compounds; this was continued until no more iron was perceived to go into solution. The ore was then washed with hot water and transferred to the gold pan, where the panning was carried on irrespective of the loss of some fine tin which floated off with the tailings, giving them a chocolate-brown colour. As the main object was to obtain a pure black tin, the loss was unavoidable. The panning was continued until no more impurities were visible to the naked eye; under the microscope, however, particles of garnet with a little quartz were still visible. The black tin obtained was dried and intimately mixed by passing it repeatedly through a 20-mesh screen and rolling it on glazed paper. The now uniform ore was sampled down, and the final average sample pulverised in an agate mortar and put aside for chemical analysis. The weight of the purified black tin obtained, which was to form the basis of the experiments, was 7.968 grms. To find the size of the different particles, 500 grms. were taken and screened through different-sized sieves. The result of the mechanical analysis is given in Table I.

TABLE I.

Passed through sieve No.	Remained on sieve No.	Grms.	Per cent
40	60	90	18
60	80	80	16
80	100	65	13
100	—	265	53
—	—	500	100

The very brittle character of the cassiterite will be seen from this table, as 53 per cent of the entire ore passed through a sieve of 100 meshes to the linear inch, although as has been said, the greatest care was taken to grind in such a manner as to produce as small an amount of slimes as possible.

* "Traité des Essais," 1847, vol. II., p. 435.

III. Analysis of the Purified Black Tin.

In making the analysis of the average sample of the purified black tin, the Rose method was followed, as modified by Chauvenet, who substitutes potassium carbonate for the potassium carbonate commonly used. Two separate determinations were made, taking 0.5 grm. in each case with three grms. of a mixture consisting of equal parts of potassium carbonate and sulphur, and fusing in a No. 1 Royal Berlin porcelain crucible. The first sample was heated three quarters of an hour over a Berzelius alcohol lamp, and then for the same length of time over a gasolene lamp, after which the fused mass was treated with water in a beaker. Brown, gritty cassiterite now became visible at the bottom, showing that the decomposition was incomplete. The soluble potassium sulphostannate was then filtered off, and the filtrate acidulated with sulphuric acid and put aside; the residue on the filter was treated with hot dilute nitric acid, and the iron, manganese, and lime solution also kept. The residue was again fused with potassium carbonate and sulphur, but in a different way. The No. 1 porcelain crucible was placed within a No. 3 porcelain crucible, and this within a No. 6 plumbago crucible, the bottom of which had been filled with refractory material, that the porcelain crucible might be nearly as high as the plumbago crucible. The three crucibles were then each covered with a lid, and the fusion performed in a pot-furnace, heated with anthracite coal at a moderate red heat. This lasted one hour. The fused mass was then treated as before, and the resulting decomposition found to be perfect. The fusion for the second analysis was made directly in the three crucibles, and was complete in one operation. To make sure of this, the fusion was repeated, and, on acidulating the aqueous solution with sulphuric acid, the precipitate was found to have the milky white colour of sulphur.

The reason that the first fusion over the gasolene lamp was not successful, although prolonged until the fused mass became dry, must be sought in the fact that the air was imperfectly excluded. By fusing in a crucible which is enclosed in others, this exclusion can be entirely accomplished; in fact, upon removing the outer lid when the crucible had been taken from the fire, but had not yet cooled, a strong odour of sulphurous acid was perceived, showing that not only had the air been excluded, but that the fusion had taken place in an atmosphere of sulphur.*

The analyses were both made by the usual methods for separating iron, manganese, and lime, and the results corresponded so closely that they can be expressed by a common average:—

SnO ₂	86.24 = 67.84 Sn.
Fe ₂ O ₃	2.62
Mn ₂ O ₃	0.50
CaO	0.66
MgO	trace
Insoluble	9.39
99.41	

If this be compared with the analysis of the purest crystal of Nigger Hill Stream tin† that could be found,—

SnO ₂	93.06
Fe ₂ O ₃	3.08
Insoluble	3.90

100.04

it will be seen that the cleaning of the stream tin, as described above, was very successful, the ore sample showing only 2.4 times as much insoluble residue as the crystal.

(To be continued).

NOTICES OF BOOKS.

The Foundations of Chemistry (Grundlagen der Chemie).

By D. MENDELEEFF, Professor at the University of St. Petersburg. Translated from the Russian by L. JAWEIN and A. THILLOT. St. Petersburg: Carl Ricker.

FOR a work on the principles of chemistry to be worthy of the attention of any save the merest tyro is a rare event. No less rare is it for such a work to add anything to the reputation of its author, especially if he has already acquired a high and widely recognised standing. Yet such an exception is presented by the work before us. Not merely pupils but *savants* who have already "won their spurs" in the fields of research may read the work before us with pleasure and profit. Rarely has it been our good fortune to meet with an exposition at once so profound and so luminous, of the scope and methods of scientific research, of the ideas of matter, element, phenomenon, and reaction. We may here remark that the English language has lost by misuse a word which would have been very useful in discussing the philosophy of chemistry. Our "stuff" is the exact rendering of the German "stoff." Yet whilst "stoff" means "kind of matter," as distinguished from body or portion of matter, the English "stuff" has got to mean (a) a kind of textile fabric, (b) something of little value, and (c) rarely a kind of matter, simple or compound, as in "dye-stuff." We cannot avoid noticing with satisfaction that whilst 'οι πολλοι of scientific authors speak of all phenomena as being ultimately reducible to motion, Prof. Mendeleeff writes that we endeavour to conceive of phenomena as motion—an important distinction.

The author does not entertain the view that our present elements have been developed from any simpler state of matter or that they are capable of mutual transition. He writes:—It has been established by spectral analysis that the simple bodies exist in the most remote stars, and that they bear the highest temperatures which can be reached without decomposition.

The facts elicited by the spectroscopic examination of the stars seem to us to admit of a different interpretation. In proportion as the stars are more brilliant and in appearance hotter, the smaller is the number of elements recognised in their spectra, whilst those which are less luminous and presumably cooler display richer and more complicated spectra. Hence it seems not unreasonable to conclude that the latter class contain other and more numerous elements than the former—elements which can exist only at lower temperatures.

Prof. Mendeleeff considers that the next great task of science is to constitute molecular or chemical mechanics. The general laws of mechanics recognised by Newton will probably, he thinks, form the initial point for molecular mechanics. Passing from these generalities the author proceeds to the specialities of chemistry, treating of water and its compounds, of its composition, and of hydrogen.

The work is to be completed in eight parts, and will apparently extend to about 1000 pp.

Principles of General Organic Chemistry. By Prof. E. HJELT. Translated from the Author's German Edition of the Original Work by J. BISHOP TIMOLZ, Ph.D., F.C.S. London: Longmans, Green, and Co.

It is refreshing to find a general work on chemistry which has a definite purpose, and which does not compel us to raise unpleasant questions as to its possible *raison d'être*. We have, as the author remarks, systematic text-books, large and small. But as a matter of necessity they are largely filled up with the description of individual compounds, especially if new; their preparation, composition, and properties, with less regard to the

* This use of the three crucibles was suggested by Dr. W. F. Henden, Professor of Chemistry at the Dakota School of Mines.
† "Report of the Dakota School of Mines," 1888, p. 142.

meaning and the mutual bearing of all these facts. Hence the student, like the traditional Swabian knight-errant, cannot see the forest for trees. The aim of Prof. Hjelt has been to present concisely and clearly "the main points of general and theoretical organic chemistry."

We are, further, glad to note that the translator has not thought it necessary to adapt this book to the supposed needs of the British student by inserting a string of examination questions or by re-arranging the work in accordance with some "syllabus."

The author, in defining organic chemistry, makes a clear distinction between *organic* compounds, capable of synthetic reproduction, and being in general the by-products or the *rejectamenta* of life, and *organised* bodies, "the special material conductors of the vital functions," which hitherto have not been obtained artificially. The study of such bodies should, he thinks, be more correctly known as "organic chemistry." There are, of course, a number of questions which the author does not raise, but which the "chemistry of the future" will some day have to take in hand. We do not yet know why carbon lends itself so much more readily than the other elements to the formation of complicated and multifarious products, silicon making the nearest approach. The reason commonly given merely pushes the difficulty a step further away, but leaves it still unsolved. It may not be irrelevant to remark that the author, like Prof. Mendeleeff, is of opinion that petroleum is not a product of the decomposition of organic remains, but has been generated by the action of water upon ignited iron carbides in the interior of the earth, and may still be continuously produced.

The chapter on relations between colour and constitution will be found exceedingly instructive for the student.

In these days, when so much reading is demanded, great caution becomes necessary in recommending any work. But Prof. Hjelt's treatise may be advantageously taken up by any student as an explanatory accompaniment to any systematic text-book.

Law of Trade-Marks and their Registration, and Matters connected therewith, including a Chapter on Goodwill; together with the Patents, Designs, and Trade-Marks Acts 1887-88 and the Trade-Marks Rules and Instructions thereunder; Forms and Precedents, The Merchandise Marks Act, 1887, and other Statutory Enactments; the United States Statutes 1870-81 and the Rules and Forms thereunder; and the Treaty with the United States, 1877. By LEWIS BOYD SEBASTIAN, B.C.L., M.A., of Lincoln's Inn. Third Edition. London: Stevens and Sons, Limited.

This work is a useful companion-volume to Edmunds on "Patents." The subject-matter in this case, however, is one of much less interest. A patent may, and often does, involve questions which require to be decided by the chemist, the physicist, or the mechanic as the case may be. In disputes on trade-marks nothing of this kind can arise.

A valuable feature of the work before us is that it makes clear the distinction between patent, trade-mark, and copyright, which are often confounded. As we here learn, in the case of a trade-mark "the article sold is open to the world to manufacture, and the only right the plaintiff seeks is that of being able to say:—"Don't sell any goods under my mark." The property and right to protection is in the device or symbol which is invented and adopted to designate the goods to be sold, and not in the article which is manufactured or sold." A patent, while it lasts, will protect a process, whilst a trade-mark obviously cannot. We are told that the courts will discourage any attempt to prolong the term of a patent by means of a trade-mark. The insertion or retention in a trade-mark of the words "patent" or "patented," so as to indicate the protection of an existing patent, may invalidate a trade-mark.

On the other hand, "a copyright, like a patent, relates to the substance of an article, but differs in that it has reference to a literary instead of a material production." The registration of trade-marks under the Copyright Acts is shown to be useless. Still, certain quacks, "if they will permit us to call them so," have the labels for their bottles, pills, and other alleged curative appliances registered under the Copyright Acts.

On Cremation. A Discourse delivered February 13, 1890, before the Natural Science Association of Mulhouse. With an Appendix and Five Illustrations. By Prof. Dr. FRIED. GOPPELSRÖDER. Mulhouse: Wenz and Peters.

THAT Prof. Goppelsröder, as a chemist, must be a champion and advocate of cremation as *the* method for disposing of the bodies of the dead is almost a matter of course. He combats most ably the objections which have been urged against this pure and safe mode of dealing with masses of putrescent and often moribund matter. He enumerates several more or less plausible arguments which have been advanced by the adherents of interment. Foremost comes the religious scruple, which, though it has been successfully refuted by Lord Shaftesbury and Bishop Fraser, still dominates too many minds. The expression "Christian burial" still carries with it much weight, especially in a country like Britain, where we are governed by phrases and catch-words. In reality, the idea that a person can, by the incineration of his remains, forfeit all hopes of a future existence is purely materialistic.

The æsthetic side of the question is still more easily dealt with. For a couple of days after death the state of the corpse may be likened to sleep. But could the poets and novelists who dwell on this similitude ever watch the actual process of putrefaction to its end they would be simply sickened. In reality the ultimate results of incineration and of putrefaction are the same. But fire does its work rapidly and without the formation of intermediate products, always disgusting and frequently dangerous.

The third objection—the loss of manurial matter—is of little weight. Under our present system great care is taken that the remains of the dead, even a century after their deaths and after their identity has been lost sight of, shall not be again permitted to enter into the great circulation of Nature. We have heard of a contractor who was conducting alterations in a churchyard closed by authority being prosecuted for having sold to market-gardeners some loads of a soil formed in part of decayed human remains. Prof. Goppelsröder very rightly suggests that if the ash of cremated corpses is not preserved in urns it had better be given back to the soil.

The fourth objection is raised by criminal lawyers, who fear that murders may remain undiscovered if the bodies are destroyed by fire. It is certainly true that poisons have been detected in exhumed bodies, but our author shows that the longer a corpse has remained in the grave the more doubtful becomes the evidence to be obtained by a toxicological examination. What is wanted is a systematic autopsy in all cases. Such an examination would not be, on the average, more expensive or circumstantial than the perfunctory scrutiny of a coroner's jury.

The author scarcely lays sufficient weight on the pollution of soil, waters, and air, by the existence of cemeteries. The charges which Dr. Walker—"Churchyard Walker," as he was named by parochial anti-sanitarians—brought against the old City churchyards now hold good in a gradually increasing degree against our suburban cemeteries. We have visited some of these establishments in calm mild weather, and have detected odours whose nature was beyond question and beyond rational tolerance. Details we cannot give; the libels are not merely the shield but the sword of the quack and of the perpetrator of nuisances.

Prof. Goppelsroeder might have noticed a semi-reform in the disposal of the dead. We refer to the so-called "earth to earth" system of interment, which differs from that in common use merely in the circumstance that the corpse is placed, not in a firm wooden coffin, but in a slight structure of wicker-work. That this arrangement may quicken decay we admit, but that it can alter the nature of putrefaction and render it free from nuisance and danger we must deny. Hundreds and thousands of men and horses have been buried on battlefields without any coffins at all. The same has been frequently done in visitations of pestilence, but in neither case has there been any absence of offence or any impunity from danger. Most decisive is an observation made by M. Pasteur, with a quite different end in view. Some cattle attacked by splenic fever had been shot and buried three or four yards deep in the soil. Some sheep, penned afterwards over the spot, caught the very same disease. The *materies morbi*—whether it be considered as organised or unorganised—had not been destroyed by burial in immediate contact with the soil, but had been conveyed up to the surface by the earth-worms. When once there the flies would effect its distribution and even its inoculation into man and beast. In case of visitations of the plague cremation is, as we here learn, legally compulsory in Russia. A similar law, we believe, is in force in Brazil in epidemics of yellow fever.

We cannot conclude this short notice of a valuable little work without acknowledging the service rendered by Herr Fr. Siemens to the cause of cremation by the application of his regenerative furnace.

The Colour Reactions of the Carbon Compounds. For Chemical, Physiological, Micro-chemical, Botanical, Medical, and Pharmaceutical Investigations. Compiled by Dr. EMIL NICKEL. Second Edition, Revised and Enlarged. Berlin: W. H. Peters.

THE author tells us in his preface that the investigations here made public have sprung from a study of the chemistry of lignification. It appeared to him desirable to submit the entire sphere of the coloured reactions of the hydrocarbons to a thorough revision, and to test the customary reagents as to their trustworthiness. By so doing he has conferred a great boon, not merely on students of certain departments of chemistry, but upon biologists and microscopists. He first takes up the coloured reactions with an aromatic character, those obtained with the co-operation of nitrous acid and its derivatives (exclusive of the production of the azo-colours). Here he particularly discusses the colour-reactions with the reagents of Millon, Hoffmann, Plügge, and Liebermann and certain new reactions with new reagents. The above reactions he proposes to classify as the nitroso-reactions. Then follow the reactions with nitric acid, that with xantho-proteic acid, Scherer's inosite test, and Serdel's reaction. Next we have the colour-reactions, comprising the formation of the azo-colours, such as Weselsky's reaction and its extensions, and Ehrlich's reactions with paradiabenzol sulpho acid.

Chapter IV. treats of the colour reactions which depend on the formation of triphenylmethane dyes and analogous compounds.

Next we come to coloured reactions in which ferric salts and chromates are concerned. Here the caution is given that these reactions are not necessarily specific, and that they, consequently do not at once prove the presence of tannin or its modifications.

In the second part the author considers colour-reactions in which nuclei are not concerned and those with an unknown character. Here belong the colour reactions with which the cyanogen group is involved, those in which murexide and its analogues are formed, and those in which inorganic colouring matters are produced. Instances of this class are given by the reagents of Nessler and Froehde.

This little treatise will be the means of preventing many confused or contradictory results, or, we might venture to say, much bad work.

Catalogue of Minerals For Sale by G. L. English & Co. Chestnut Street, Philadelphia, and Broadway, New York. Fifteenth Edition.

THE demand for mineralogical specimens, whether for the cabinet or as subjects for chemical, &c., examination is now sufficiently extensive to make it worth the while of a respectable firm to take up this subject as a speciality.

Messrs. English & Co. offer a very extensive collection of minerals from all parts of the world, and especially American rarities, some of them exceedingly interesting.

Among the illustrations the figure of Almandite garnets embedded in mica-schist may be mentioned as especially beautiful.

CORRESPONDENCE.

OZONE PHOSPHORESCENCE.

To the Editor of the Chemical News.

SIR,—I have been especially interested by Mr. Ernst Fabrig's paper on this subject in your last issue, for in January of this year I had an opportunity of witnessing the experiment, and I can bear testimony to the fact of the production of a distinct glow or phosphorescence on the addition of distilled water, previously shaken with strongly ozonised oxygen, to about a litre of Thames water obtained by myself from near Blackfriars Pier. The experiment was performed in a quite dark room, under the close observation of fourteen or fifteen persons standing around, all of whom, I believe, saw the phosphorescence. The phenomenon impressed me very much, and I have felt it a misfortune that pressure of work has hitherto prevented me from making any experiments in this direction worth describing.

I may mention that a statement was made, on the occasion to which I have referred, that the phosphorescence is not produced when an ozone solution is added to sterilised distilled water, and that water of fair organic purity will only yield a very faint glow: the explanation suggested being that the phosphorescence is the result of the action of ozone upon the micro-organisms—and perhaps, also, the dead organic matter—present in impure water. I notice, however, that some of Mr. Fabrig's observations scarcely tend to confirm this opinion.—I am, &c.,

EDWY GODWIN CLAYTON, F.I.C., F.C.S.

Certain Applications of Thermo-Chemistry to the Study of the Constitution of the Organic Alkalies.—

A. Colson.—In one and the same group the molecular heat of neutralisation falls gradually from the primary to the tertiary amine, the sum of the solution-heat and of the neutralisation-heat, or total heat, remaining constant. The molecular heat of neutralisation for one and the same acid increases with the weight of the mol. in the primary amines of the fatty series. If we call *strong bases* those which exactly neutralise acids, and a small excess of which turns tincture of litmus to a blue, and *weak bases* those which do not fulfil these conditions, we remark that the non-saturated bases of the fatty series are strong bases, but their total heat and their solution-heat are strikingly rendered. If the amidogen group is directly joined to the aromatic nucleus experience shows that the base becomes feeble. Nicotin, which is bibasic, is a strong base by one of its basicities and a feeble base by the other.—*Revue Generale des Sciences Pures et Appliquees*, Vol. i., No. 12.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 2, July 15, 1890.

The Laws of Berthollet.—Albert Colson.—The bases may be subdivided into categories of the same order independently of their nature. Keeping in view the two principal groups, the one comprising bases strong enough to precipitate magnesium chloride, the other composed of feeble bases, unable to displace magnesia, we find that a dissolved salt formed by a strong base is not decomposed by a weak base, whilst a salt constituted by a weak base is decomposed by a strong base, whatever may be the solubility and the nature of the two bases if the salt which tends to be formed is soluble.

Researches on the Double Rhodium Nitrites.—E. Leidé.—The author has re-examined the reactions of the alkaline nitrites as given by Claus, Lang, and Gibbs. He finds errors and contradictions in their memoirs, and has repeated their work with especial reference to the rhodium and potassium nitrites, and the corresponding double sodium and ammonium salts, and the rhodium barium nitrite. The properties of these double salts are valuable in analysis; especially those of the double rhodium-potassium salt may be utilised for extracting rhodium in a state of purity, separating it from the other platinum metals, and determining it in its combinations. These points will be developed in a future communication.

Certain Compounds of Camphor with the Phenols and their Derivatives.—E. Léger.—The author has demonstrated that camphor produces with the phenols two combinations, which their great instability and the ease with which they are split up by heat, by solvents, and alkalis have caused to be mistaken for mere mixtures. He establishes that camphor and the phenols unite in simple proportions to form the bodies in question. These bodies when solidified by heat give crystals of which the portions formed successively have always the same composition. The introduction of the phenols into the alcoholic solutions of camphor diminish its rotatory power by nearly the half.

On Certain New Derivatives of β -Pyrazol. A Contribution to the Study of the Nitric Ethers.—M. Maquenne.—This paper is not adapted for useful abridgment.

Colouring Reagents of the Fundamental Substances of the Vegetable Membrane.—L. Mangin.—See p. 52.

Bulletin de la Société Chimique de Paris.
Series 3, Vol. iii., No. 10.

Reclamation by MM. Vincent and Delachanal on the Determination of the Acetone contained in the Methylenes.—In reply to the claim of M. Messenger based on publication in the Berlin *Berichte*, November 28, 1888, the authors show that their process was published in 1882.

Extraction of Raffinose from Treacles.—L. Lindet.—The author finds indirect proof of the existence of compounds intermediate between saccharose and raffinose.

Chloro-Derivatives of the Amylamines.—A. Berg. This paper is not adapted for useful abstraction.

FOR SALE. — THE CHEMICAL GAZETTE.

PRINCIPLES OF
GENERAL ORGANIC CHEMISTRY.

By PROFESSOR E. HJELT,
of Helsingfors.

Translated from the German by J. BISHOP TINGLE,
Ph.D., Assistant in the Laboratory of the Heriot
Watt College, Edinburgh.

In this work the fundamental theories of organic chemistry are presented in a clear and concise form, and their application is fully illustrated by examples. The relations between the constitution of compounds and their chemical and physical properties are prominently exhibited. A considerable number of general reactions are discussed and explained; in all cases these are classified according to the results; for instance, reactions involving oxidation are grouped together, and examples are given of the effects of oxidation on different classes of compounds: a lucid account is also given of the special application of particular oxidizing agents.

LONDON: LONGMANS, GREEN, AND CO.

PATENTS, DESIGNS, & TRADE MARKS ACT, 1883.

NOTICE IS HEREBY GIVEN that

ARTHUR GEORGE GREEN, of the firm of Brooke, Simpson, and Spiller, Limited, of Hackney Wick, County Middlesex, has applied for leave to amend the Specification of Letters Patent No. 15,449 of 1886, for "Improvements in the preparation of a Beta-naphthylamine Sulphonic Acid and of colouring matters therefrom."

Particulars of the proposed amendment were set forth in the Illustrated Official Journal (Patents) issued on the 23rd July, 1890.

Any person may give notice (on Form G) at the Patent Office, 25, Southampton Buildings, London, W.C., of opposition to the amendment within one month from the date of the said Journal.

(Signed)

H. READER LACK,
Comptroller-General.

THE LONDON HOSPITAL MEDICAL

COLLEGE.—The WINTER SESSION will commence on Wednesday, October 1st.

The Hospital, which is the largest general hospital in the kingdom, contains nearly 800 beds, all in constant use. There are wards for accidents, surgical and medical cases, diseases of women and children, and ophthalmic cases. Special departments for diseases of the eye, ear, throat, skin and teeth, and for cancer, tumours, diseases of the bladder, piles and fistula. Number of in-patients last year, 905; out-patients, 109,899; accidents, 11,400.

Surgical operations daily.
APPOINTMENTS.—Resident accoucheur, house physician, house surgeons, &c. Forty of these appointments are made annually. Numerous dressers, clinical clerks, post-mortem clerks, and maternity assistants are appointed every three months. All appointments are free. Holders of resident appointments are also provided free board. Two Entrance Science Scholarships, value £75 and £50, and two Buxton Scholarships, value £30 and £20, will be offered for competition at the end of September to new Students. Sixteen other Scholarships and prizes are given annually.

The London Hospital is now in direct communication with all parts of the metropolis. The Metropolitan District, and other railways have stations within a minute's walk of the Hospital and College.

For further information apply, personally or by letter, to—

MUNRO SCOTT, Wardens.

Mile End, E.

PATENTS.

MR. J. C. STEVENS will Sell by Auction at his Great Rooms, 38, King Street, Covent Garden, on Friday, August 15, the following Patents, with Specifications and Drawings:—

1. Patent for Improvement in the Manufacture of Sulphuric Acid.
2. Patent for Improvement in the Distillation of Tar in the Manufacture of Oil, Illuminating and Heating Gas.
3. Patent for Improvement in the Purification of Sewage and making Alkali and Cement therefrom.
4. Patent for Improvements in the Manufacture of Soda by the Ammonia Process.
5. Patent for Improvement in the Construction of Retorts for Destructive Distillation of Shale and other Substances for Extracting Oil.
6. Patent for Improvements in the Manufacture of Sulphate of Soda and Bleach.

Specifications and drawings on view after 2 p.m. the day prior, and morning of sale.

THE CHEMICAL NEWS.

VOL. LXII. No. 1602.

THE OCCURRENCE OF CANE SUGAR IN THE SWEET POTATO.

By W. E. STONE.

THE sweet potato is said by De Candolle to be "sugary as well as farinaceous." This "sugary" nature undoubtedly constitutes one of its most attractive qualities as an edible, although it is also to a high degree farinaceous. The analytical data which I have been able to collect are scattering and somewhat at variance, while with one or two exceptions they were obtained many years ago, by methods which would now hardly be regarded as accurate.

One analysis by Henry is as follows:—(only data relating to the carbohydrates are cited.)

Water	73.1 per cent.
Starch	13.3 "
Sugar	3.3 "

Another analysis by Johnson is:—

Starch, 40.9	per cent.
Gums, 1.4	"
Sugar, 19.7	"

These percentages undoubtedly relate to dry matter.

In "Ure's Dictionary" an analysis is also cited as follows:—

Water	74.3 per cent.
Starch	15.1 "

The absence of any mention of sugar in this is noticeable. Analysis made at the department of agriculture from partially dried samples gave:—

Starch	65.29 per cent.
Sugar	14.83 "

Some more recent analyses are, one made at the Connecticut experiment station:—

Water	73.89 per cent.
Carbohydrates	23.60 "

and at the New York experiment station:—

Water	74.38 per cent.
Nitrogen-free extract	17.98 "

The ambiguous term "sugar" used in these data gives us no clue to the specific nature of the carbohydrates indicated thereby. In only one place have I found a reference to the character of this sugar, viz., in connection with the analysis made at the United States Department of Agriculture. Here it is stated that the potato meal, on mixing with cold water, contained no glucose, but after heating to boiling acquired the power of reducing Fehling's solution. The original form of this reducing sugar was stated to be sucrose, for which, however, the above described behaviour cannot serve as convincing proof. In the complicated mixture existing in the watery extract of vegetable tissues, reducing compounds may arise from quite other sources than sucrose at boiling temperature. So also in the quantitative inversion of such an extract, with strong acids, many other substances besides sucrose are subjected to hydrolysis, and may give similar results. It is recognised at present that the one

conclusive proof of the occurrence of a specific saccharine compound consists in its isolation in a pure state, and the application of characteristic reactions, chief of which is the determination of its *specific rotation*. To this end samples of two well-known varieties, Southern queen and American red, were taken in hand. The date was fully three months after harvest, but the potatoes were still fresh and sound. As bearing upon this point, the following determinations were made:—

	Specific gravity.	Moisture.	Dry matter.
Southern queen ..	1.017 ..	59.37 ..	40.63
American red ..	1.059 ..	61.22 ..	38.78

The flesh of both sorts showed most intense colouration with iodine, indicating large quantities of starch. A watery extract from the grated flesh of the Southern queen samples had no effect upon Fehling's solution, even after maceration for several hours in the cold. A similar preparation from the American red gave only a slight reduction. In both cases the watery extract was sweet to the taste. Often in the course of investigation, similar tests were made with other samples, and always with the same results, *i.e.*, often without reduction of Fehling's solution and never with anything more than a slight reaction, from which I conclude that under ordinary conditions the sweet potato contains no reducing sugar; or at least only slight traces of the same.

About 300 grms. of the finely grated pulp of each variety were digested at boiling temperature during three hours with 600 c.c. of strong alcohol, in flasks connected with return condensers. The alcoholic extracts thus obtained were filtered, and the filtrates evaporated to the consistency of thin syrup. Both products were very sweet and somewhat dark coloured; that from the American red was reddish coloured, due to matters extracted from the dark red skin of this variety. These residues were boiled with four to five volumes of strong alcohol, and on cooling a thick dark coloured gummy syrup settled to the sides and bottoms of the flasks. The clear alcoholic solutions were decanted and treated with animal charcoal, whereby much of the colouring matter was removed. After filtering from the charcoal, the alcoholic solutions were evaporated and left to crystallise. That from the Southern queen soon became quite solid from the formation of sugar crystals. The syrup obtained from the American red, however, contained several transparent oily globules, and refused to crystallise. This oily substance was soluble in alcohol, and had accompanied the syrup through all the refining operations. On treatment with water, however, it was precipitated as a white flocculent mass. By filtration and evaporation of this watery solution, a syrup was obtained which also soon crystallised.

The crystalline products thus obtained from the two varieties were apparently identical in their nature. They were united in one portion and purified by repeated recrystallisation from alcohol and water. The ultimate product was crystalline, pure white, and sweet to the taste.

A small portion was placed in a flask with compressed yeast, and in the course of a few hours a distinct fermentation had followed. The gas evolved was collected in a eudiometer tube, and proved to be carbon dioxide. The sugar did not directly reduce Fehling's solution, but after treatment in solution with a few drops of hydrochloric acid, showed a strong reducing action.

To determine the specific rotation, 4.1334 grs. were dissolved in water and made up to a volume of 50 c.c. This solution was polarised in the Laurent's polariscope made by Schmidt and Haensch of Berlin, and in a tube of 200 m.m. length showed a dextro-rotation of 10.87°. From these data the specific rotation is calculated to be (α)_D=65.7°, which agrees practically with that for cane sugar as determined by Tollens.*

There seems no doubt, therefore, that the sugar of the sweet potato is sucrose.

Several months were occupied in obtaining these results, but early in the investigation, after ascertaining that the sugar present was non-reducing, an attempt was made to determine the same quantitatively by means of polarisation. Two portions of the freshly grated pulp of the American red were extracted with strong alcohol, during two or three hours, in a Soxhlet apparatus, the clear extract made up to 100 c.c. and polarised in a 200 m.m. tube in the above-mentioned Laurent's apparatus. The results were as follows:—

1. 35.30 grs. of pulp extracted and diluted to 100 c.c. showed a dextro-rotation of $4.5^\circ = 2.09$ per cent sucrose.

2. 34.95 grs. of pulp in the same proportion as above, showed a dextro-rotation of $4.46^\circ = 2.10$ per cent sucrose.

A similar determination with the Southern queen gave the following results:—

3. 35.31 grs. of pulp in the proportions already given gave a dextro-rotation of $3.17^\circ = 1.44$ per cent sucrose.

These results fall somewhat below those already cited at the beginning of this paper, and while considerable variation undoubtedly exists between different varieties, and even between samples of the same variety grown in different localities, yet I believe the methods of polarisation may be safely applied to the quantitative determination of the sucrose existing here. The data quoted were undoubtedly obtained by methods of inversion, and if so would naturally be too high. On the other hand, as we have seen, the amount of reducing sugar (glucose) present in the fresh potato is minimal, if not entirely wanting, and by no means sufficient to produce an appreciable diminution of the reading produced by sucrose present. From data obtained, therefore, it would appear that the percentage of sucrose present in the varieties named is from one and a-half to two per cent.

If we take a sweet potato, the flesh of which has been previously found to be quite free from reducing substances, bake it in the ordinary domestic fashion, crush it and macerate the mass with cold water, the extract thus obtained will reduce Fehling's solution strongly. The temperature applied in baking has produced inversion among the carbohydrates originally present.

To a watery extract obtained as above, two volumes of strong alcohol were added, by which a voluminous, flocculent, white precipitate was thrown down. This was filtered, and the filtrate evaporated to a syrup, which was of a brownish yellow colour, very sweet, and still retained its reducing power.

The precipitate, which was at first somewhat sticky and gummy, by repeated washings with strong alcohol and ether, became pulverulent and no longer deliquescent on exposure to the air. This substance was readily soluble in water, but the solution was not sweet to the taste. With iodine solution a most intense violet or purple colour was produced, which, however, was quite distinct from the ordinary starch reaction. The solution reduced Fehling's solution after heating, but the appearance was different from the normal glucose reduction. A solution of 1623 grms. in 100 c.c. of water produced in a 100 m.m. tube a dextro-rotation of 2.86° , from which the specific rotation $(\alpha)_D = 176.3^\circ$ may be calculated. This substance corresponds in its behaviour to some of the compounds occurring in the transition from starch to dextrine or, eventually, dextrose. The specific rotation is too low for mere soluble starch, which according to Brown and Morris is $(\alpha)_D = 194.8^\circ$, and approaches more nearly that of malto-dextrose $[(\alpha)_D = 174.5^\circ]$. The latter, however, does not give the iodine reaction. The substance in question was undoubtedly a form of soluble starch or amylodextrine, produced by the action of heat upon the starch of the potato.

The syrup obtained by evaporation of the watery extract from which the soluble starch had been precipitated, was of a very sweet and altogether agreeable taste.

It reduced Fehling's solution strongly. In spite of attempts at purification and decolourisation, it remained somewhat dark coloured and refused to crystallise. After standing some weeks, it was still perfectly clear and amber-like in appearance. Its behaviour indicated that while some of the original cane sugar may have been present, it was also accompanied by a considerable quantity of invert sugar. Treatment of a portion of this syrup with phenylhydrazin chloride, according to the prescribed method,* gave an abundance of the characteristic yellow product which in this case seemed to be the phenyl-glucosazon. This, after re-crystallisation from alcohol and desiccation, melted at 200° to 204° C., practically agreeing with the number (204° to 205° C.) for pure glucose. The syrup was therefore an impure glucose resulting from the inversion of the original sucrose of the potato.

Briefly stated the results of the inquiry are:—

The saccharine substance of the sweet potato exists chiefly, if not entirely, in the form of sucrose.

The use of the polariscope in the quantitative determination of the same seems possible. Such determinations showed one and a-half to two per cent of sucrose in the fresh potatoes.

The temperature of cooking (baking) inverts the sucrose, and converts more or less of the starch into a soluble form.

A part of this investigation was made at the laboratory of the Tennessee Experiment Station, the remainder at Purdue University.

NEW PROCESS FOR THE TITRATION OF ALDEHYD BY MEANS OF CHROMIC ACID.

By R. BOURCART.

THE process is substantially the same as that described for alcohol. 1 mol. aldehyd requires $\frac{1}{2}$ mol. bichromate for conversion into acetic acid. 1.2442 grms. of pure paraldehyd is made up to a solution of 100 c.c. with water. The solution of bichromate contains exactly 10 grms. of the salt to 1 litre, and a hyposulphite solution of 24 grms. per litre, of which 104.2 c.c. correspond to 100 c.c. of the bichromate solution. The determination is carried out as for alcohol, heating for three hours to 100° . The quantities taken were 10 c.c. solution of paraldehyd, 20 c.c. sulphuric acid of 10 vol. per cent, 50 c.c. of the bichromate solution, and 20 c.c. potassium iodide of 10 per cent.—*Soc. Indust. de Mulhouse and Chemiker Zeitung.*

ON A NEW PROCESS FOR DETERMINING THE MINERAL MATTER IN SUGARS BY MEANS OF BENZOIC ACID.

By E. BOYER.

THE direct incineration of sugars for determining the inorganic matter is a long and delicate operation, for which there has been substituted in industrial analysis the empirical procedure indicated by Scheibler, which consists in incinerating a known weight of sugar in presence of pure concentrated sulphuric acid until a perfectly white ash is obtained. It is generally assumed that if we deduct the tenth of the weight of the sulphated ash the figure remaining will represent the weight of the

* One part of the sugar or syrup, two parts phenylhydrazin chloride, three parts sodium acetate, and 20 parts water are warmed together in a water bath to 70° to 80° C., whereby fine yellow crystals are gradually formed. This compound, $C_{12}H_{16}N_4O_4$, has a characteristic melting-point accordingly as it is derived from one or the other of the sugars.

mineral matter. Several chemists, especially MM. Aimé Girard and Violette hold that this correction is insufficient, the ash of sugar consisting chiefly of alkaline carbonates and chlorides, and they propose to deduct 2-roths of the gross weight in order to obtain the real mineral matter of sugars.

We see, in fact, by a calculation of the equivalents, that this latter correction approaches the reality.

The process which the subject of this paper embraces has the advantage of dispensing with any correction, since it gives directly the mineral matter of sugar in its natural state. It consists in effecting the carbonisation of the sugar in presence of a volatile acid, benzoic acid. To facilitate the mixture of this acid with the sugar it is preferably employed in solution, and as it is but sparingly soluble in water, alcohol at 90 per cent is used as solvent, 100 c.c. to 25 grms. benzoic acid.

He weighs into a platinum capsule 5 grms., which are moistened with 1 c.c. distilled water; the capsule is gently heated over a Bunsen burner so as to caramelise the sugar without charring it, so that all the carbon may be ultimately formed in presence of benzoic acid. The addition of water renders this manipulation easy. He then adds 2 c.c. of the alcoholic benzoic solution, say 0.5 gm. of the acid, and evaporates on the sand-bath, heating at first gently until the alcohol is entirely driven off, and then raising the heat to effect the carbonisation.

The decomposing benzoic acid gives off abundant vapours, which swell up the sugary matter, especially if we take the precaution of giving the capsule a rotatory movement. The heating is continued until all the benzoic acid is volatilised.

The carbon obtained is bulky and of a brilliant black. To effect the combustion the capsule is put at the entrance of a muffle furnace heated to dull redness. The incineration is complete in half-an-hour, and the ash obtained is white and bulky.

The capsule is weighed rapidly after cooling in order to avoid the absorption of moisture by the alkaline carbonates.

The weight obtained represents the mineral matter in 5 grms. sugar. Ammonium benzoate may be used instead of benzoic acid, but whichever is taken we must first ascertain that it leaves no residue in the conditions of the analysis.

The results given by this method are accordant, and justify the deduction of 2-roths from the weight of the sulphated ash to obtain the real mineral matters of sugars of the first and second quality. Subjoined are some determinations compared with the results of the sulphuric determinations corrected by the successive deduction of 1-roth and 2-roths:—

Kind of Sugar.	Benzoic Incineration.	Sulphuric Incineration.		
		Uncorrected.	1-roth corrected.	2-roths corrected.
Blank experiment ..	0.06	0.08	0.07	0.06
First quality ..	0.73	0.90	0.81	0.72
Second ..	0.94	1.18	1.06	0.94
Mixture ..	1.81	2.25	2.03	1.80

RECOVERY OF ABSORBED MORPHINE FROM THE URINE, THE BLOOD, AND THE TISSUES.*

By THEODORE G. WORMLEY, M.D., LL.D.,
Professor of Chemistry and Toxicology, Medical Department,
University of Pennsylvania.

Historical.—Of all the ordinary poisons there is none that has more frequently been attended with failure to recover it from the body, both in poisoning of the human

subject and in experiments on animals, than the alkaloid morphine. These failures have occurred even when the quantity taken or administered was very large, and all the attending circumstances apparently the most favourable for its recovery. Indeed, in the numerous experiments thus far made upon animals, the results have been negative, save in a few instances.

Among the earlier observers, Dr. Christison ("On Poisons," Amer. Ed., p. 537) failed to detect morphine in the contents of the stomach of a young woman who died in five hours after taking two ounces of laudanum; and in another instance the contents of the stomach, withdrawn four hours after two ounces of laudanum had been taken, failed to furnish satisfactory evidence of the presence of the poison.

M. Dublanc (*Archives Gen.*, i., 150) sought in vain for morphine in the blood and urine of animals killed by it. And M. Lassaigue (*Ann. de Chim. et de Phys.*, xxv., 102) could not detect the alkaloid in the blood drawn from a dog twelve hours after thirty-six grains of the acetate were injected into the crural vein; nor, again (*Four. de Chim. Med.*, 1841, 488), in the liver or the blood of a dog poisoned with eight ounces of Sydenham's laudanum.

Orfila ("Traité des Poisons ou Toxicologie," trois. Ed., ii., 58) failed to find the poison in the blood of three dogs that had been given respectively twelve, fifteen, and eighteen grains morphine acetate, and found it in only one instance in the urine.

Bouchardat (*Bull. Gen. de Ther.*, Dec., 1861) believed he had found the alkaloid in the urine of a person who had taken 0.05 gm.; and Lefort (*Four. de Chim.*, xi., 93, 1861) concluded that it was eliminated by the urine. But the tests relied upon by these observers—iodine in potassium iodide by the former, and iodic acid by the latter—have no positive value.

Dr. Taylor ("On Poisons," London, 1875, 34) mentions two cases, one in his own practice, in each of which one grain of morphine hydrochloride had been taken, and death took place in ten and thirteen hours respectively; but no trace of morphine could be detected in the stomach in either case.

Dr. Ebertz (*Ann. d'Hyg.*, 1875, July, 220) failed to find a trace of the poison in any part of the body of a woman who had taken 0.25 gm. (nearly four grains) of a salt of morphine, and died from its effects within fifty minutes afterward.

Dr. Ogston ("Lectures on Medical Jurisprudence," 1878, 567) records a case in which nine or ten grains of morphine hydrochloride caused death within a few hours, and none of the poison had been ejected and no remedy applied. A most searching examination, by himself and Professor Gregory failed to detect any trace of morphine in the alimentary canal or elsewhere.

In a fatal case of laudanum poisoning recorded by Dr. Tidy ("Forensic Medicine," 1877, 376), repeated analyses of the contents of the stomach failed to reveal the presence of a trace of either meconic acid or of morphine.

In experiments upon three rabbits, Erdmann (*Annal. d. Chem. u. Pharm.*, Bd. 122, 360, 1862) found the poison in the first, in the stomach; in the second, only traces in the urine; and in the third, only traces in the blood, none being found in the urine, brain, or spinal cord. He concluded that morphine was decomposed in the system.

Cloëta (*Virchow's Archiv.*, xxxv., p. 376, 1866) examined, by Erdmann's method, the urine of a patient who had taken for some time daily six to seven grains morphine acetate, but failed to find a trace of the poison.

In a case of morphine poisoning, Dr. Kreyssig ("Inaugural Dissertation," Leipzig, 1856; quoted by Landsberg) found the poison in the vomited matters by the iron test, but failed to find a trace either in the blood or urine. Prof. Maschka (*Prager Vierteljahr.*, Bd. 66, p. 65, 1860) reports a similar case in which none of the poison was found in the stomach.

* From the *University Medical Magazine*.

Prof. L. A. Buchner (*Neues Repert. f. Pharm.*, Bd. 16, p. 43, 1867) relates the case of a child quickly killed by three doses of morphine acetate of two grains each, and he failed to find any evidence of morphine either in the contents of the stomach or alimentary canal. And in another case, in which a child quickly died from the effect of extract of poppies, similar negative results were obtained.

H. Köhler (*Schmidt's Jahrb.*, Bd. 141, p. 21, 1869) states that the recovery of morphine from bodies by the known methods more frequently fails than succeeds. Prof. Guy ("Forensic Medicine," p. 518, 1881) remarks that it is now well understood that in cases of poisoning with opium the best methods of analysis will often fail to yield any evidence whatever of the presence of the poison in the contents of the stomach.

Gscheidl (*Arbeiten aus dem Physiol. Laborat.*, Würzburg, Bd. 32, 1869) says that morphine injected into the jugular vein of rabbits may be found in the urine; but this may be due to the great amount administered.

Kauzmann (*Zeitsch. f. Analyt. Chemie*, viii., pp. 103, 243, 1869) found that morphine might be recovered unchanged from the stomach, feces, the blood, and urine. He employed the Usler-Erdmann method.

E. Vogt (*Archiv. der Pharmacie*, Bd. 207, p. 23, 1875) failed to find morphine in the urine for twenty-four hours of an old man who took daily large quantities of the drug, but he found it in the feces. In like manner, Bornträger (*Archiv. der Pharmacie*, Bd. 217, p. 119, 1880) failed to find the poison in the urine of a person who took daily 0.5 to 1.0 gm. subcutaneously.

Jacques ("Localisation des Alcaloides dans le Foie," Thèse Bruxelles, 1880; cited by Landsberg) relates the case of a person, sixty years old, who took for five years daily 1.3 grms. morphine in solution, and in addition every second day 2.0 grms. subcutaneously, yet he failed to find the alkaloid in the urine, but found it in large quantity in the feces collected for three days.

Dr. W. Eliassow ("Inaugural Dissertation, Königsberg," 1882) examined with negative results the urine of a person who took daily 0.14 gm. of a salt of morphine. So, also, R. Burkart (*Volkmann's Sammlung Klinischen Vorträge*, N. 238) failed to find it in the urine of persons who took morphine in large doses; yet on adding directly 0.002 gm. morphine to 50 c.c. urine, he readily obtained evidence of its presence.

E. Landsberg (*Pfäuger's Archiv. f. Physiologie*, Bd. 23, p. 425, 1880) injected subcutaneously into three dogs quantities of morphine hydrochloride, varying from 0.2 to 0.4 gm. The urine from these animals failed to show the presence of morphine. In another case 1.0 gm. of the morphine salt was injected; the next day 0.5 gm., and on the third day 1.0 gm. Four hours after the last dose the animal was killed, and 170 c.c. urine collected. But no morphine was found in this fluid, nor in the brain, medulla oblongata, or in the liver. In another case 2.7 grms. of this salt were injected in divided doses over several days; 130 c.c. of urine and the blood were then examined, but with negative results. One gm. of the salt was administered, in two portions, by the stomach. Again the urine failed to show the presence of the poison, but it was readily obtained from the feces. From these and other experiments Landsberg concluded that morphine undergoes decomposition in the system.

R. Schneider (*Jahresbericht für Tierchemie*, 1884, p. 236), under the action of Froehde's reagent, found morphine in the urine of three persons who took daily from 0.02 to 0.36 gm. morphine acetate, partly internally and partly by subcutaneous injection.

Dr. J. Donath (*Archiv. f. d. ges. Physiologie*, Bd. 38, p. 541, 1886) examined the urine of a patient who had for five years taken large doses of morphine subcutaneously, and during forty-eight hours had employed 0.36 gm. of the alkaloid. Two litres of urine collected during the two following days, examined by Landsberg's method, failed to reveal the presence of a trace of mor-

phine. The urine of this patient was examined subsequently a second and a third time, with like negative results. In another case, in which the patient was using subcutaneously 0.75 gm. of a morphine salt daily, 1200 c.c. of the urine failed to give any positive evidence of the presence of morphine. In a third case, in which 1.5 grms. were injected during forty-eight hours, not a trace of morphine was found in 2.5 litres of urine. From these examinations Dr. Donath concludes that morphine entirely disappears in the animal organism, and is not converted into any product that responds to the tests for morphine.

With the cases now cited may be mentioned the results of the writer's ("Micro-Chemistry of Poisons," 867, 502) own investigations, made some year's since, in which the blood from eight different cats and dogs poisoned by opium gave little or no evidence whatever of the presence of the poison, save in one instance, in which two grains of morphine and two ounces of laudanum had been administered.

Methods of Analysis.—In the early history of this subject about the only method known for the recovery of morphine and the alkaloids in general, from complex mixtures and the tissues, consisted in extracting the finely divided solids by water acidulated with acetic acid, evaporating the filtered liquid, and extracting the residue with alcohol. In the further purification of the extract, acetate of lead was used to separate foreign organic matter, and the alkaloid was finally precipitated by sodium carbonate.

After this general method M. Lassaigne (*Ann. de Chim. et de Phys.*, xxv., 102) recovered morphine when the quantity was not less than two grains in eight ounces of the complex mixture.

About the only tests then known for the recognition of morphine were the iron and the nitric and iodic acid tests.

In 1851 Professor Stas (*Bull. de l'Académie de Médecine*, ix., 304), of Brussels, proposed a general method for the recovery of the alkaloids from organic mixtures, based upon the fact that these bodies in the free state are, for the most part, more or less soluble in ether. This method consists essentially of first extracting the alkaloid in the form of a salt, from the complex mixture, by acidulated alcohol, evaporating the alcoholic extract to dryness, dissolving the residue in water, and treating this solution with an alkali to set free the alkaloid. The alkaline liquid is then agitated with several volumes of ether, which will extract the eliminated alkaloid, and, on evaporation, leave it in a more or less pure state.

Professor Otto (*Ann. Chem. Pharm.*, 100, 44, 1856) proposed to modify this method by first agitating the acidulated liquid, before the addition of an alkali, with ether for the purpose of removing certain foreign matters. The aqueous liquid, after decanting the ether, is then rendered alkaline and again extracted by ether. This proved to be an important modification of Stas's original method.

Although the method of Stas has proved of the greatest importance for the recovery of the alkaloids in general, yet it has only a limited value for the recovery of morphine, since this alkaloid requires about 7000 times its weight of ether for solution. Nor is chloroform, as first advised by Rodgers and Girdwood (*Lancet*, London, June, 1856, 718) for the recovery of strychnine, well fitted for this purpose, since morphine is about as insoluble in this liquid as in ether.

For the recovery of the alkaloids in general, but more especially for the extraction of morphine, Usler and Erdmann (*Annal. d. Chemie. und Pharmacie*, 120, p. 121) in 1861, proposed the use of amyl alcohol, in which morphine is rather freely soluble. This liquid being immiscible with water, the principle and method of application is the same as in the process of Stas.

Soon after the introduction of this method for the recovery of morphine, Froehde (*Zeitschr. Anal. Chem.*, v.,

p. 214, 1866) made the important observation that morphine and its salts in the solid state, when brought in contact with a drop of concentrated sulphuric acid holding a little molybdic acid in solution, gives rise to a beautiful purple or crimson colouration. This reaction has proved of great value for the detection of morphine, since, when properly observed, it is less open to fallacy than most of the other tests, and surpasses them all in delicacy of reaction.

(To be continued).

ON THE CHEMICAL COMPOSITION OF THE OILS OF WINTERGREEN AND BIRCH, AND THE CHARACTERS OF THE SYNTHETIC OIL OF WINTERGREEN.

By Prof. Dr. FREDERICK B. POWER,
University of Wisconsin.

In the *American Journal of Pharmacy*, 1889, p. 398, there appeared a "Contribution from the Chemical Laboratory of the Philadelphia College of Pharmacy," entitled "The Oils of Wintergreen and Birch," by Henry Trimble and Hermann J. M. Schroeter, in which the authors introduce the subject of their investigation by the following statement:

"The history of these oils has recently been written by Dr. E. R. Squibb (*Ephemeris*, Oct., 1887, p. 951), and the papers there referred to from the first in 1842 by Professor Procter to the last in 1884 by Mr. H. P. Pettigrew, can all be found in the *American Journal of Pharmacy*."

Although this carefully worded statement is literally true, I may call attention to the fact that all the literature concerning these two oils is not contained in the journal cited. In August, 1888, a paper was read by me before the Chemical Section of the American Association for the Advancement of Science, Cleveland Meeting, "On the Constituents of Wintergreen Leaves" (Power and Werbke), which was subsequently printed in abstract in the *Proceedings* of the above Association, p. 124, and in full in the *Pharmaceut. Rundschau*, Sept., 1888, p. 208, as also in the *London Pharm. Journal*, Nov. 3, 1888, p. 349, and in abstract in the *Bericht* of Messrs. Schimmel and Co., Leipzig, Oct., 1888, p. 40, and in some other periodicals. In this paper, in connection with some observations on the oils in question, and other constituents of wintergreen leaves, I also took occasion to suggest that the synthetic oil of wintergreen might properly be recognised in the next revision of the U.S. Pharmacopœia.

Since Messrs. Trimble and Schroeter have omitted any direct reference to my previous paper on this subject, it would be charitable to presume that they were unaware of its publication, but from some of the statements in their article it would not appear probable that such was the case, and having thus directed attention to this matter it may be passed without further comment.

The statements made by these gentlemen in their recent publication concerning the oils of wintergreen and birch are, however, so remarkable in many respects that I have taken the liberty of reviewing the results and conclusions of their investigation; and although good and sufficient reasons might be presented for inferring *a priori* the incorrectness of many of their statements, yet in the interest of scientific truth, and in order that the critical remarks which I desire to make may be as thoroughly substantiated as possible, I have also undertaken anew the investigation of the three products which form the title of this paper.

In order that the essential points of this discussion may be clearly understood, it may be stated in the beginning that attention has been specially directed to the consideration of the following observations or asser-

tions. As is probably well known, previous investigations have shown the oil of wintergreen to consist of methyl salicylate, associated with small amounts of a hydrocarbon or terpene, termed gaultherilene, and the oil of birch to consist of pure methyl salicylate. These statements the writer believes to be perfectly correct, and to present in a concise form the actual chemical composition of these oils.

Messrs. Trimble and Schroeter, in their recent paper (*loc. cit.*), affirm, however, that the oils of wintergreen and birch are both physically and chemically identical, that they both contain a hydrocarbon or sesquiterpene of the composition $C_{15}H_{24}$, which is present even to a larger extent in the oil of birch than in the oil of wintergreen, but that that from the oil of wintergreen has a lower melting-point. Furthermore that both of these oils contain small amounts of benzoic acid and ethyl alcohol, and that a representative sample of the artificial oil of wintergreen did not have the chemical composition of the natural oils, and was not pure methyl salicylate, but contained a large amount of methyl benzoate.

From previous observations, as well as from the results of the present investigation, I am forced to believe that most, if not all, of the foregoing conclusions of Messrs. Trimble and Schroeter are positively incorrect, so far at least as they relate to the pure oils in question; and this I hope to be able to demonstrate.

The oils examined by me in the present investigation were obtained from the following sources:—

I. *Natural Oil of Wintergreen*.—This was obtained directly from Mr. Robert B. Wilson, of Black River Falls, Wis., who had distilled the oil himself, and therefore no doubt could exist as to its absolute purity.

II. *Natural Oil of Birch*.—This was obtained from Mr. C. M. Driggs, of White Haven, Pa., the source from which Messrs. Trimble and Schroeter obtained their oil of birch, and at least one specimen of their oil of wintergreen.

Another small sample of the oil of birch in my possession represents a portion of the same oil as that used by Mr. Pettigrew in his investigation (*Amer. Journ. Pharm.*, 1883, p. 385).

III. *Artificial or Synthetic Oil of Wintergreen*.—This was kindly furnished me by Messrs. Fritzsche Bros. of New York, and was manufactured by their Leipzig House, Messrs. Schimmel and Co., who have made a specialty of this product.

PHYSICAL PROPERTIES OF THE OILS.

Specific Gravities.

These were determined in the present instance by means of a pycnometer, provided with an accurate and delicate thermometer, indicating tenths of a degree. All the specific gravities recorded represent a comparison of the oils with an equal weight of distilled water at the temperature of 15° C. The natural oils used for this determination had been once rectified, in order to remove traces of water and dark coloured oxidation products, such as are invariably formed when the oils are kept for some time. After this treatment they were perfectly clear and colourless.

I. *Natural Oil of Wintergreen*.—This was found to have a specific gravity of 1.1835 at 15° C., which is somewhat higher than that of a freshly distilled sample previously examined by me (*Pharm. Rundschau*, 1888, p. 209) namely 1.1766, or than that observed by Procter (*Amer. Journ. Pharm.*, 1842, p. 213 and 1843, p. 244), namely 1.173, but agrees well with that observed by Trimble and Schroeter (*Amer. Journ. Pharm.*, 1889, p. 399), namely 1.1838 and 1.1845.

II. *Natural Oil of Birch*.—The specimen of oil supplied to me by Mr. C. M. Driggs for this investigation, who assured me that it was perfectly pure, had the remarkably low specific gravity of 1.1606 at 15° C. The cause of this will be explained in connection with the chemical examination of the oil.

A new determination of the oil of birch used by Mr. Pettigrew gave a specific gravity of 1.1851 at 15° C. Trimble and Schroeter found the specific gravity of the oil of birch used by them to be 1.1840 at 15° C.

III. *Synthetic or Artificial Oil of Wintergreen.*—This was found to have a specific gravity of 1.1838 at 15° C. The product examined by Trimble and Schroeter is stated by them to be 1.1833 at 15° C.

Boiling Points.

These were determined in a glass fractionating vessel with a Geissler normal thermometer, so adjusted that the mercurial column should be entirely in the vapour of the boiling liquid. By this method the results admit of more accurate comparison, although the temperatures so recorded are probably 3 or 4 degrees higher than would be the case with a large portion of the tube of the thermometer exposed to the outer air. In each case the barometric pressure was also observed and recorded.

I. *Natural Oil of Wintergreen.*—This was found to distil quite constantly between 218 and 221° C., under a pressure of 731 millimetres.

II. *Natural Oil of Birch.*—The sample of this oil began to boil somewhat above 100° C., but the main portion of the oil distilled between 217 and 220° C., under a pressure of 734 millimetres. The cause of the low boiling-point of a portion of this oil, as well as its low specific gravity, previously alluded to, will be subsequently explained.

III. *Synthetic Oil of Wintergreen.*—This was found to boil very constantly at 221 to 223° C., under a pressure of 735 millimetres. Trimble and Schroeter record the boiling-point of the oils examined by them as follows: wintergreen 216° C., birch 217° C., and artificial oil of wintergreen 217° C. It would appear probable from this that they observed only the temperature at which the oils begin to boil, as it would be rare in the distillation of any amount of such a compound ether not to find the boiling point fluctuate within the limits of at least one or two degrees. If, moreover, the artificial oil of wintergreen examined by them contained such an amount of benzoic acid or benzoate of methyl as they have represented (about 15 per cent), it would seem strange that the boiling-point should not have been somewhat reduced, since benzoate of methyl is stated to boil at 198.5° C., under a pressure of 761 millimetres (See *Neues Handwörterbuch der Chemie*, Bd. I., p. 1084).

Optical Behaviour.

For these observations the Schmidt and Haensch improved form of the Soleil half-shadow polarising apparatus was employed. The degrees of rotation recorded by it would probably not agree with the angular rotation expressed by some other differently adjusted instruments, such as the polaristrobometer of Willd., although quite as useful in this instance for the purpose of comparison.

The natural oil of wintergreen obtained from Mr. Wilson, as also a sample of oil of wintergreen distilled in my own laboratory from fresh wintergreen leaves, deviates the ray of polarised light two degrees to the left, in a tube 200 millimetres in length.

The oil of birch obtained from Mr. Driggs, as also the specimen of oil of birch previously referred to as having been used in Mr. Pettigrew's investigation, and the artificial oil of wintergreen manufactured by Messrs. Schimmel and Co., have not the least action on polarised light. These observations serve to establish the following facts:—

1. That the oil of wintergreen supplied to me by Mr. Wilson was pure, since it presents the same optical and other physical characters as the oil distilled by myself.
2. That the natural oil of wintergreen contains a small amount of an optically active substance, which is not present in the natural and pure oil of birch.

This optical activity of pure wintergreen oil can of

course only be attributed to the small amount of terpene which it contains. The statement of Trimble and Schroeter that the oils of wintergreen and birch are physically identical, appears to be based simply upon the approximate agreement of their specific gravities and boiling-points.

That the pure oil of birch, which I maintain to consist simply of salicylate of methyl, as well as the synthetic oil of wintergreen, have no action on polarised light, is also quite in accordance with the numerous and well authenticated observations that all ordinary benzol derivatives in which the three double bonds of the C₆ nucleus remain intact, and which can consequently contain no asymmetrical carbon atoms, are optically inactive. (Compare Landolt, *Das optische Drehungsvermögen organischer Substanzen*, 1879, pp. 22 to 30 et seq.).

(To be continued).

THE POLLUTION OF STREAMS BY PAPER WORKS.

By JOHN C. THRESH, D.Sc., M.B.,
Medical Officer of Health.

IN the list of subjects submitted to Members of this Association as suitable for discussion before the Public Health Section was the one now introduced. I was led to select it because on several occasions I have had to examine the waste products from paper mills, to ascertain their effect upon the streams into which they were cast, and have also had to advise how the pollution of comparatively pure streams could be prevented, and to devise processes whereby the filthy river waters of Lancashire could be rendered sufficiently pure for use in the manufacture of paper.

A paper on such a subject as this must necessarily be more or less technical in character, but County Medical Officers and those aspiring to hold such positions will require to make themselves acquainted with many trade processes if they wish to become efficient in the discharge of their duties. In the short time allotted for the reading of the paper I will endeavour to give as clear an account as possible of the origin of the matters with which paper makers pollute our streams, and also of the methods which have been proved practicable for preventing such defilement.

The amount of polluting material produced by a paper mill depends upon its size, and also upon the kind of fibre-yielding material used, and the special quality or kind of paper manufactured. The largest amount is produced by the mills using Esparto grass for newspaper making, and the smallest by the makers of millboard and of brown and other coarse kinds of paper.

In order to realise the relative importance of the various waste products it will be necessary to enumerate the materials used in paper making, to classify the waste materials, and to briefly describe the processes by which they are produced.

The raw materials used in paper making may be grouped in three classes:—

1. The fibre-yielding materials. Esparto grass, straw, wood-pulp, rags, paper shavings, old sacks, ropes, cotton-waste, &c.
2. The chemicals used in preparing the fibre. Caustic soda (usually manufactured at the paper works from soda-ash and lime), chloride of lime, antichlor (sodium thiosulphate), &c.
3. The substances used in glazing, colouring, and weighting the paper. China clay, ultramarine, ochre, alum, glue, resin, &c.

The first stage in the process of paper making is the

* Read before the British Medical Association, Birmingham, 1890

beating or "dusting" of the raw material to remove as much as possible of the dirt and dust. The fibre-yielding material is then packed in large iron cylinders and heated under pressure with strong caustic ley. The usual charge of a boiler is 50 cwts. of Esparto or 20 cwts. of straw, with an amount of caustic ley corresponding to 17 or 18 lbs. of caustic soda per cwt. of material and about 1400 galls. of water. For rags a much smaller quantity of alkali is required, probably on an average only 3 lbs. of caustic soda to the cwt. Where prepared wood-pulp or paper shavings are used this boiling process is unnecessary, the material being already what is technically called "half stuff." After boiling the liquor is drawn off, and, in the majority of cases, is allowed to flow directly into the river. This waste ley, technically called "boilings," varies in composition with the nature of the material treated. The Esparto "boilings" are dark reddish brown in colour, almost black in bulk, and have a very characteristic balsamic odour. The reaction is strongly alkaline, and it froths very freely, even when largely diluted with water. It is the cause of the abundant froth found near the weirs on streams into which it is cast. I find the average density is 1060, and each gallon contains about 8000 grains of solid matter in solution, of which about 5000 grains consists of organic matter derived from the Esparto. Grass "boilings" are not quite so dark in colour, have no balsamic odour, and contain about 3600 grains of matter in solution, of which a little over 2000 are organic. The density is about 1030. Both contain a little caustic soda, the former, on an average, 500 grains, and the latter 100 grains per gallon of the "boilings." Rag boilings vary considerably in colour, strength, &c., according to the quality of rag treated. Most paper makers regard rag boilings as much more objectionable polluting agents than Esparto or grass boilings. When thrown into a stream with lime residues or waste bleach liquor a glutinous precipitate forms, adhering to the sides and bed of the river and, when exposed, readily decomposing and becoming offensive.

To make one ton of paper about two tons of Esparto or grass are required; the amount of organic matter therefore removed by the "boiling" and subsequent washing is simply enormous. On one small stream in Scotland I found there were six paper mills, casting into it every day 26 tons of solid matter, of which at least 12 tons was organic, and I know one large paper mill at Lancashire which alone throws daily into the adjoining stream fully this amount of polluting matter. At this mill no attempt was made to utilise any portion of these waste materials until I showed that one portion could be used for purifying the filthy river water in order to enable it to be used in the works. Unfortunately the sludge so produced is periodically flushed into the river, so that its last state is, if possible, worse than its first.

Returning now to the process of paper making. After the strong ley or "boilings" had been drained away, cold water is run into the boiler, and this, when drawn off, constitutes the "first coolings," and consists of ley about one-third the strength of the original "boiling." The washing process is repeated several times, producing second, third "coolings," &c., which of course consist of still further diluted ley. After the process of cooling is completed, the fibre passes to the "beating engine," to be pulped and washed with a still larger quantity of water. It is next transferred to the bleaching tanks to be treated with a clear solution of bleaching-powder, in the making of which another waste product arises—the calcium hydrate or insoluble portion of the bleaching-powder. During the bleaching process the hypochlorite of calcium in solution becomes converted into the chloride, and this solution is also thrown into the streams. After bleaching, the fibre is again washed, and finally with or without the addition of China clay, size, colouring-matter, &c., it passes on to the paper machine. The machine water, if containing the size, &c., is usually pumped back and used over and over again.

In making millboard and the coarser kinds of paper the bleaching and washing processes are considerably curtailed.

We are now in a position to classify and consider the various sources of river pollution from the paper making industry. We may divide them into two groups—the solids and the liquids.

The solids comprise—

1. The dirt and dust collected during the "dusting" of the fibre-producing material.
2. The carbonate of lime resulting from the manufacture of the caustic soda.
3. The insoluble portion of the bleaching-powder.

The liquids comprise—

1. The "boilings" and "coolings."
2. The washings from the pulping machine (breaking engine) and other waste wash waters.
3. The waste bleach.
4. The waste from paper machine containing size, colouring material, &c.

(We may take most of these seriatim).

The "dustings" are most considerable where Esparto is largely used. As it is rarely cast into the streams, and usually finds a ready sale for manurial purposes, we need not further consider it.

The lime residues are in most cases thrown, either openly or surreptitiously, into the rivers. There can be no excuse for such pollution. The lime residue from the soda-making process should be allowed to drain in tanks, made in duplicate. Whilst one is filling the other is draining, and, when sufficiently dry, should be carted away. In some districts the farmers would gladly avail themselves of it for agricultural purposes. The slacked lime forming the insoluble portion of the bleach should be utilised in causticising the soda ash.

Of the fluid polluting materials, by far the most important are the alkaline boilings and coolings, and these we will consider last. In the washings from the "breaker" engine the suspended fibrous material is the most objectionable constituent. These washings vary in composition during various stages of the process. A sample of mixed washings, when examined, contained in each gallon—

Matters in solution	52 grains.
Matters in suspension	170 "
Total	222 "

The reaction was faintly alkaline.

By passing this liquid through fine wire cloth "save-alls" a considerable portion of the fibre is recovered, but a portion passes through and remains in suspension. This strained fluid, especially if mixed with the waste from the paper machine containing size, &c., forms a turbid mixture which it is most difficult to treat. The solid particles settle very slowly, and rapidly choke up all kinds of filters. Where sewers are available, and provided the quantity is not too considerable, I see no objection to the strained solution being allowed to flow therein. As the washing processes are at present conducted an enormous amount of water is used, but it has been proved over and over again that if the fibre be more thoroughly washed by percolation before removal from the boilers the amount of water subsequently required for washing in the breaker engine is reduced very considerably. Such a change in the process of manufacture necessitates the use of a larger number of boilers in proportion to the paper made, and therefore the outlay of more capital, but on the other hand it is more economical because a much smaller amount of fibre is lost in the washing. Where no sewer is available, or the amount of turbid fluid produced is considerable, it may be passed through settling tanks and precipitation hastened by the addition of a little sulphate of alumina. The sludge

* Probably understated. Flow very variable

would have to be drained and carted away, possibly it would be used as manure. In most cases the effluent would be sufficiently pure to pass into the stream. Where a still higher standard of purity is for any reason required intermittent filtration through land as suggested by the Rivers Pollution Commissioners would have to be resorted to.

The waste bleach consists of a solution of calcium chloride with a little fibre in suspension. This might be mixed with the washings from the "breaker" engine and treated therewith, and the same may be said of the waste from the paper-making machine. Where the "boilings" are run into the river with the waste bleach is said to cause a flocculent precipitate settling in the deep pools and quiet corners. I do not regard this objection as well founded, especially in works where Esparto and straw are chiefly used, for I found on mixing fairly strong solutions the precipitate which formed settled very slowly, and became again diffused by the slightest agitation, and it showed no signs of adhering to the sides of the containing vessel. Dilute solutions (1 in 200) produced only a turbidity, and after standing 12 hours there was no sediment deposited. These experiments were conducted to ascertain whether the mixed liquors, if allowed to flow into a sewer, would tend to form a deposit therein. The conclusion I arrived at was that the alkaline fluid had a cleansing rather than a fouling action.

We must now consider the "boilings" and "coolings," which constitute by far the most serious source of pollution, both as regards quality and quantity. The objectionable constituents are the free alkali, the soap formed by the action of the alkali on the resinous constituents of the fibre, and the other organic matters also held in solution. In the first place the amount of these fluids should be reduced to a minimum by a more systematic and efficient method of removing the ley from the fibre. At the present time about two-thirds of the polluting matter is removed at each drawing off, so that the boilings, when withdrawn, leave one-third behind, the first coolings one-ninth, and the third one-twenty-seventh. By a little different manipulation three-fourths of the ley can be withdrawn each time, so that the "boilings" and "first coolings" together would contain fifteen-sixteenths, or nearly 94 per cent of the polluting matter. The next cooling would contain 4 per cent, leaving only about 2 per cent to be removed by further washing. The soda could then be recovered from the "boilings" and "first coolings," whilst the "second cooling" could be used for making fresh caustic ley. The further washings could be mingled with those from the breaker engine and treated therewith.

In a few mills the soda is recovered from the "boilings" only, the "coolings" passing into the river, and in a still smaller number of mills the "boilings" and first "coolings" are evaporated. The old method of soda recovery consists in evaporating the alkaline liquors in shallow open pans, to drive off the water, and partially

burn the residue. The solid matter is then fired in caves, for it contains a considerable amount of combustible matter, whereby the mass smoulders, leaving behind an impure soda ash. This process gives rise to a serious nuisance from the disagreeable odour evolved, and a very large amount of soda is lost in the dense fumes given off. Less than 50 per cent of soda is recovered by this primitive method.

The two more modern and most economical processes for soda recovery are the "Porion" and the "Yahyan." The "Porion" system is the invention of the late Émile Porion, a wealthy distiller of Wardrecques, Pas de Calais. A diagram of a section of the whole apparatus is exhibited. At the commencement of the apparatus are the fireplaces, behind this in succession are the calcining hearths, the combustion chamber, the "Porion" chamber, and the chimney. Over the calcining hearth and combustion chamber are placed shallow pans for heating the alkaline liquid by the waste heat. When this liquid has reached the boiling point it is allowed to flow into the "Porion" chamber, where it is dashed into spray and evaporated by the passage through it of the intensely heated air from the furnace to a suitable strength for further treatment. It is then run into a tank placed over calciners to keep it hot and fluid. It flows from here to the calcining hearth, where, by the action of the flame from the furnace, the organic matter is all consumed, and impure soda ash alone remains.

This process will recover 80 per cent of the soda ash at a cost of about £1 8s. per ton of 46 per cent ash.

The "Yahyan" system of evaporation was worked out by the American engineer whose name it bears. Here the evaporation is quite distinct from the calcination, and is effected in a "multiple effect" vacuum apparatus. (A diagram of the most recent form of the apparatus was exhibited). The liquid to be evaporated is passed through a series of tubes, each set of coils being enclosed in an iron cylinder containing superheated steam (25 lbs. pressure). By aid of a pumping engine and condenser, a high vacuum is maintained in the tubes in the last cylinder (four cylinders are employed in the most effective form of the apparatus). The fluid is passed continuously into the tube of the first cylinder, where it begins to boil vigorously, and is drawn rapidly forward, flowing out of the fourth cylinder in a condition suitable for introduction into any form of roaster or calciner. At the Esk Paper Mills, Messrs. Brown and Co. have adopted this process of evaporation, and calcine the residue in one of their patent Duplex Reversible Roasters. They state the cost of recovering the soda ash does not exceed 15s. per ton.

In the United States, where more attention is paid to the utilisation of by-products, still better results have been obtained. The recovery of soda from weak waste liquor has been brought to such perfection that not more than three to five cwt. of coal are used per ton of 48 per cent ash recovered, whilst the percentage of recovered ash, compared with the total consumption is from 80 to

90 per cent. These results are obtained by using the "Warren Rotary Furnace" and Yahyan evaporator. The waste heat from the furnace is utilised for raising steam to work the vacuum pump, so that the only coal used for the recovery of ash is that burned in the fire box of the rotary furnace. A large plant of this kind is now being erected at an English paper mill.

It is unnecessary for us to discuss the relative advantages and disadvantages of the rival systems. It is enough that we are satisfied that by either the paper manufacturer can not only get rid of his alkaline liquors, but do so at an actual profit to himself. A knowledge of the fact that this can be done, that the prohibition of the pollution of rivers by the alkaline leys will not prejudice the industry, is one of great importance to County Councils and all Sanitary Authorities having paper manufacturing within their districts. There needs be no anxiety about enforcing the law, and we may reasonably hope that before long some systematic attempt will be made in some country or district to compel all the paper makers to use the "best practical and available means" of treating their waste products, instead of casting them all into the rivers and streams, as is almost the universal practice now.

In conclusion, I append a table of analyses of the water taken from various points along the course of a river receiving the discharges of a number of paper mills, and the sewage from villages, &c., on its banks. The calculated percentages of sewage and fluid mill discharges are also given. Considering the large proportion of mill discharge, it will be noticed that the impurity is not so large as would be expected, but it must be remembered that these waste products are not passed in uniformly and continuously, but only at intervals, often during the night. In some cases also the lime residues are stored until the river is in flood, when they are boldly flushed in and rapidly carried away.

THE FIXATION OF ATMOSPHERIC NITROGEN.*

By A. A. BRENNEMAN, S. B.†

INTRODUCTION.

THE great industrial problem indicated in the title of this article has been before chemists for half a century. It is doubtful whether there has been any real progress towards its solution since the ending of the first attempts to manufacture cyanides commercially and economically made by Possoz and Boissiere, at Newcastle-upon-Tyne, in 1844-1847. It would seem that the development of chemical theory within the same period should have thrown some light upon the more obscure points of the process, and the author has attempted in the following pages to define the present aspect of the problem, theoretically as well as practically. That the treatment is inadequate to the greatness of the subject he is fully aware. The limitations of his own time have made a fuller inquiry impossible at present. He can only hope that others may be led to follow up the subject more thoroughly. There is room for further experiment in this direction, both in the laboratory and on a large scale. The fixation of atmospheric nitrogen is an industrial problem to be compared with that involved in the manufacture of ammonia soda or of water-gas, each of which passed through quite as discouraging an experience before attaining success as has, so far, been the lot of the nitrogen question. The question is still an open one, inviting further investigation. It has been taken up anew

in recent years by Berthelot, from the theoretical side, and by Weldon from the industrial or practical side, and there is nothing in theory or practice at present to warrant the assumption that it is a hopeless question; in commercial importance it outranks either of the processes mentioned.

The matter given herewith relates principally to the preparation of cyanogen. The question of the synthesis of ammonia has been put somewhat in the background for lack of time and space. It is evident, however, that the fixation of atmospheric nitrogen in any one form is the solution of the general problem.

PART I.—HISTORICAL SUMMARY.

SHOWING THE PROGRESS AND DEVELOPMENT OF PROCESSES FOR THE MANUFACTURE OF CYANOGEN AND ITS DERIVATIVES.

Prussian Blue.

The familiar colouring matter, prussian blue, was discovered about 1710, but the chemical substance cyanogen, the radical common to prussian blue and to a large series of complex substances now known to chemistry, was not isolated until more than a hundred years later. The name cyanogen (generator of blue) was given by Gay Lussac, in 1814, to the new substance which he found to be the characteristic ingredient of this blue and of compounds related to it. The familiar name of "Prussiates," still applied in trade to the double cyanides of iron and potassium, as well as the common name "Prussic Acid," by which hydrocyanic acid is known, bear evidence of the importance which the blue colour originating in Prussia had early acquired as a commercial product.

Some time before the year 1710* a German manufacturer named Diesbach, working with the so-called Dippel's animal oil (commonly obtained by destructive distillation of bones, blood, or other animal waste) happened, in handling a sample of this oil made from blood, to add to it a solution of potash (crude potassium carbonate) and obtained thereby a blue colour. The process was soon applied upon a commercial scale. It was first described in a book called *Miscellanea Berolinensia*, published in 1710. But the discoverer of the colour was not known by name until mentioned by Scheele in 1731.

Woodward and Brown, English chemists, each published a paper in 1724 upon the new blue. Woodward refers to a German from whom he had received directions for preparation of the blue, but gives no name.†

The process, as reported by Woodward, consisted in deflagrating a mixture of saltpetre and argols (crude potassium bitartrate) and fusing the product with dried blood. The resulting mass was lixiviated with water and the solution was treated with copperas and alum, producing a greenish precipitate, which on heating with hydrochloric acid, yielded the blue colour which has since been known as Prussian or Berlin blue. Brown (*loc. cit.*) substituted animal flesh for blood in the process. He also suggested that iron was essential to the colour of the new substance.

Geoffroy, in 1725, proposed the use of wool and charred horn instead of blood or flesh.

Scheele in 1731 published the name of Diesbach as the original discoverer. (R. W., *loc. cit.*)

In later modifications the use of nitre was abandoned and scrap iron was added to the mixture. The process as thus originated is, in its essential features, that which exists to-day for the manufacture of potassium ferrocyanide, from which prussian blue is made by precipitation with a ferric solution.

* "Richardson-Watt's Chemical Technology," vol. i., p. 1, *et seq.* (Referred to hereafter as R. W.)

† *Phil. Trans.*, 1724, 33-34, 15-25. In the original edition of the Transactions, Woodward's article is in Latin and the name of Diesbach is not mentioned. In the later, uniform edition the article is in English, and the name of Diesbach is given, in a foot note, as the German referred to.—B.

* *Journal of the American Chemical Society*, vol. xi., Nos. 1-2.

† The substance of this article was prepared as an appendix to a commercial report, but has not been printed heretofore in any scientific journal.—A. A. B.

Potassium Ferrocyanide.

Macquer (1750—60?) first made ordinary yellow prussiate of potash (potassium ferrocyanide) in the crystalline form by treating prussian blue with a concentrated solution of caustic potash.

Beaumé in 1773 proved the presence of iron in the same salt. The fact that iron was an essential ingredient of the salt remained for a long time unknown; as the proportion of iron varied in blue from different sources it was regarded as an impurity and many attempts were made to prepare a blue free from iron. Berthollet (1800—1806) determined the iron quantitatively.

The researches of Gay Lussac, in 1814, first placed the composition of prussian blue and its related substances upon an intelligible basis by showing that they all contain the radical cyanogen, a compound of carbon and nitrogen (CN) which combines with hydrogen to form an acid and with metals to form simpler or complex cyanides, of which latter prussian blue, ferric ferrocyanide, $(Fe_7(CN)_{18})$ is a good example.

This knowledge at once led to inquiries into the chemistry of the commercial manufacture of yellow prussiate of potash, a process which had previously been purely empirical.

The researches of Liebig led to the general theory at present accepted, namely, that potassium cyanide is the first product of the fusion of nitrogenous animal matters with potash, and that the yellow prussiate found in the liquor after leaching the fused mass results from decomposition occurring between potassium cyanide and a compound of iron, generally ferrous sulphide, which is formed in the fused mass by action of metallic iron upon the sulphur of the animal matters. In proof of this view potassium cyanide can be extracted by alcohol from the fused mass previous to the addition of water.

Muspratt, in 1820 (*loc. cit.*) obtained by direct lixiviation of the fused mass crystallised yellow prussiate, which had been obtained previously, by the method of Macquer, from prussian blue.

Mackintosh in 1824 used closed pots for fusion and applied mechanical stirrers.

Gautier (*J. de Pharm.*, 1827, 11) suggested in 1827 and Gentile (*Dingl. pol. J.*, cxxix., 352) in 1835 practically applied the use of raw animal matter instead of charring it before fusion with potash, as had been done previously.

Naumann in 1837 allowed the flame to play directly upon the fused materials.

Up to this time the large loss of nitrogen during fusion and the small yield of ferrocyanide with respect to the theoretical yield (never more than one-third, generally much less) seems to have attracted comparatively little attention. But the increasing demand for the prussiates in dyeing, and the relatively greater cost of animal waste drew attention to the chemical problem involved in preventing this escape of nitrogen. It was found that the nitrogen was volatilised largely during fusion, as ammonia or organic bases, and the collection and utilisation of these was attempted.

Kuhlmann in 1838 (*J. pr. Ch.*, xxvi., 410) discovered that when ammonia was passed over red hot charcoal, cyanogen and ammonium cyanide were formed, and by using a mixture of charcoal and potash for absorption he obtained potassium cyanide.

The idea of obtaining cyanides by passing ammonia over hot carbon, however, was probably of earlier origin.

Jaquemyn, applying this idea, passed the vapours from the prussiate pots over hot charcoal to obtain cyanides, and Berry (*Eng. Pat.*, Jan. 21, 1840; *Jsb. chem. Tech.*, 1858, 184) patented the same principle.

These facts relating to the conversion of ammonia into cyanides by the action of hot carbon are of interest as showing the development of chemical ideas upon the subject of cyanogen. They had their origin, however, mainly in the practical experience of the prussiate manufacture, with its waste of nitrogenous vapours. Whatever interest they may have in connection with the history of

the subject, they probably would not have led to the idea of atmospheric nitrogen as a source of cyanogen, except for another discovery originating also in an industrial process.

Cyanogen from Atmospheric Nitrogen.

Zinken in 1813 (*J. pr. Ch.*, xxv., 246) had found a mass of fused salt mixed with carbonaceous matter in the lower part of a furnace at Rothebütte, which he partly examined and supposed to be principally chlorides. Koch (*loc. cit.*) found a similar mass at Königshütte in 1819. Berthier (*Jsb. chem. Tech.*, 1879, 28) also in 1826 remarked the presence of potassium carbonate as fused salt in the lower part of an iron furnace. No one seems to have tested these deposits or exudations for cyanogen until Daves in 1835 announced the existence of potassium cyanide in them. No quantitative determination was made.

In 1837 Neilson first introduced the use of the hot blast at the Clyde iron furnaces. Shortly afterwards,* a peculiar exudation of fused salt which hardened on reaching the air to a white, opaque mass was noticed upon the walls of the furnace near the boshes. The substance was regarded with much curiosity, and it is related by Clark, who made the first analysis of the product, that its alkaline character was soon discovered by the workman and that it was used by the wife of one of them, for a time, as a substitute for soap in washing clothes.†

Clark's analysis showed it to contain potassium cyanide 43·4 per cent, potassium carbonate 45·8 per cent. No ferrocyanide was present. The mixture gave no blue colour on addition of hydrochloric acid, but yielded a blue precipitate when ferrous sulphate (copperas) was added previous to the addition of the acid in excess. This furnace went on producing potassium cyanide for three years from this time.

Zinken and Bromeis (*J. pr. Ch.*, xxv., 246) found in the bottom of a hot blast charcoal furnace at Magdesprung in the Harz a carbonaceous mass containing iron and lead and a saline matter, which, on lixiviation, yielded the following potassium salts, namely, ferrocyanide, cyanide, carbonate, silicate, and manganate. A similar substance was noticed by Redtenbacher (*R. W.*, *loc. cit.*) in a hot blast furnace at Mariazell in Styria. Potassium cyanide was produced so abundantly in this case that it was sold commercially for galvanic gilding. The substance was found at the light hole, where the gases issue, and also in the pipes through which the gases pass from the furnace to the stove.‡

Bunsen and Playfair (*Report of British Association*, 1845) made an elaborate investigation of a furnace at Alfreton which yielded cyanides. The production of the substance was so abundant that it was estimated to amount to 224·7 lbs. in twenty-four hours. A hole was made in the front wall of the furnace, two feet nine inches above the tuyere or blast pipe, and the gases from that point were drawn off through a pipe for examination. Fumes of potassium cyanide escaped with the gases and condensed in the tube. Cyanides were obtained only from the lower part of the furnace; above the boshes none

* Probably produced more copiously in consequence of the action of the hot blast, as the circumstance had been only once reported before and has since been a common phenomenon of hot blast furnaces. Neilson had used the hot blast in iron furnaces as early as 1828, however. See "Bauer's Metallurgy of Iron," p. 175.—B.

† *Pogg. Ann.*, xl. 315; *Dingl. pol. J.*, lxxv., 466.
‡ I have, in my own experience, seen two cases of cyanide produced in blast furnaces. One from an anthracite furnace as an exudation from the wall below the boshes, the other from a furnace (at Irondale, West Va.), using coke, both, of course, hot blast furnaces. In the latter case no cyanides appeared upon the wall of the furnace, but a heavy, stony, grayish deposit formed in the downcast pipe through which the gases passed to the stove. It accumulated rapidly, forming a deposit like limestone in appearance, which threatened to clog the pipe and had to be broken away from time to time. Both samples were examined qualitatively, and found to be rich in cyanides. The gray colour of the second sample was probably due to coke dust. The mass was probably formed from spray or vapour of fused potassium cyanide, which, passing out of the furnace, condensed and solidified upon the wall of the pipe where it first became chilled, binding together, as it hardened, the furnace dust which accompanied it.—B.

were found. These chemists believe that cyanides were produced only at a temperature corresponding to that at which potassium oxide gives up its oxygen to carbon. In the higher parts of the furnace cyanogen acts as a reducing agent and is destroyed by oxygen from the ores. When cyanides fall as low as the tuyere, on the other hand, they are burned, according to these authorities, by the blast of air. The conditions necessary for their production, therefore, are a reducing (deoxidising) atmosphere or presence of hot carbon, and a temperature of the degree above mentioned.

Gases drawn from the furnace, as described above, had the following composition:—Nitrogen, 58.05 per cent; carbonic oxide, 37.43 per cent; hydrogen, 3.18 per cent; cyanogen, 1.34 per cent. These figures correspond to nitrogen 79.2 per cent, oxygen 22.8 per cent (instead of 20.08 per cent; oxygen corresponding to water found in the gases is deducted). There is evidently here a deficiency of nitrogen as compared with ordinary air. At two feet above the tuyere no oxygen nor carbonic acid was found in the gases.

R. F. Smith (*Ysb. chem. Tech.*, 1879, 44) in 1865 found a compound oozing from the crevices of an old blast furnace at Kilmarnock, which on analysis yielded 21.45 per cent potassium cyanate, 47.73 potassium cyanide, 10.13 per cent potassium carbonate.

A. v. Kerpely (*CHEM. NEWS*, 1865; *Ysb. chem. Tech.*, xi., 54) describes the escape of a quantity of fused salts, chlorides, and cyanides, from the slag hole of the blast furnace of Alsó Sajón in Hungary, just before the escape of the slag.

(To be continued).

NOTICES OF BOOKS.

The Maybrick Trial: A Toxicological Study. By C. MEYMOTT TIDY, M.B., F.C.S., and RAWDON MACNAMARA, F.R.C.S.I. London: Baillière, Tindall, & Cox.

INTENSE as was the sensation stirred up by the Maybrick trial, when the opponents of capital punishment, out of pure humanitarianism, threatened the Home Secretary with violence, the case presented little to excite the interest of chemists. It was not asked whether the right tests had been applied for the detection of the poison, whether there had been any neglect, oversight, or want of skill on the part of the experts employed for the prosecution. It is painful, we must add parenthetically, that experts are still retained for the prosecution or for the defence, instead of being employed by the court to explain the scientific phase of the question just as does the judge expound its legal aspects.

But this we let pass. No one denied that arsenic was discovered in the viscera, the flesh, &c., of James Maybrick. But the defence contended, and contends yet, that the quantity of arsenic found in the body, $\frac{1}{10}$ grain, or according to Prof. Stevenson $\frac{1}{10}$, was insufficient to cause death, or, at least, was very much smaller than the minimum quantity of arsenic which is recorded to have proved fatal. Further, it was shown that the deceased had been in the habit of dosing himself, and had, amongst other medicines, made use of arsenic.

Our authors further contrast the symptoms from which Mr. Maybrick actually suffered with those which ought to have appeared had he been under the influence of a fatal dose of arsenic. Supposing these two lists of symptoms to have been fairly enumerated and accurately described—a point on which our opinion is worthless—Dr. Tidy seems quite justified in saying that “everything, in short, it would seem, was present that ought to be absent, and was absent that ought to have been present, were it a case of arsenical poisoning,” and again, “the symptoms are not even consistent with arsenical poisoning.”

It will be observed that the authors lay more weight on

the evidence given by the witnesses for the prosecution at the coroner's inquest and the magistrate's inquiry than that actually produced at the trial. These remarks refer especially to the post mortem appearances. Dr. Humphreys before the coroner testified that there were patches of redness in the bowels, but made no mention of “petechiæ.” Two months later, at the trial, the same witness supplemented his statement by speaking of “a dotted condition of the stomach, the dots appearing like flea-bites.” Drs. Tidy and Macnamara here disclaim the inference which doubtless would be drawn in a certain quarter, viz., that “Dr. Humphreys had been looking up the subject of arsenical poisoning and possibly came across a drawing representing the usual condition of the stomach in such cases.” Here we are forcibly reminded of one of the defects of our system of obtaining the evidence of experts by examination and cross-examination. Such a witness may, we submit, easily forget some important fact, and if he afterwards wishes to correct his omission he is accused of inventing something to save his own credit and bolster up his case. Hence it would be much better if, instead of the catechetical method, scientific witnesses were required to give in a systematic written report, from which they could not depart.

Dr. Tidy is fully justified in insisting that the distribution of arsenic in the liver or in the intestines generally is anything but uniform. He quotes approvingly the late Dr. Letheby's advice: “Never examine a portion of the liver for a poison until you have mashed up the whole of it first.” Had Prof. Stevenson acted on this principle the sum total obtained might have been found less, or possibly much more than what he calculates.

If we remember rightly, in some cases where the ingestion of arsenic had been prolonged or was of old standing some of the poison was found to have accumulated in the brain—a part which, in this case, does not seem to have been submitted to analysis.

We may further ask whether it is prudent in toxicological inquiries to turn attention to the detection of one poison only, when possibly more than one may be present.

The “study” before us is drawn up with great ability, and confirms our impression that, whether as an expert witness or in his new capacity as a barrister, Dr. Tidy will prove a formidable antagonist.

CORRESPONDENCE.

GLASER'S ALCOHOL METHOD FOR IRON OXIDE AND ALUMINA DETERMINATION.

To the Editor of the Chemical News.

SIR,—A number of trials of the above method—which I have conducted in accordance with the directions given in *Zeitschrift für Angewandte Chemie*—have convinced me of its superiority as compared with the old processes involving the use of acetic acid. But it seems to be characterised by an imperfection that I should like to see removed if possible:—the liability, namely, of traces of the Fe and Al oxides to escape being collected on the filter. Whether from incomplete precipitation or from dissolving by the washing, a slight additional precipitate frequently shows itself in the filtrate and washings when boiled, and this necessitates re-filtering. I can never feel sure of having the whole of the iron oxide and alumina on the filter till after boiling the filtrate; and I sometimes find that traces of precipitate will appear even in the second filtrate when made alkaline and boiled.

I should be glad to know whether any of your readers have had similar experience, and whether they have been able to adopt any modification of the process that obviates the difficulty.—I am, &c.,

A.I.C.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 3, July 21, 1890.

New Researches on the Relative Stability of Salts, whether Alone or in Presence of Water. Salts of Aniline.—M. Berthelot.—This is in reality a thermo-chemical paper. The author takes the formation-heat of salts, referred to the solid state, as the measure of their relative stability. He compares the formation-heat of the properties of the aniline salts possessing a certain stability, such as the sulphate, nitrate, or chloride, with the unstable salts, like the acetate and the benzoate.

Formation-Heat of Certain Amides.—MM. Berthelot and Fogh.—The formation of the anilides from the solid and the gaseous base liberates more heat than that of the corresponding amides, a circumstance correlated with a greater stability as against the decomposing action of water. This stability results also from another cause acting in the same direction, the slight formation-heat of the aniline salts.

The Sensitiveness of Plants, viewed as Simple Reagents.—Georges Ville.—From the results given it appears that by means of beer-yeast it is possible to recognise the presence of 0.0005 grm. of phosphate in 1 litre of water, which corresponds to 5-10,000,000ths of the weight of the liquid. But agricultural plants are also reagents of an extreme delicacy and accuracy. The author gives as an example the sugar-cane, the dominant food of which is calcium phosphate. With the complete manure the cane gives a harvest of 57,000 kilos. per hectare. If we omit the phosphate the yield is only 15,000 kilos. Hence 600 kilos. superphosphate, containing 90 kilos. phosphoric acid, determine an excess of crop of 42,000 kilos. per hectare, which represents 70 times the weight of the phosphate and 466 times the weight of the phosphoric acid. If referred to the 4,000,000 kilos. of vegetable soil covering the surface of a hectare, the phosphate represents less than 1-6000th part of the weight of the soil and the phosphoric acid less than 1-40,000th. The author hopes to fix the limits of this method.

Researches on the Double Titanium, Tin, and Copper Phosphates.—L. Ouvrard.—Titanic acid dissolved in melted potassium phosphate yields two sorts of products. If relatively little titanic acid is employed, and if the mixture is slowly cooled, we obtain PO_5TiO_2 in cubo-octahedra, without action on polarised light. If the proportion of titanic acid is increased the result is a potassium phosphotitanate, $3\text{PO}_5\cdot 4\text{TiO}_2\cdot \text{KO}$, in small, nearly cubic crystals, strongly double-refractive. Stannic oxide furnishes products parallel to those of titanic acid. Copper oxide also, like the dioxides, yields double salts of the general formula $3\text{PO}_5\cdot 4\text{MO}_2\cdot \text{NaO}$, and $4\text{PO}_5\cdot 3\text{MO}_2\cdot 6\text{NaO}$.

Researches on Dispersion in Organic Compounds (Ether Oxides).—Ph. Barbier and L. Roux.—In examining oxides of formenic radicles the authors find that the dispersive powers B and the specific dispersive power $\frac{B}{d}$ increase with the molecular weight. Their values are almost the same for the different isomers of the same condensation in carbon. On passing from a compound to its superior homologue, the introduction of CH_2 into the mol. occasions an increase of molecular specific dispersive power = 8.2. The oxides belonging to the allyl radicle present an interesting peculiarity: in

place of varying with the molecular weight, B and $\frac{B}{d}$ have values approximately constant. The dispersive power augments as the proportion of hydrogen decreases. In the oxides containing the benzyl radicle the dispersive power diminishes as the molecular weight augments.

Certain Hydrates of Simple Ethers.—M. Villard.—The author undertakes to examine if ethers other than methyl chloride and bromide cannot furnish crystalline compounds with water. He has experimented upon methyl iodide, ethyl chloride, bromide and iodide, and methyl and ethyl fluorides. Of these bodies all except ethyl bromide and iodide have given the expected result.

On Oxygluconic Acid.—L. Boutroux.—Oxygluconic acid is not identical with glucuronic acid, notwithstanding the identity of their percentage composition:—(1) Glucuronic acid, on the evaporation of watery solution, furnishes an anhydride in large brilliant crystals fusible at 167° . Oxygluconic acid, if evaporated in the water-bath in like manner, yields merely a brown syrup which gradually blackens. (2) Glucuronic acid is dextro-rotatory; oxygluconic acid is lævo-rotatory. (3) Glucuronic acid is insoluble in alcohol, whilst oxygluconic acid is very soluble. (4) The potassium and sodium glucuronates, according to Herr Thierfelder, can be easily crystallised, whilst those of cadmium and calcium cannot. With oxygluconic acids the author has obtained the exactly opposite result. Yet oxygluconic acid approaches closely to glucuronic acid by its double function of a monobasic acid and an aldehyd.

Detection of Impurities contained in Alcohol.—Ed. Mohler.—The sulphuric acid reaction cannot serve to determine the impurities in alcohol, and it can merely serve to detect the presence of products which are colourable by sulphuric acid. Rosaniline disulphite gives an approximate idea of the quantity of aldehyd contained in a commercial alcohol if we compare it with a standard solution. Aniline acetate in an acid solution is the special reagent for furfural. Upon other solutions of aldehyds, alcohols, and ethers its action is negative. It may serve for the colorimetric determination of furfural. Potassium permanganate is reduced by pure ethyl-alcohol as well as by the impurities in question, the only difference being in the time required.

A New Process for Determining the Mineral Matter in Sugars by Means of Benzoic Acid.—E. Boyer.—(See p. 64).

The Mineral Springs of Cranson.—Ad. Carnot.—The nature of this paper is sufficiently shown by its title.

Combinations of Hæmoglobine with Oxygen.—Christian Bohr.—In company with the well-known compound oxyhæmoglobine there exist at least three others, all of which are dissociable, and have the same spectrum, but do not contain the same proportion of oxygen. There exist four oxyhæmoglobines containing respectively per grm. about 0.4 c.c., 0.8 c.c., 1.7 c.c., and 2.7 c.c. of dissociable oxygen. Hæmoglobine may combine at once with oxygen and carbon dioxide.

Vol. LXII. No. 1603.

EXAMINATION OF OILS, FATS, AND ALLIED SUBSTANCES.

By THOMAS T. P. BRUCE WARREN.

FROM the singular result obtained with sulphur chloride on poppy oil and mixtures containing this oil, I was inclined to believe that this oil was peculiar in yielding a black or very dark pasty magma; I therefore prepared a little from the seeds of the Horn poppy (*Glaucium flavum*), and from the seeds of the *Papaver somniferum*, by expression and by percolation with solvents.

As poppy oil is said to be largely used for adulterating olive oil, I thought it would be interesting to find out whether the source of adulteration was from an unknown plant, or whether the behaviour was due to changes brought about by time. Poppy oils recently made yielded light coloured products; those which had been a little time in hand yielded darker products; whereas those which had been obtained a long time ago gave black pasty magma. Similar products were obtained from mixtures containing these oils; hence the oxidation process was suggested for bringing about in a few hours what some months' ordinary exposure would require.

I give here the results obtained on poppy oils, 5 grms. being used in each case:—

No. of sample.	Sulphur chloride.		Iodine abs. per cent. Original oil.	Remarks.
	Magma.	Soluble.		
1.	6.46	1.958	131.1	Four yrs. old.
27.	6.36	1.538	135.0	
74.	6.08	2.382	92.4	Very old.
29.	6.50	0.692	135.2	Gl. fl. express.
50.	6.55	0.629	139.1	
86.	6.46	0.768	140.7	Gl. fl. by CS ₂ .

The iodine absorption shows the variation arising from oxidation. The weight of magma by sulphur chloride shows that the yield of soluble matter is increased as the total weight is reduced. Sample 74 gave a black pasty magma. Oils extracted by solvents yield less than those obtained by expression. Oils thickened by oxidation (blown oils) give less total magma than the same oils not blown.

The following results were obtained with rape oil and cotton oil:—

No of sample.	Sulphur chloride.		Iodine abs. per cent. Original oil.	Remarks.
	Magma.	Soluble.		
7.	6.03	0.606	58.4	Thickened rape.
40.	6.41	0.178	112.9	German rape.
38.	—	—	101.8	English rape.
42.	6.13	0.351	104.9	Colza.
41.	6.19	0.318	98.9	"
47.	5.87	0.833	71.6	Thickened cotton.
57.	6.18	1.514	127.5	Refined "
22.	6.22	1.397	118.7	"
21.	6.28	1.300	112.4	Crude "

The conclusion is that the thickened oils yield less magma than the same oils not thickened or oxidised. The product from the former is darker in proportion to the extent of oxidation, and from the consequent loss of glycerin the soluble extract is greater. In addition to these remarks, cotton oil not thickened gives a very large proportion of soluble matter, and this is probably not due entirely to changes introduced by refining, for the crude oil product also yields a large proportion of soluble matter

to CS₂. Experiments with sulphur chloride on sample 47, as regards the soluble matter, show that oxidation has rendered some of the oil insoluble.

As a general rule, the drying oils give the greatest yield of total magma, and which is for the same oil nearly proportional to the iodine absorption. Oils extracted by solvents give a smaller yield of magma and have a lower iodine absorption than the same oils drawn by pressure. The results obtained on linseed oil and walnut oil (30) from the decorticated nuts were as follows:—

No. of sample.	Sulphur chloride.		Iodine abs. per cent. Original oil.	Remarks.
	Magma.	Soluble.		
3.	6.36	0.844	162.4	By CS ₂ .
46.	6.34	0.936	162.6	"
44.	6.45	0.724	170.1	Pressure, hot.
45.	6.57	0.603	176.3	" cold.
81.	—	—	172.7	"
30.	6.55	0.536	150.6	Walnut, by CS ₂ .

Oils drawn by hot pressure have a low iodine absorption; this is due to the liability of such oils to oxidise in manufacture.

Boiled linseed oil gives a dark pasty magma, similar to old poppy oil; this might have been expected, if we bear in mind that the object in boiling is to obtain an oxidised oil which assists in drying.

CHEMICAL COMPOSITION OF THE OILS OF WINTERGREEN AND BIRCH, AND THE CHARACTERS OF THE SYNTHETIC OIL OF WINTERGREEN.

By Prof. Dr. FREDERICK B. POWER,
University of Wisconsin.

(Continued from p. 68).

Chemical Examination of the Oils.

I. Natural Oil of Wintergreen.—400 grms. of this oil were decomposed by heating on a water-bath for about two hours, in a flask provided with a reflux condenser, with a solution of 200 grms. of caustic potassa. The liquid was then further diluted with water, and distilled until oil drops ceased to come over. This distillate was then again separately distilled, in order to bring the drops of oil, or the terpene, within a smaller compass, and thus more easily effect its separation from the water. The liquid or terpene so obtained had precisely the same properties as that isolated by me on a former occasion, and was also in this instance only contained in the original oil to the extent of a small fraction of one per cent. It is a somewhat viscid, yellowish liquid, possessing to a marked degree the pepper-like odour described by Cahours, and has a specific gravity of about 0.940, as recorded in my former paper.*

The hydrocarbon separated by Messrs. Trimble and Schroeter from the oil of wintergreen, as also from the oil of birch, by extracting the saponified oil with ether or petroleum ether, they state to have the following remarkable properties. "The products both solidified on standing for a day or two, or at once on cooling. That from wintergreen commenced to melt at 10° C., and was clear at 15° C., but the hydrocarbon from birch did not commence to melt below 18° C. and was clear at a few degrees above that temperature," &c.

In connection with this statement I may say that the terpene obtained by me from oil of wintergreen, in the manner above described, does not separate any solid matter when kept for three hours in a freezing mixture at a temperature of 10° C., but remains perfectly transparent. It is difficult to believe that a pure terpene, as separated

* Pharm. Rundschau, 1888, p. 209

from a volatile oil, would solidify at any such temperature as that above noted.

Notwithstanding the probability that the substance experimented with by Trimble and Schroeter was a mixture, from their vapour density determination of it they assign to it the molecular formula $C_{15}H_{24}$. In the latter determination they appear to have employed the method of Victor Meyer, as they state that a certain amount of the substance displaced a certain amount of air. Why they should have taken the pains to record these figures, without at the same time giving the other physical constants which enter into the calculation of the molecular formula, it is difficult to conceive; for such an isolated statement does not permit of a re-calculation of their results, and can therefore of itself possess no scientific value.

In order to confirm, if possible, the correctness of this statement, I have also attempted to obtain the vapour density of the liquid separated by me from the wintergreen oil. It was first deprived as much as possible of any adhering moisture by allowing it to remain for some time in contact with freshly ignited potassium carbonate, and the method of Victor Meyer was then employed,* with the use of a paraffin-bath. In the first determination the temperature of the bath was somewhat above $300^{\circ}C$, and in the second the temperature was somewhat above the boiling point of mercury, but in both instances the liquid under examination was observed to vaporise very slowly, and at the same time to become completely decomposed, with the separation of a tarry substance. Concordant results could therefore not be obtained, nor could they under such circumstances be regarded as possessing any scientific value.

In my former paper† the results of such a determination, as recorded in the *Neues Handwörterbuch der Chemie*, Band III., p. 343, were noted, where the boiling point of this terpene is stated to be $160^{\circ}C$, and its vapour density 4.74, which agrees with the molecular formula $C_{10}H_{16}$. Although having had previously no occasion to doubt the accuracy of this statement, it would now not seem possible that it could be correct as applied to the substance separated by me on different occasions from true wintergreen oil, for its viscous character would indicate a much higher boiling point, and it certainly cannot be vaporised without considerable decomposition. That it may belong to the class of polyterpenes is possible, and the application of Raoult's method‡ for the determination of its molecular weight might be attended with success, but the very small amount of substance available has prevented my further examination of it in this direction.

The original, strongly alkaline liquid remaining in the flask after the distillation of the terpene was subsequently shaken with ether, but the latter, on evaporation, afforded simply a small amount of a dark coloured resinous substance. From the alkaline liquid the salicylic acid was then separated by means of pure hydrochloric acid, and, after being collected on a strainer, and washed, was recrystallised from boiling water. The further examination of this acid will be subsequently referred to.

II. *Natural Oil of Birch.*—This oil, as previously stated, was obtained from Mr. C. M. Driggs, of White Haven, Pa., who had supplied Messrs. Trimble and Schroeter with the oil examined by them, and who had assured me of its perfect purity. Its low specific gravity, 1.1606 at $15^{\circ}C$, led me, however, in the beginning to believe that it possessed a somewhat abnormal chemical composition, although it was considered that this might indeed be due to the fact that it contained a considerable amount of a terpene, especially since Trimble and Schroeter have stated this oil to contain more of the latter than the oil of wintergreen. It will be remembered,

on the other hand, that the original oil had no action on polarised light.

Three hundred grms. of the oil in question were treated in a manner similar to that described in connection with the oil of wintergreen. After the process of saponification had been completed, a considerable amount of a light liquid was observed on the surface of the alkaline mixture, which was separated as completely as possible by means of a pipette, and placed in contact with freshly ignited potassium carbonate. The strongly alkaline liquid in the flask was then further diluted with water, and distilled, in order to recover the remaining portion of the hydrocarbon. On finally shaking the alkaline mixture contained in the distilling vessel with ether, and allowing the latter to evaporate, only a small amount of dark coloured, resinous matter was obtained, as in the case of the pure oil of wintergreen.

The liquid separated in the above manner from the oil of birch amounted to 13.5 grms., or 4.5 per cent of the original oil. The amount actually present, with consideration of a little unavoidable loss, was therefore probably about 5 per cent. Its specific gravity was 0.8066 at $15^{\circ}C$, and upon distillation it was found to possess no constant boiling point. It commenced to boil somewhat above $100^{\circ}C$, and about one-fourth of the liquid distilled over below $220^{\circ}C$, about one-half between the temperatures of 220° and $270^{\circ}C$, and the remainder, which was allowed to remain in the distilling flask, was dark coloured and somewhat viscid. The portion of liquid distilling below $270^{\circ}C$ was perfectly colourless, and, as would naturally have been inferred by the behaviour of the original oil, was without any action on polarised light. It was then subjected to analysis, with the following result:—

I. 0.1115 gm. of substance gave 0.1365 gm. H_2O = 0.0152 gm. H, or 13.63 per cent H; and 0.3290 gm. CO_2 = 0.0897 gm. C., or 80.45 per cent C.

After once redistilling over sodium, it was again analysed.

II. 0.1815 gm. of substance gave 0.2205 gm. H_2O = 0.0205 gm. H, or 13.49 per cent H; and 0.5420 gm. CO_2 = 0.1477 gm. C., or 81.37 per cent C.

	I.	II.
C.. ..	80.45 per cent.	81.37 per cent.
H	13.63 "	13.49 "
	94.08	94.86

It was evident from these results that the liquid in question was a mixture of hydrocarbons, containing some oxygenated bodies, which I did not attempt to completely remove, as its character had already become sufficiently revealed.

That it was a mixture, and not a simple body, was clearly shown by the inconstancy of its boiling point, and the latter, as well as its optical inactivity and low specific gravity, also proved quite conclusively that it was not a terpene. It was furthermore found not to be acted upon by powdered iodine, nor by strong nitric acid or sulphuric acid, and possessed, especially when allowed to evaporate on the hand, the unmistakable odour of petroleum. All the characters of the substance, both chemical and physical, have indeed conclusively established the fact that it is simply kerosene oil. That the gentleman who supplied me with this sample of the oil of birch believed it to be perfectly pure, I have not the slightest doubt, as it was not distilled by himself, but an enquiry as to how such a contamination could occur has elicited neither any explanation nor a reply. In any event it is not probable that the opinion would be advanced that petroleum is a natural constituent of the oil of birch, even though birch trees may grow in close proximity to the oil wells of Pennsylvania.

The chemists of Messrs. Schimmel and Co., Leipzig, have found this adulterant in both cassia oil and citron-

* *Berichte der Deutsch. Chem. Ges.*, 1878, II., p. 2253.

† *Pharm. Rundschau*, 1888, p. 209.

‡ *Comptes Rendus*, Tome 64, p. 1517; 95, p. 188; 96, p. 1653; as also *Pharm. Zeitung*, 1889, p. 617.

ella oil,* but I believe the use of petroleum for the adulteration of oil of birch has not hitherto been observed. In consideration, however, of this fact, it would seem not unreasonable to suppose that the solid substance separated from the liquid obtained by Trimble and Schroeter from oil of birch might have consisted of a paraffin, rather than a terpene, for, as I have shown, the terpene separated from a pure oil of wintergreen does not possess any such properties as they describe. They also mention the fact that by the distillation of the saponified oil of birch they obtained but 0.084 per cent of the so-called terpene, whereas by extracting the alkaline mixture with petroleum ether 0.447 per cent was obtained. If the substance in question were really a terpene, at least such as those at present known to occur in volatile oils, it should not have been impossible to have recovered it by distillation with water.

The results of this investigation may also serve to throw some light upon the following remark of Dr. Squibb, in his paper on "The Oil of Wintergreen as a Therapeutic Agent" (*Ephemeris*, vol. iii., 1887, p. 953), "Oil of birch is said by Pettigrew to be pure methyl salicylate, but this can hardly be true of the oil accessible in the markets, since several authorities state that in distilling the oil the distillation begins many degrees below the permanent boiling point." In the writer's opinion there is now no reason to doubt but that the oil of birch hitherto found in commerce, having the characters thus referred to, was not a pure natural product, but, like the specimen examined by me, was contaminated to a greater or less extent with petroleum.

The examination of the oil of birch by Mr. Pettigrew† was conducted under my observation in the Chemical Laboratory of the Philadelphia College of Pharmacy, and, although several years have since passed, I can distinctly remember that after the saponification of the oil, and subsequent distillation with water, no trace of oil drops could be observed in the distillate, so that if any terpene or other hydrocarbon were present it could not have amounted to more than very insignificant traces.

The small sample of oil of birch now in my possession, which represents a portion of that examined by Mr. Pettigrew, is not sufficient to admit of confirming his results by the method of saponification and subsequent distillation. I have already shown, however, that this oil possesses a quite constant boiling point (219–221° C.), and that it is completely devoid of action on polarised light. I have also recently subjected it to ultimate analysis, with the following result:—

0.2460 grm. of substance gave 0.1180 grm. H_2O
= 0.0131 grm. H, or 5.32 per cent H; and 0.5665 grm.
 CO_2 = 0.1545 grm. C, or 62.80 per cent C.

Calculated for methylsalicylate:—

	$C_9H_8O_3$	Found.
C	63.16 per cent	62.80 per cent
H	5.26 "	5.32 "
O	31.58 "	31.88 "
	100.00	100.00

A pure methyl salicylate could hardly afford more closely agreeing analytical numbers, and I must therefore maintain my former opinion, in confirmation of that expressed by Mr. Pettigrew, that the natural oil of birch consists of pure methyl salicylate, and is not perfectly identical, either chemically or physically, with the natural oil of wintergreen. Competent observers, such as Dr. Squibb and Professor Maisch, are, moreover, capable of recognising a distinction in the odour of the two oils.‡

Messrs. Trimble and Schroeter have endeavoured to support their argument that the oil of birch does not

consist of simple methyl salicylate by the statement (*loc. cit.*, p. 398) that "it is the exception when a product as simple as oil of birch is described by Pettigrew to be is produced in nature, such substances are more frequently found to be made up of a series of compounds."

It is very evident from this expression that the authors have either forgotten or are unaware of the fact that oil of birch is regarded as belonging to the class of so-called ferment oils,* and that it is the rule, not the exception, that such oils are quite simple bodies, or at least are not made up of a series of compounds. As a prominent example of this class it is only necessary to mention the volatile oil of mustard, consisting of the sulphocyanate of allyl, C_3H_5-NCS , and although this oil in its pure and natural condition may sometimes contain small amounts of carbon bisulphide, the presence of the latter has been quite satisfactorily proved to be due to a secondary reaction of the acid potassium sulphate formed in the fermentative process on the mustard oil itself.†

As another example of an oil of simple composition of this class, which is familiar to most chemists, may be mentioned the oil of bitter almonds, consisting of benzaldehyde, C_6H_5-COH , with small amounts of hydrocyanic acid. Even the relatively small amount of the latter present in this oil can not be set forth as an argument in favour of its complex character, for, in the light of recent investigations, the product of the reaction of emulsin on amygdalin in the presence of water is a simple chemical compound, which has received the appellation of benzaldehydcyanhydrin—

After the separation of the petroleum from the oil of birch, as previously described, the alkaline mixture was treated with pure hydrochloric acid, and the salicylic acid thus obtained, together with that from the oil of wintergreen, will be subsequently referred to.

(To be continued).

COLORIMETRIC METHOD FOR ESTIMATING THE MORPHINE STRENGTH OF LAUDANUM AND OTHER PREPARATIONS OF OPIUM.

By S. J. HINSDALE, Fayetteville, N.C.

PREPARE an official tincture of opium with assayed opium. You will know the morphine strength of this tincture.

Make three dilutions of it with dilute alcohol, as follows:—

One 3 parts tincture and 1 part dilute alcohol.
One 2 " " " " " "
One 1 " " " " " "

Put 12 c.c. of the tincture and of the dilutions in vials, and add to each 12 c.c. dilute alcohol—cork well and keep them as standard dilutions of known strength. Label them Nos. 1, 2, 3, and 4. Let the dilute official tincture be No. 1. Dissolve 0.04 gramme potassic ferridcyanide in 500 c.c. water and add to it fifteen drops *Liquor Ferri Chloridi*. Call this *Ferridcyanide Mixture*. (This must be freshly prepared, as it will be partly decomposed in a few hours). Prepare it in a glass stoppered bottle with water entirely free of iron.

Place four 50-c.c. clean glass tumblers or wine-glasses on a white surface and deliver with a pipette (about one-third filled) one drop of the dilutions in the glasses, commencing with No. 4 (the weakest), blowing out the

* See Schimmel and Co.'s *Bericht*, April, 1889, pp. 10 and 20; also *Pharm. Rundschau*, 1889, pp. 122 and 269-270.

† *Amer. Journ. Pharm.*, 1883, p. 385.

‡ *Ibid.*, 1885, p. 586, and *Ephemeris*, vol. iii., 1887, p. 953.

* See Procter in *Amer. Journ. Pharm.*, 1843, vol. xv., p. 246.

† *Pharm. Zeitung*, 1887, p. 543; and *Pharm. Rundschau*, 1887, p. 266.

‡ *Pharm. Zeitung*, 1887, p. 694; *Pharm. Journal*, 1887, p. 537; and *Proc. Amer. Pharm. Assoc.*, 1888, p. 484.

pipette after each dropping. (The pipette should be about four inches long, and made of $\frac{1}{4}$ -inch tubing, and should deliver drops of the dilutions weighing about 0.016 gramme or $\frac{1}{2}$ grain. To test the pipette, see how many drops will balance a 0.200-gramme weight. The reason for using so small a drop, and for diluting the tincture, is because a full drop of the undiluted tincture would develop too deep a blue colour).

Now add to each glass about 5 c.c. ferridcyanide mixture (it is convenient to use a homœopathic vial as a measure), and in about one minute add 15 or 20 c.c. water, and observe the shades of colour. This observation must be made *within five minutes*, as the air and light will soon cause all to be uniformly blue.

By comparison with the shades of colour produced by these standard dilutions, you can easily estimate the strength of any sample of laudanum with much accuracy. The sample must, of course, be diluted with an *equal part of dilute alcohol*. The presence of tannin interferes with this method, but opium does not contain tannin. Tannin is easily detected with a solution of a salt of iron. The ferridcyanide mixture *must be freshly prepared* and the glasses must be *clean and clear*, as the slightest bluish tinge interferes. Wash them with caustic soda and then with hydrochloric acid and rinse if they are soiled with Turnbull's blue.

The ferridcyanide mixture is probably the best confirmatory test for morphine. If one drop of water containing 0.00001 gramme of morphine is mixed on a white slab with one drop of the ferridcyanide mixture a blue colour will be developed within *one minute*. With water alone the mixture will become of a bluish shade in about *ten minutes*, owing to the action of air and light.

To estimate the strength of vinous or aqueous compounds of opium, they must be brought to about the same specific gravity as the "standard dilutions" with alcohol, that the drops may be uniform in size.

THE DRY ASSAY OF TIN ORES.*

PART I.

By HEINRICH O. HOFFMANN,
Assistant Professor of Mining and Metallurgy.

(Continued from p. 59).

IV. The Assay in Detail.

THE different methods of assaying black tin in the dry way may be grouped under two heads:—

a. Those which aim at finding the actual amount of tin contained in the ore.

b. Those which determine approximately how much metallic tin can be recovered by treatment on a large scale.

The first class divides, according to the character of the resulting metal, into methods (a) yielding a button of metallic tin, and those (b) yielding an alloy of tin with copper or iron.

Class A (a).

1. *The German Method of Assay.*—This method, as given by Kert† and by Balling‡, is as follows:—

Five grms. of ore are intimately mixed with 0.75 to 1 gm. of charcoal dust, and charged into a clay crucible; on top are placed 12.5 to 15 grms. of black flux (or the substitute, two parts of potassium sodium carbonate and one part of flour), with 1 to 1.25 grms. of borax glass, then a salt cover, and finally a piece of charcoal. The crucible is covered, heated in a muffle or a pot-furnace at a moderate, gradually increasing temperature until the boiling has ceased, and then for from half to three-

quarters of an hour at a white heat. The crucible is removed from the fire, broken when cool, and the tin button weighed.

The process that takes place is simple. With the gradually rising temperature the tin becomes reduced to the metallic state by the charcoal, with which it has been intimately mixed, while any ferric oxide contained in the cassiterite will be reduced only to ferrous oxide and taken up by the slag. At a certain stage the black flux, or the flour of the substitute, becomes decomposed, the result being that finely divided carbon is uniformly distributed through the flux. This hinders any particles of stannic oxide from combining with the alkali when fusion begins, and assists the reduction of particles of ore that have not been completely converted into metal by the charcoal. The active fluxes—potash, soda, borax—combine with the gangue contained in the ore and form a slag; the neutral salt cover assists in making the slag liquid, and thus favours the collecting of tin particles, and prevents prills from adhering to the sides of the crucible; the charcoal finally, being slowly consumed, furnishes the reducing atmosphere above the charge. When the reactions have taken place and the fusion has become tranquil, the different parts settle according to their specific gravities: at the bottom, the tin button; next, the borax slag; above this the salt slag; any unconsumed charcoal remaining on top.

In carrying out the assays the above method was closely followed. The crucibles were size F, of the Battersea make; the charcoal was made to pass a 40-mesh sieve before it was mixed with the ore; the black flux substitute—two parts of potassium carbonate and one part of flour, to which 1 gm. of borax glass had been added—was used for flux.

The charge melted readily, and the slag was very thin, showing when cool a smooth surface. The crucible was not corroded by the fluxes, and no particles of tin were visible at the sides. On breaking it the salt slag separated readily from the borax slag, the former being coarsely crystalline and brittle. It had a resinous lustre, was subtranslucent, and of a dark purple colour. This colour must be attributed to finely divided carbon resulting from the charcoal on top. On dissolving the slag in water, a fine black slime remained. This proved to be pure carbon, and the solution showed only a trace of iron. The borax slag was vitreous, hard, subtranslucent, and olive-green. The button separated well from the slag, was white, bright, easily cut, and malleable; scrapings were not attracted by the magnet, showing the absence of iron. The tin, however, did not all collect in the button, as usually happens with tin assays. Prills remained suspended in the slag, and some adhered to that part of the crucible in contact with it. In the assays the salt slag, the borax slag, and the lower part of the crucible were ground together and screened through a 40-mesh sieve. The scales of each set of assays were weighed together, and the fine pulp of the same set panned, and the resulting fine tin weighed. It seemed advisable to do it in this manner, because the amount of scales and siftings in the separate assays was so small that it might easily have caused an error in the results.

If the percentage of tin recovered in the assays Nos. 1, 2, 3, 67.58 per cent, and in Nos. 4, 5, 6, 67.46 per cent, be compared with the actual amount of tin present, 67.84 per cent, it will be seen that the results obtained by this method are all that could be desired. The two averages differ only by 0.12 per cent, which is also very favourable. That assays Nos. 1, 2, 3 agree accurately is mere accident. It will be seen that 67.40 per cent collected in the button, and that only 0.28 per cent was scattered through the slags and adhered to the crucible. Assays Nos. 4, 5, 6 agree within 0.2 per cent. Less tin was collected in the button than in Nos. 1, 2, 3, and the total result is slightly lower, although still very good, *i.e.*, accurate within 0.5 per cent.

Average..	3'373	67'46	3'303	66'06	0'015	0'30	0'055	1'10

To see what influence would be produced by variations of time and temperature, assays Nos. 7 to 10 were made, increasing the time to two hours with Nos. 7, 8, 9, 10, and keeping Nos. 9 and 10 hotter than Nos. 7 and 8, and these last hotter than Nos. 1 to 6.

(To be continued).

RECOVERY OF ABSORBED MORPHINE FROM THE URINE, THE BLOOD, AND THE TISSUES.*

By THEODORE G. WORMLEY, M.D., LL.D.,
Professor of Chemistry and Toxicology, Medical Department,
University of Pennsylvania.

(Continued from p. 67).

Recovery of Morphine by Amyl Alcohol.

In the following examinations in regard to the application of amyl alcohol for the extraction and recovery of morphine, Kahlbaum's alcohol was employed. It was apparently perfectly pure, and had a density, as observed by a picnometer, of 0'811, at 20° C.

Amyl alcohol is about wholly insoluble in water, but a limited quantity of water is dissolved or taken up by the alcohol. If 100 volumes of the alcohol be agitated with 20 volumes of water, after complete separation of the liquids, the alcoholic liquid will measure 109 volumes, the aqueous being reduced to 11 volumes. In other words, under these conditions one volume of water is taken up by 11'11 volumes of the alcohol, with a corresponding increase of volume of the latter liquid.

On digesting excess of finely powdered pure morphine with amyl alcohol at the ordinary temperature for some hours, with frequent agitation, one part of morphine is taken up or dissolved by about 150 parts by weight of the alcohol. Under the action of heat one part of morphine may be dissolved in about 50 parts of the hot liquid. A hot saturated solution of this kind, after cooling and standing one hour, will still contain one part morphine in about 62 parts of the alcohol; after standing twenty hours, one part in about 82 parts of the alcohol. The salts of morphine are more or less extracted from their aqueous solution by amyl alcohol, differing in this respect somewhat according to the form of salt present. On dissolving, in the form of a salt, the equivalent of 25 m.grms. pure morphine in 5 c.c. water, agitating this solution with 25 c.c. pure hot amyl alcohol, then allowing the mixture to stand for twenty hours, the clear amyl alcohol held in solution, of the morphine, as follows:—

	Amyl alcohol extracted. M.grms.	Aqueous solution retained. M.grms.
Morphine, as acetate ..	8'93	16'07
" " sulphate ..	4'2	20'8
" " hydrochloride ..	3'6	21'4

* From the University Medical Magazine

Under similar conditions, only that 25 c.c. of amyl alcohol already saturated with water were employed, the following results were obtained:—

	Amyl alcohol extracted. M.grms.	Aqueous solution retained. M.grms.
Morphine, as acetate ..	5'0	20'0
" " sulphate ..	2'8	22'2
" " hydrochloride ..	2'5	22'5

These results indicate that on extracting an aqueous solution of a salt of morphine with pure amyl alcohol, a very notable portion of the alkaloid may be taken up by the alcohol; that this proportion may be diminished by first saturating the alcohol with water, and, finally, that a greater proportion of the alkaloid is taken up when in the form of acetate than when present either as sulphate or hydrochloride.

In the extraction of morphine in its free or uncombined state from the urine, by amyl alcohol, the results are more or less interfered with by the large proportion of urea taken up by the alcohol.

On digesting excess of finely powdered urea with hot amyl alcohol, and allowing the mixture to stand some hours, it was found that the liquid still held in solution one part of urea in 78'8 parts of the alcohol.

A still more serious interference is the extraction by the alcohol of certain extractive matters of the urine, which, having a strong reducing action, may mislead in regard to some of the tests for morphine.

Cases Examined.

CASE I.—A dog, weighing 10 kilos., whose bladder had just been emptied by means of a catheter, was given, Nov. 7th, 1889, 3'0 grms. (46 grains) of pure morphine, dissolved by the aid of acetic acid in 10 c.c. water, the solution being introduced into the stomach by means of a tube.

Within ten minutes the animal became very drowsy; soon thereafter there was great stupor, but a slight noise would startle the animal. After about one hour there was great weakness or partial paralysis of the hind legs. At the end of twenty-four hours the animal was much better, the weakness of the hind legs having disappeared; but it remained more or less drowsy for fifty hours, when it was killed by being bled to death.

1. Urine.—A.—Obtained from the animal by catheterisation, two hours and forty minutes after administration of the morphine, 12 c.c. turbid urine. This was acidulated with hydrochloric acid, and then extracted by agitation with two volumes hot amyl alcohol, which had already been saturated with water. After decanting the alcohol, the aqueous fluid was rendered alkaline by ammonia, and again extracted by two volumes hot amyl alcohol, and finally washed with a fresh portion of the alcohol. The alcohol thus employed was passed through a filter previously moistened with amyl alcohol and evaporated to dryness.

The alcoholic residue was treated with a little acidulated water, the solution filtered, then rendered alkaline by ammonia, and again extracted by hot amyl alcohol. The residue from the evaporation of this alcohol was treated with a little water, a drop of acetic acid added, the liquid filtered, then concentrated to a small volume. Slight excess of ammonia was now added, and the liquid allowed to evaporate spontaneously.

On applying to this residue the principal tests for morphine, they promptly indicated the presence of a very notable quantity of the alkaloid. After washing out the crystallised urea present with a little cold water, the morphine was obtained partly in the crystalline state. The total quantity of morphine present in the residue was estimated at about four m.grms.

B.—Withdrawn by catheter twenty-two hours after administration of the morphine, 160 c.c. urine, having a strong alkaline reaction, and which strongly effervesced on addition of hydrochloric acid, due to the presence of ammonium carbonate. Evaporated the urine to 60 c.c., cooled, and strained. Extracted the strained liquid, while still acid, with about two volumes hot amyl alcohol, previously saturated with water.

The aqueous liquid, after decanting the alcohol, was treated with slight excess of ammonia and extracted by two volumes hot amyl alcohol. This was decanted, filtered, and evaporated to dryness.

Minute portions of the residue thus obtained clearly indicated, by Froehde's reagent and other tests, the presence of morphine in considerable quantity.

The residue was treated with a small quantity of acidulated water, the solution filtered, then rendered alkaline, and again extracted by hot amyl alcohol. The residue from the evaporation of this alcohol was extracted in like manner a third time by amyl alcohol.

The final residue was treated with about 5 c.c. water acidulated with acetic acid, and the filtered solution treated with slight excess of ammonia. Very quickly crystals of morphine separated, and there was finally obtained from the solution, after washing with cold water and with ether, 24 m.grms. of finely crystallised, nearly colourless morphine.

It may here be noted that on washing the urea from a residue consisting of morphine, urea, and extractive matters, with cold water, the morphine will be dissolved greatly in excess over its solubility in pure water. This excess may sometimes be recovered, in part at least, by concentrating the liquid to a small volume, adding a trace of ammonia, and allowing the mixture to stand in a closed tube for some days or longer; the morphine may then separate in the form of colourless crystals, even from highly coloured liquids.

2. The Blood.—Fifty hours after the administration of the morphine, the dog still being strongly under the influence of the drug, 300 c.c. of blood was obtained from the animal. This was treated with 500 c.c. strong ordinary ethyl alcohol, 5 c.c. of acetic acid added, and the whole frequently agitated in a strong cylinder during two days. Decanted the liquid, and pulverised the solids in a mortar, returned the mass to the liquid diluted with water to 1000 c.c. and moderately heated the mixture. The cooled liquid was strained and the solids washed and preserved for future examination (**B**).

A.—The strained liquid was concentrated, filtered, and finally reduced to 50 c.c. It was then rendered alkaline by ammonia, and extracted with twice its volume of pure hot amyl alcohol. This was separated, filtered, and evaporated to dryness; and the residue thus obtained, after solution and filtration, was again extracted by fresh hot amyl alcohol.

The residue from the second amyl alcohol extract, when treated in the usual manner, furnished 14 m.grms. morphine, chiefly in the crystalline state, but rather highly coloured.

B.—In order to ascertain whether the above albuminous solids still contained a notable quantity of morphine,

which might be recovered by a stronger acid, the mass was treated with 500 c.c. water and 10 c.c. hydrochloric acid, and allowed to stand one day. The mixture was then largely diluted with water and again allowed to stand.

As the mixture was slimy and would not strain, it was about neutralised by sodium hydroxide, then strongly acidulated with acetic acid. The liquid was then strained, concentrated, filtered, and finally reduced to 100 c.c.

This, after addition of ammonia, was extracted with hot amyl alcohol; and the residue obtained on evaporating this liquid extracted a second time by a fresh portion of amyl alcohol.

From the second alcoholic extract, 8.5 m.grms. of very nearly pure morphine were obtained.

3. Liver.—The liver was cut into small shreds, these crushed in a mortar, and extracted at a moderate heat with 500 c.c. water strongly acidulated with acetic acid.

The solution thus obtained was filtered, then reduced to 100 c.c., rendered alkaline, and extracted with twice its volume of hot amyl alcohol. The residue from this alcohol was extracted a second time, and this in turn a third time, with fresh portions of amyl alcohol.

From the final alcoholic extract, 41 m.grms. of essentially pure morphine were obtained.

4. Brain.—The brain was removed immediately after the death of the animal. It presented a rather anæmic condition, being free from any signs of congestion.

The organ was crushed in a mortar, and extracted with diluted alcohol strongly acidulated with hydrochloric acid. The final aqueous solution obtained was extracted by amyl alcohol, and the purification by the alcohol repeated a second and third time.

The final residue clearly showed the presence of morphine, but the total quantity present was very minute.

5. Stomach.—An examination of the contents and scrapings of the stomach, consisting of little else than glairy mucus, showed the presence of morphine in very minute quantity. So far as known, the animal did not vomit, nor did it take any food after the administration of the morphine.

CASE II.—Injected hypodermically into the side of a dog, weight about 10 kilos, 1.0 gm. pure morphine, dissolved by acetic acid in 10 c.c. water, the bladder of the animal having previously been emptied by means of a catheter. The animal soon showed the ordinary symptoms of the poison, but after some days fully recovered. The urine was withdrawn and examined as follows:—

a. Two hours after administration of the morphine, 20 c.c. urine of feeble acid reaction was obtained. This was directly neutralised by ammonia, and extracted by hot amyl alcohol. This liquid, after filtration and evaporation, left a residue which readily showed the presence of morphine in decided quantity. After a second extraction by amyl alcohol, and further purification, 19 m.grms. of nearly colourless crystals of morphine were obtained.

b. Five hours and a half after, the injection obtained 40 c.c. of slightly alkaline urine. This was reduced to 20 c.c., and then extracted by amyl alcohol. The residue from this extraction, when purified as before, furnished 23.8 m.grms. crystallised morphine.

c. Twenty six hours after, the injection obtained 80 c.c. urine of slightly acid reaction and sp. gr. 1.016. This, rendered alkaline by ammonia, was extracted directly by amyl alcohol. The residue obtained from this extract, when further purified, readily showed, under several tests, the presence of morphine, but repeated efforts failed to obtain it in the crystalline state.

d. Twenty-eight hours after, the injection obtained 20 c.c. urine. From this obtained very satisfactory evidence of the presence of morphine, but only in the amorphous state. The quantity present was obviously much less than in the preceding examination.

e. Seventy-two hours after, the injection obtained 60

c.c. of urine. This still clearly showed the presence of morphine, but in further diminished quantity.

f. Twenty c.c. urine obtained at the end of ninety-six hours still showed under Froehde's reagent the presence of morphine, but beyond this reaction the results were doubtful.

CASE III.—Injected subcutaneously 0.2 grm. morphine, in 10 c.c. water, into a dog. This was the same animal used in last experiment, but twelve days thereafter. Marked symptoms appeared within ten minutes.

a. Two hours after the injection obtained 28 c.c. urine. This was concentrated to 14 c.c., and extracted in the usual manner. The final residue readily showed the presence of morphine, but the alkaloid was not obtained in the crystalline state. Fine crystals of the chromate, however, under the action of potassium chromate, were obtained.

b. Five hours and a half after the injection obtained 50 c.c. urine of acid reaction and sp. gr. 1.016. This was concentrated to 20 c.c., and extracted in the usual manner. The final residue showed the presence of morphine in perhaps somewhat larger quantity than found in the previous examination, but it was obtained only amorphous.

c. From 14 c.c. urine withdrawn at the end of twenty-eight hours the final residue, after purification by ether, gave under Froehde's reagent very marked morphine reactions.

(To be continued).

THE FIXATION OF ATMOSPHERIC NITROGEN.*

By A. A. BRENNEMAN, S.B.†

(Continued from p. 73).

THE facts just given had an important influence upon chemical thought. The source of the large quantities of nitrogen combined in the cyanides thus obtained became a subject of active discussion. It was not at once admitted that the free nitrogen of the air could be taken into combination with carbon to form cyanogen under the conditions existing in the blast furnace. The tendency was, at first, rather to find the source of nitrogen in the fuel or in the ammonia of the air. But the answer was given in a series of accurate experiments which left no room for doubt, and the direct fixation of atmospheric nitrogen by hot carbon under given conditions has long been accepted as a fact in chemistry.‡

The paper of Bunsen and Playfair was read before the British Association in 1845, but to take up the discussion methodically we must go back a few years. As has been said, the production of cyanides in the blast furnace at once raised the question of the source of the combined nitrogen, and the problem suggested by the furnace was soon transferred to the chemical laboratory.

Lewis Thomson, of Newcastle-upon-Tyne, in 1839 (*Dingl. pol. J.*, 73, 281) first proved that potassium cyanide is produced when coke, potash, and iron filings are heated to a high red heat in contact with air, and he received the medal of the Society of Arts for his discovery. Priority is claimed for Defosses, who made a similar discovery about the same time at Besancon in France.

Fownes and Young (*J. pr. Ch.*, xxvi., 407) also con-

firmed these statements in 1841, using carbon prepared from cane sugar and pure potash.

Erdmann and Marchand, however, in 1842 (*J. pr. Ch.*, xxvi., 412) repeated Fownes's experiments and reported that the process was uncertain and required very exact regulation of conditions to produce any cyanides at all. They concluded that no cyanogen is produced when the materials are perfectly dry.

Berzelius (*J. b. d. fortschr. d. Chem.*, 1844, 23) remarked that these results of E. and M. agreed with the earlier results of Wöhler, in that water was shown to be necessary to the reaction. It was suggested that water plays the part of an intermediary in the reaction, first forming ammonia, which is then converted into cyanide.

Langlois (*Ann. ch. phys.*, [3] i., 117) discussed the question raised by Erdmann and Marchand. He made two experiments. 1. Moist, purified air was passed over a mixture of pure carbon and potash heated to high redness. Cyanogen was obtained. 2. Dry air under the same conditions also yielded cyanogen. The production of cyanogen in each case was tested by converting it into prussian blue in the solution obtained from the fused mass of carbon and potash. He found, however, that if a lead glazed earthen tube were used instead of a porcelain tube, no cyanogen was obtained—lead in the glaze apparently decomposing cyanogen—and he ascribes the errors of Erdmann and Marchand to this fact.

Bunsen and Playfair (*B. A. Rep.*, 1845) also attacked this question in their investigation above quoted. They passed nitrogen over a mixture of pure carbon and potash heated to high redness in a tube and obtained potassium cyanide. As the nitrogen was free from ammonia and the materials were chemically pure the origin of the nitrogen in the cyanide was placed beyond doubt.

Rieken (*Dingl. pol. J.*, cxxi., 286) by very careful experiments confirmed the conclusion of Bunsen and Playfair as to the formation of cyanogen from pure carbon and nitrogen at a high temperature. He obtained pure carbon by heating pure cane sugar, and pure potash by igniting pure crystallised potassium bicarbonate. The mixture of carbon and potash was then put into a tube and heated to whiteness, and nitrogen, prepared from air, was passed over it. This nitrogen was prepared by passing air through strong sulphuric acid and then through calcium chloride—thus removing both ammonia and water—then over iron filings heated white hot in a gun-barrel and finally through the mixture of white hot potash and charcoal. The highest white heat was required and the previous heating of the nitrogen was found to be essential. When the temperature was below whiteness no trace of potassium cyanide was formed.

Delbrück (*J. b. Chem.*, i., 473) added further to the weight of evidence in favour of the conclusion of Bunsen and Playfair. He showed that the direct union of carbon and nitrogen was incontestable and extended the limits of existing knowledge upon the subject by describing other related reactions in which cyanogen is formed. Nitric oxide and "potassium carbonic oxide" were shown to produce cyanogen when heated. Carbon dioxide (CO₂) mixed with ammonia, or even with nitrogen, when passed over hot metallic potassium, or ammonium carbonate kept in contact with fused potassium, also yielded cyanogen.

The fact of the direct union of nitrogen and carbon being settled, and the practicability of carrying out the reaction on a commercial scale having been, in a certain sense, proven by the accidental phenomena of the blast furnace, attempts were made to build up a new manufacture, in which cyanides should be made direct from the nitrogen of the air.

The first patent taken out in England for manufacture of cyanides on the new principle was by A. V. Newton. (*Dingl. pol. J.*, xcvi., 293; Eng. Pat. No. 9985, Dec. 13, 1843) A patent taken out in 1839 by John Swindells (Eng. Pat., No. 8036) for the manufacture of cyanide

* *Journal of the American Chemical Society*, vol. xi., Nos. 1-2.

† The substance of this article was prepared as an appendix to a commercial report, but has not been printed heretofore in any scientific journal.—A. A. B.

‡ The experiments of Bunsen and Playfair showed also that, on the small scale and with a very slow current of nitrogen, all of the nitrogen was absorbed by the hot mixture of potash and carbon. It is much to be regretted that no record of the composition of the escaping gases was made in the commercial manufacture of cyanides by Possoz and Boissiere.—B.

• The compound of the potassium retort (?)—B.

might have come partly under the same head, as it involved the fusion of potassium or sodium sulphate, coal and iron in a reverberatory furnace. A portion of the nitrogen of the fire gases might have been taken into combination under these conditions as an alkaline carbonate is formed, but the process avowedly looked only to fixing the nitrogen of the coal as cyanide.

The specification of Newton especially prescribes that nitrogen from any source, but free from "oxidating substances," be forced through a layer of small pieces of charcoal saturated with "pot-ashes" and heated to redness, the vapours containing cyanides to be absorbed by suitable liquids. He states that oxygen decomposes the cyanides at high temperatures; the necessity of excluding oxygen has always been recognised by other writers upon the subject as an essential feature of the process.

Newton used either charcoal, coal, or coke, but preferred the former, in pieces the size of a hazel-nut. The charcoal was saturated with a strong solution of potash and dried before being put into the retort. A definite maximum proportion of alkali was used; an excess prevents complete absorption of nitrogen and a deficiency involves loss (of carbon?). Twenty-five to one hundred parts of potash are used to one hundred of coal, according to the density of the latter. Nitrogen should always be in excess, but must not be passed too rapidly. A certain pressure upon the gas and much friction with the solids through which it passes are favouring conditions.

Newton recommends the use of waste gases from the sulphuric acid chambers after passing through ferrous sulphate and lime-water, to remove oxides of nitrogen. The use of these chamber gases has also been suggested by Binks, Firman, and others ("R. W.," vol. i., Pt. 5, 61-65).

Before the date of Newton's patent, however, Possoz and Boissiere (*Jsb. chem. Tech.*, 1855, 83; 1858, 191; *Dingl. pol. J.*, civ., 446; cvii., 444; cxix., 361; cxlix., 56) had been at work upon the same industrial problem in France, and had in operation at Grenelle, near Paris, in 1843, a small plant which was turning out yellow prussiate at the rate of 15,000 kilos., or more than fifteen tons per annum. The high price of fuel and the need of a cheap and abundant supply of highly refractory clay for making the retorts used in the process led them to remove, in 1844, to Newcastle-upon-Tyne, England, where they went into the operation on a large scale, under the patronage and co-operation of Bramwell and Hughes. The works here, in 1845, turned out yellow prussiate at the rate of more than a ton a day. They were run until 1847, and were then abandoned after considerable loss. The salt was said to be produced at the rate of less than two francs per kilo., and was of exceptionally fine quality.

This is the most persistent attempt on record to establish commercially a process for the fixation of atmospheric nitrogen, and as such deserves close consideration.

The process consisted of passing the gas from a coal fire through large vertical cylinders or retorts of fire clay filled with a mixture of wood charcoal and potash. The charcoal was prepared by saturating it with a solution of potash and then drying. Much stress was laid by P. and B. upon exclusion of water in the process. The retorts were kept at the highest possible temperature—a white heat being preferred—as the rate of conversion of potash into cyanide was found to be proportional to temperature. The conversion was commonly completed after ten hours, but 2-3 hours in some cases was sufficient, with a good white heat. The cyanised charcoal was withdrawn at the bottom of the cylinder and dropped into a tank of water containing powdered spathic iron ore in suspension, by which the cyanides were converted into ferrocyanides or prussiates. The solution was finally filtered and evaporated to crystallisation. The apparatus worked continuously.

In the French experiments the retorts were seven to eight feet long with walls 2-3 inches thick. In England, much larger and heavier retorts were used. The high temperature, in connection with the alkalies, caused rapid destruction to the retorts. They were heated white hot before the introduction of the alkalis. White hot flues also served to superheat the nitrogen or furnace gases before entering the retorts. In later forms of the apparatus air was admitted directly to the cylinders, oxygen being removed in passing through the upper layers of carbon. The presence of carbonic oxide or carbon dioxide, as in the fire gases, was found to be disadvantageous. Coke yielded less cyanogen than charcoal. The production of cyanide was said to be greater for a given weight of potash than by the old prussiate process. The alkalis charcoal contained 30 per cent of potash. Soda was found inferior to potash and required a higher temperature. Water, even in small quantities, hindered the production of cyanogen. This fact was ascribed by P. and B. to decomposition of the latter by water to form ammonia.

In the latest constructions the cylinders were 10 feet in length and 2 feet in diameter with walls 9 inches in thickness. These were built of fire brick, and their massive character enabled them to retain heat and to resist wear so as to last several months in use. Lateral slits were also made in the walls of the cylinders for admission of air direct, and through these slits the contents could be stirred to prevent clogging by fused potash, which had been one of the chief obstacles in the process. The current of gas was upward and the charcoal was fed in at the top in moist condition and dried thus by waste heat. A pump drew the gases through the cylinders.

The causes of failure assigned in England were the rapid destruction of apparatus owing to corrosion of the retorts by the alkali, and the great loss of alkali by volatilisation, or absorption by the cylinders. Much potash was wasted in the fine charcoal after lixiviation or converted into silicates and other salts useless for further application in the process. Bramwell (*Dingl. pol. J.*, civ., 446) patented some of the later improvements of P. and B.'s plant which were devised by him (Eng. Pat., Oct. 8, 1846). He preferred to convert oxygen of the air into carbonic acid rather than carbonic oxide before carrying it into the cylinders. The use of lateral slits is also a feature of his patents.

This process is said also to have been applied at several places in France, but was ultimately abandoned.

R. Laming, in 1843 (Eng. Pat., No. 9832, July 13, 1843), patented a process for manufacture of hydrocyanic acid by passing ammonia through red-hot charcoal.

Swindell, in 1844 (Eng. Pat., June 12, 1844), patented a process in which nitrogen or air or oxides of nitrogen were passed through charcoal or other carbonaceous material, heated to full redness in a perfectly close retort. If ammonia is to be formed, steam is mixed with the nitrogenous gas.

J. Laming obtained a patent in 1845 (Eng. Pat., No. 10,955, Nov. 18, 1845), (for another party), by which charcoal or other form of carbon in powder is mixed with alkali and the mixture is kept in fusion while a current of ammonia is passed through it for the production of cyanides.

Bunsen (*Rep. Brit. Assoc.*, 1845) proposed the construction of a furnace for the production of cyanides on the plan of the blast furnace. It was to be charged with alternate layers of coal and alkali and the fused cyanide was to be drawn off periodically at the bottom (*ante*). No industrial application of this idea is known, although Binks is said (R. W., p. 66), to have taken out a patent for a similar furnace.

Armengaud patented in France, in 1846, a furnace for manufacture of cyanides from the nitrogen of the air. (*Dingl. pol. J.*, cxx., 111 (with diagram); *Genie Industriel*, 1853, 315) Unlike P. and B. he regards the presence of steam as favourable to the process and prescribes its

* A cut of P. & B.'s furnace is given in "R. W.," p. 63.

its regular admission to the furnace. The charcoal, which must be in excess, is intimately mixed with potash, soda, or lime, the mass is heated to a cherry red, and over it is passed a mixture of furnace gases and steam. The absorption chamber resembles a reverberatory furnace. The product is leached with water at 75–85° C. The volatile products from the furnace are carried into a solution of ferrous sulphate.

F. Ertel in 1846 took out a French patent for a process very similar in principle to the above (*Dingl. pol. J.*, cxx., 77; French Pat., Nov. 16, 1846) involving the use of steam, or better, as the inventor says, of hydrogen. Air from a coal fire is passed through a column of coal or coke heated to a cherry red, and from this through a mixture of charcoal powder and alkaline carbonates or lime, also heated to cherry red. The distinctive features of Armengaud's and Ertel's process are the use of steam and the application of a comparatively low temperature, whereas Possoz and Boissiere insisted upon a white heat and the exclusion of steam as essential conditions.

The history of later attempts to utilise the nitrogen of the air for the manufacture of cyanides, shows, up to the present time, no commercial success. The few further plans or suggestions bearing upon the question are added here as having a possible bearing upon the future study of it.

Marguerite and Sourdeval in 1862 (*Jsb. chem. Tech.*, 1873, 361; *Ber.*, 1873, 79) found that when air is passed over a hot mixture of baryta and carbon, nitrogen is absorbed freely, forming barium cyanide, and that this compound in presence of steam at 300° C. yields ammonia. In another form of the process they passed a mixture of illuminating gas and nitrogen over a mixture of coal and barium carbonate. The resulting barium cyanide was decomposed in solution by potassium sulphate. They also used iron filings in one of their methods similar in other respects to the foregoing. This process, which seemed to promise much for the industrial uses of nitrogen, has never received any commercial application, even as a source of ammonia. (*Comptes Rend.*, l., 1100; *Dingl. pol. J.*, clvii., 73, 357) English patents for the process were taken out by Clark.

Diess in 1873 (*E. Meyer, Jsb. chem. Tech.*, 1874, 442) patented in France a method for the manufacture of cyanides which differs in no essential feature from that of Possoz and Boissiere (*ante*).

S. Q. and A. Brin, in 1883 (*Eng. Pat. No. 5802*, Dec. 18, 1883), patented a process for manufacture of ammonia by passing moist nitrogen over coke containing baryta, which recalls that of M. and S. They also utilised oxygen separated from the air by another process.

Berthelot (*Jsb. chem. Tech.*, 1869, 260; *Comptes Rend.*, lxvii., 1141; *J. pr. Ch.*, cvii., 272), in 1868, made a valuable contribution to the theory of the synthesis of cyanogen. He obtains acetylene (C_2H_2) by direct combination of its elements (under the influence of the electric spark) and converts this in presence of nitrogen by the same means into hydrocyanic acid (HCN). He says that when nitrogen acts upon a highly heated mixture of nitrogen and potash, the compound potassium acetylene (C_2K_2) is first formed, and that this, by direct union with nitrogen, forms two molecules of potassium cyanide (KCN).

J. Blair (*Scientific American*, 1878, 21, with cut, *Dingl. pol. J.*, ccxxx., 93) in 1878, patented an apparatus in the United States for manufacture of cyanides. Gases from a coal fire (a stack with a deep layer of coal) are drawn over a layer of heated iron ore to form carbonic acid by oxidation of the carbonic oxide. The former is absorbed by passing the gases through milk of lime, and the resulting nitrogen is carried to a holder. The nitrogen is then carried upwards through a hot mixture of potash and charcoal in a stack heated externally by a fire in a larger stack which encloses it. The charcoal is drawn from the bottom and leached. Fumes of potassium cyanide which escape from the stack are condensed in a chamber adjoining

ing and the lighter fumes are absorbed by a solution of a salt of iron.

Walter Weldon, in 1879 (*Jsb. chem. Tech.*, 1879, 472), obtained a patent in England for the manufacture of cyanides. He finds that the temperature necessary for absorption of nitrogen by alkaline charcoal is not so high as has been supposed.* Instead of a white heat, Weldon finds that a comparatively low temperature, a bright red, or even a lower heat, suffices to produce cyanides from mixtures of alkalis or alkaline earths with carbon in presence of air. His apparatus consists of a rotatory furnace similar to that used in preparation of black ash (soda ash).

V. Alder, in 1881 (*Jsb. chem. Tech.*, 1881, D. R. Pat. 12,351; 1882, 509), brought forward a method involving some new features. Oxides, hydrates, or carbonates of the alkalis or alkaline earths with charcoal are used to absorb nitrogen prepared by passing air or fire gases through solutions of potassium, or barium sulphide, or by passing air over iron, copper, or zinc. He asserts that presence of finely divided metallic iron is useful in the process,† and supplies this by saturating charcoal or coke with a solution of ferrous sulphate and then igniting it in a current of hydrogen. Sulphates and sulphides of the alkalis are also used, together with lime, in place of other alkaline bodies above mentioned. In a later patent (D. R. Pat., No. 18,945, 1881), the admixture of hydrocarbon gases or carbonic oxide with the nitrogen is recommended; also the fuel in fragments is coated with a pasty mass made by mixing a strong solution of a soluble salt with charcoal powder, sawdust, &c. These modifications are introduced with the object of increasing the surface available for absorption of nitrogen.

Ludwig Mond, in 1882 (U. S. Pat. 269,302, Dec. 19, 1882), obtained a patent for manufacture of cyanides and ammonia by calcining, out of contact with air, a mixture of carbon, barium carbonate, or oxide, and magnesia, previously compressed into blocks, and then exposing these heated blocks to a current of nitrogen. In an improvement he first heats the nitrogenous gas by passing it through hot barium salts, and then passes it through fresh layers of barium salts and carbon at the temperature required for forming cyanogen compounds.

Fogarty (U. S. Pat. 288,323 and 402,324, Nov. 13, 1883), in 1883, took out two patents in the United States for production of cyanides and ammonia, which consisted essentially in dropping a mixture of powdered carbon and alkali into superheated furnace gases or superheated "generator gas" (a mixture of nitrogen, hydrogen, carbon monoxide, and steam), whereby cyanides were produced, which were subsequently decomposed by steam, yielding ammonia. He also obtained two similar patents in 1887 (U. S. Pat. 371,186, and 371,187, Oct. 11, 1887). In one of these processes the mixture of superheated furnace gases or generator gas is mixed with steam in excess, with the object, as explained by the author, of first producing cyanides and cyanates, and then, in the same mixture, decomposing these by the steam present to produce ammonia.

In the second of these patents both air and steam are in excess. Cyanides are supposed to be produced, and subsequently decomposed by the excess of steam to produce ammonia. The latter, in presence of carbonic acid of the mixed gases, is supposed to form ammonium carbonate, and this is said to be decomposed by gypsum, yielding calcium carbonate and ammonium sulphate.

* Armengaud and Ertel (*ante*) both advocated the use of moderate temperatures—cherry red—and Marguerite and Sourdeval showed that baryta in presence of charcoal absorbed nitrogen at a comparatively low temperature, and that a light red or even a lower temperature is sufficient.

† This was suggested by L. Thomson in 1839. It would naturally occur to any one familiar with the old prussiate process, but the conditions are different in the two cases, and the reason for using it here is not apparent. The carbide of iron may possibly play an intermediate part in the production of cyanogen, such as Berthelot supposes to be played by C_2K_2 , as above quoted.—B.

These processes have been tried on a large scale experimentally, but are not as yet commercially successful.

J. Young, in 1884 (*Ysb. chem. Tech.*, 1887, 675), patented a process for cyanides intended to meet the difficulty hitherto encountered in the rapid destruction of the apparatus. He proposed to use magnesian limestone or other suitable basic substance for constructing the retorts.

Siepermann (Eng. Pat. No. 16,046, Dec. 6, 1884), 1887, obtains cyanates by passing ammonia over a mixture of barium carbonate with alkaline carbonates. For cyanides he adds coal-powder to the mixture. He gives the results of experiments, showing the effect of temperature upon the production of cyanides. Excessively high temperatures yielded poorer results than a moderate red heat.

Dickson, in 1887 (U. S. Pat. No. 370,768, O.G. 4, 1887), patented a process for production of cyanides and ammonia by injection of a mixture of air, steam, coal-dust, or hydrocarbon vapour, and powder of alkalis or alkaline earths into a chamber heated by the combustion of the injected, finely divided fuel alone. His method also contemplates the maintaining of pressure (one to three atmospheres) in the furnace.

(To be continued).

CORRESPONDENCE.

GLASER'S "ALCOHOL METHOD" FOR DETERMINATION OF OXIDE OF IRON AND ALUMINA IN PHOSPHATES.

To the Editor of the Chemical News.

SIR,—Your correspondent, "A.I.C." (*CHEM. NEWS*, vol. lxii., p. 73), will find that by adding a solution of ammonia, in excess, before commencing the evaporation of the alcohol, and again a slight addition after the alcohol has been expelled, and the solution then boiled, the difficulties he has met with will be overcome. The precipitate of phosphate of iron and alumina will now be completely separated, and without difficulty, through a filter connected with a vacuum.

Your correspondent writes:—"A number of trials have convinced me of the superiority of the 'alcohol method' as compared with the old process involving the use of acetic acid." He is quite right; and if other chemists in this country also came to this conclusion, the remark that "no two English chemists ever agree in their iron and alumina returns" would probably never have recently been made to us by one of the leading superphosphate manufacturers.

The advantage of the "alcohol method" for determining iron and alumina in phosphates is, that it enables this estimation to be correctly done with comparative simplicity and rapidity: whereas the older methods only yield *correct* results after an expenditure of time and care that few inorganic determinations require.—We are, &c.,

E. F. TESCHEMACHER and J. DENHAM SMITH.

1, Aubert Park, Highbury, N.,
London, Aug. 11, 1890.

OIL GAS LAMP.

To the Editor of the Chemical News.

SIR,—In the *CHEMICAL NEWS*, vol. lxi., p. 244, a scheme is described for manufacturing gas in laboratories not provided with a supply of coal gas. The writer was probably not aware that an excellent and compact lamp is sold which virtually does the same thing, without, however, the charcoal furnace to vaporise the liquid fuel; this

being done by an ingenious adaptation of the gas flame itself. It is known as the "Dangler Lamp," and is made by the Dangler Stove and Manufacturing Company, of Cleveland, Ohio. They cost about £1, and being only 7 inches in diameter and 18 inches high, go conveniently on the laboratory bench. Having no gas supply at hand, I ordered a couple when establishing this laboratory, and have found them in every respect *superior* to gas. Fusions

Dangler Lamp.

are made with the greatest ease, and no trouble has been experienced in igniting calcium oxalate to CaO, or magnesium ammonium phosphate to $Mg_2P_2O_7$. They are started in a few minutes and require scarcely any attention, and as there is no foot blower to attend to, one can be engaged in other work while a precipitate is being ignited. Here we use gasoline (of 74° to 90° flash) as fuel, but if that could not be obtained I do not doubt that any other light oil would answer equally well.

They can be purchased from Messrs. Eimar and Amend, 205, Third Avenue, New York, but I do not know whether any English houses keep them; if not, it would be well worth their while to do so.—I am, &c.,

BEVINGTON H. GIBBINS.

Ocala Mining Laboratory,
Ocala, Fla., July 23, 1890.

P.S.—I may add that I am in no way interested in the sale of these lamps, only being anxious that other chemists may know of this exceedingly useful laboratory arrangement, and friends to whom I have mentioned it in England suggested my writing to the *CHEMICAL NEWS* on the subject.—B. H. G.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 4, July 28, 1890.

The Typical Hydrate of Neutral Aluminium Sulphate.—P. Marguerite-Delacharlony.—The author has analysed a natural aluminium sulphate from Bolivia, partly crystalline and partly amorphous. The former portion answers to the formula $Al_2O_3 \cdot 3SO_3 \cdot 16HO$, whilst the amorphous incrustation contains subsulphates derived from the decomposition of a neutral sulphate. The formula $Al_2O_3 \cdot 3SO_3 \cdot 18HO$ does not correspond to any definite real body.

Rotatory Power of Camphor Dissolved in Various Oils.—P. Chabot.—The molecular rotatory power of camphor varies very little, dilution in the camphorated oils increasing as the dilution is greater. This is contrary to what has been observed in the other solutions of camphor.

On the Lithium Malonates.—G. Massol.—A thermochemical paper, treating of the neutralisation heats of the acid and neutral lithium malonates.

On Silver Malonates.—G. Massol.—This salt, $C_6H_3O_8Ag_2$, is obtained by the double decomposition of potassium malonate and silver nitrate. It is a white or faintly yellowish power formed of fine microscopic needles which blacken on exposure to light. When dried in the open air, but in the dark, it yields 67.11 per cent metallic silver. If heated it blackens slightly, takes fire, and burns with brisk deflagration, leaving a residue of metallic silver. It is slightly soluble in water; at 20° 1 equiv. dissolves in 559 litres of distilled water, absorbing -9.8 cal. The formation of this salt by double decomposition is accompanied with a liberation of heat.

Researches on Dispersion in Organic Compounds (Fatty Acids).—Ph. Barbier and L. Roux.—The authors present the results of their studies on the dispersion of the fatty acids. They have examined from this point of view the normal homologous acid from the formic to the pelargonic acids, besides two abnormal acids, the isobutyric and the isovaleric. The dispersive powers of the normal fatty acids increase with their molecular complication. Formic acid alone presents an irregularity, which disappears if, instead of the dispersive

powers, B , we consider the specific dispersive powers $\frac{B}{d}$.

The specific dispersive powers of the isomeric compounds are almost identical, those of the non-normal acids being slightly inferior to those of the normal acids. The differences between the successive values of the molecular

specific dispersive powers $\frac{B}{d}M$ are approximately

constant, and about equal to 7.8, which permits us to represent the variation of the specific dispersive power as a function of the molecular weight by a relation of the

form $\left(\frac{B}{d} - b\right)M = a$, in which we have $a = -11.515$, $b = 0.5625$.

Presence of Furfural in Commercial Alcohols.—L. Lindet.—All commercial alcohols are not accompanied by furfural, which is a mere accidental impurity, and should be struck out from the list of the products of normal fermentation.

Contributions to the Study of Artificial Musk.—Albert Bauer.—The artificial musk is a trinitrobutyltoluene. It crystallises in fine white needles, fusible at 96–97°, insoluble in water, but soluble in alcohol and ether. Its solutions have powerful odour of musk, and may be substituted for natural musk in many of its applications in perfumery. It is evidently distinct from natural musk, which is a resin not containing nitrogen. Artificial musk is not poisonous, as the author has ascertained by experiments on rabbits. The homologues of isobutyltoluene behave like the latter, and yield trinitroderivatives of a strong musky odour.

The Rare Earths.—E. Demarcay.—In this paper the author seeks to present a summary of our present knowledge of the rare earths rather than to bring forward any new facts or to present any novel conclusions. He admits that the "radiant matter test" of Mr. Crookes is far more sensitive than the "reversion process" of M. de Boisbaudran. He considers that the red phosphorescence of aluminium is due to

traces of chrome, and that the phosphorescence of yttria is in like manner occasioned by traces of foreign matter rather than to its consisting of a number of distinct elements. He contests the hypothesis of meta-elements, and concludes that in the group of rare earths we have to do not with exceptional bodies, but with bodies which our ordinary methods are unable to separate. He refers to the observation of Bunsen and Becquerel, that salts present variable absorptions according to the directions taken by the luminous rays in a crystal. M. Becquerel thinks that in (old) didymium the groups of bands characterise as many different elements. Hence there would be in (old) didymium about 10 elements, 4 of which would form components of praseodymium. The same *savant* has shown that when we examine a series of didymium compounds the bands of one and the same group are displaced by the same quantity in passing from one salt to another ($\lambda - \lambda' = \lambda_1 - \lambda'_1 = \lambda_2 - \lambda'_2 = \&c.$), a quantity which varies from group to group for the same combinations. M. Demarcay thinks that for the present any conclusion is premature. He declares that concerning gadolinium Mr. Crookes has brought forward a "series of contradictory opinions." Concerning dysprosium, Mr. Crookes is of opinion that this element contains at least another. Lecoq de Boisbaudran informs M. Demarcay that he shares this opinion, and that he restricts the name dysprosium to an element characterised by the band $\lambda - 47.5$. The researches of H. Krüss and Nilson are unfavourably criticised. Mr. Crookes declares that he has obtained results contradictory of those of these *savants*, and M. Demarcay confirms absolutely the results of Mr. Crookes. The author says groups of rare earths seems likely to be the means of an important progress in our classification of the simple bodies. Of all those hitherto attempted there is nothing sound except perhaps the linear series of Newlands, which may be regarded as a first approximation.

Falsification of Commercial Olein with Linoleic Acid.—MM. Grandval and Valser.—The use of oleic acid, known commercially as olein, has been extended of late years both in soap-making and in the woollen trade for oiling wools before spinning. A certain number of spinners prefer it to olive oil both on account of its lower price and because it can be afterwards removed by means of soda-ash, whilst olive oil requires the application of soap. Latterly the use of oleic acid has occasioned much inconvenience. White cloths woven from yarns thus greased present stripes of an indelible yellow colour, which neither scouring nor bleaching with sulphur can remove, and which show very distinctly if the cloth is dyed with a light colour. On examining the "oleins" which have caused this mischief, they are found to contain a large proportion of linoleic acid. For some years the more liquid portion of recent animal fats has been melted out at a gentle heat and sold for the manufacture of margarine, whilst the more solid parts have been sold to candle-makers, but they have been found difficult to manipulate and purify. Hence linsed oil has been added to the hard animal fats, and the oleic acid which is expressed from the mixture contains linoleic acid, which is much more siccative and liable to oxidation. If such oleic acid is used for greasing wool, then, if the yarns are woven immediately after spinning, no inconvenience seems to arise, but if the yarn is left for some weeks exposed to air and light without being woven it turns strongly yellow, especially on the outer parts of the folds. For the detection of the falsified oleic acid the following characters will suffice:—It is of a yellowish brown, paler than that of commercial oleic acid. Its sp. gr. is higher, varying from 0.912 to 0.919, whilst that of genuine oleic acid does not exceed 0.905. The

liquid is more consistent, and is not homogeneous, but clotty. If falsified oleic acid is heated to 50° it takes, when cold, a firmer condition, which becomes more decided each time the operation is increased. If we take 50 grms. of the suspected sample and add 450 c.c. of alcohol at 85° there is produced on shaking a mirror-like precipitate, whilst ordinary oleic acid dissolves completely. If mineral oil, resin, or paraffin is mixed with the oleic acid there is also formed a deposit insoluble in alcohol. If a thin layer of the fraudulent oleic acid is placed upon a slip of lead, scraped quite clean, and some pure oleic acid is put upon a similar slip of lead for comparison, the next day the impure acid will be more or less resinified, whilst the pure acid will be scarcely altered. If some drops of falsified oleic acid are mixed with an equal vol. of soda-lye, an intense yellow colour is produced; pure oleic acid, if similarly treated, merely takes a greyish tint.

PRINCIPLES OF GENERAL ORGANIC CHEMISTRY.

By PROFESSOR E. HJELT,
of Helsingfors.

Translated from the German by J. BISHOP TINGLE,
Ph.D., Assistant in the Laboratory of the Heriot
Watt College, Edinburgh.

In this work the fundamental theories of organic chemistry are presented in a clear and concise form, and their application is fully illustrated by examples. The relations between the constitution of compounds and their chemical and physical properties are prominently exhibited. A considerable number of general reactions are discussed and explained; in all cases these are classified according to the results; for instance, reactions involving oxidation are grouped together, and examples are given of the effects of oxidation on different classes of compounds: a lucid account is also given of the special application of particular oxidising agents.

LONDON: LONGMANS, GREEN, AND CO.

CITY AND GUILDS OF LONDON INSTITUTE. TECHNICAL COLLEGE, FINSBURY.

Principal—Professor S. P. THOMPSON, D.Sc.

DAY DEPARTMENT for Students not under fourteen years of age will commence on Tuesday, October 7, 1890. Fee £15 per annum.

The Course of Instruction in the CHEMICAL DEPARTMENT under Prof. R. MELDOLA, F.R.S., extending over three years, provides thorough and practical training for young men entering the profession. Chemical Laboratories, specially organised for instruction in Technical Manufacturing Processes, Gas Analysis, Preparation of Dye-stuffs, &c. All chemical students also attend Courses of Instruction in Mechanical Laboratory, Electrical Laboratory, Engineering Workshop, and in Mathematics.

ENTRANCE EXAMINATION to fill vacancies will take place on Tuesday, September 30, at 10 o'clock A.M.

For Particulars of Examination, Scholarships, and Programmes of Instruction apply at the Technical College, Leonard Street, City Road, E.C., or at the offices of the Institute.

JOHN WATNEY, Hon. Secretary.

City and Guilds of London Institute,
Gresham College, E.C.

OWEN'S COLLEGE, VICTORIA UNIVERSITY, MANCHESTER.

CHEMISTRY COURSE.

Full particulars of this Course, qualifying for the Victoria University Degrees in Chemistry and the College Certificate in Applied Chemistry, will be forwarded on application.

The Session begins October 7.

H. W. HOLDER, M.A., Registrar.

FOR SALE.—THE CHEMICAL GAZETTE.

Complete Set (unbound and uncut), 17 volumes; from November, 1842, to December, 1859.—Address, "Publisher," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Extension of Time.

COUNTY BOROUGH OF SALFORD.
(GAS DEPARTMENT).

SPENT OXIDE.

The Gas Committee invite Tenders for the purchase of about 850 tons of SPENT OXIDE. Further particulars and Forms of Tender may be obtained from the Gas Engineer, Gas Offices, Bloom Street, Salford. Sealed Tenders, endorsed "Spent Oxide," to be sent to me not later than 5 p.m. on Thursday, the 21st of August next.

By order,

SAML. BROWN, Town Clerk.

Town Hall, Salford,
August 7th, 1890.

Extension of Time.

COUNTY BOROUGH OF SALFORD.
(GAS DEPARTMENT).

OXIDE OF IRON.

The Gas Committee are prepared to receive Tenders for the supply of 500 tons of OXIDE OF IRON for purifying the gas at their Works. Forms of Tender and further particulars may be obtained on application to the Gas Engineer, Gas Offices, Bloom Street, Salford. Sealed Tenders, endorsed "Oxide of Iron," to be sent to me not later than 5 p.m. on Thursday, the 21st of August next.

By order,

SAML. BROWN, Town Clerk.

Town Hall, Salford,
August 7th, 1890.

THE LONDON HOSPITAL MEDICAL COLLEGE.—THE WINTER SESSION will commence on Wednesday, October 1st.

The Hospital, which is the largest general hospital in the kingdom, contains nearly 800 beds, all in constant use. There are wards for accidents, surgical and medical cases, diseases of women and children, and ophthalmic cases. Special departments for diseases of the eye, ear, throat, skin and teeth, and for cancer, tumours, diseases of the bladder, piles and fistula. Number of in-patients last year, 9105; out-patients, 109,839; accidents, 11,400.

Surgical operations daily.

APPOINTMENTS.—Resident accoucheur, house physicians, house surgeons, &c. Forty of these appointments are made annually. Numerous dressers, clinical clerks, post-mortem clerks, and maternity assistants are appointed every three months. All appointments are free. Holders of resident appointments are also provided free board.

Two Entrance Science Scholarships, value £75 and £50, and two Buxton Scholarships, value £30 and £20, will be offered for competition at the end of September to new Students. Sixteen other Scholarships and prizes are given annually.

The London Hospital is now in direct communication with all parts of the metropolis. The Metropolitan, District, and other railways have stations within a minute's walk of the Hospital and College.

For further information apply, personally or by letter, to—

MUNRO SCOTT, Warden

Mile End, E.

ST. PAUL'S SCHOOL.—An Examination for filling up about Fifteen Vacancies on the Foundation will be held on the 10th September next.—For information apply to the Bursar, St. Paul's School, West Kensington.

A NEW METHOD AND DEPARTMENT OF CHEMICAL RESEARCH.

By Dr. G. GORE, F.R.S.

In the *Philosophical Magazine* of May last the author has published an account of an experimental research under the above title in which he has shown that some of the chief physical and chemical properties of substances may be to a large extent represented by means of geometrical curves.

The method employed in this research was to take a small glass vessel containing 155 grains of distilled water at atmospheric temperature, immerse in the water a voltaic pair composed of an amalgamated zinc wire and sheet of platinum, connect the couple in series in the same circuit with a suitable galvanometer and thermoelectric pile, and measure by the method of balance the electromotive force of the combination. A small but known weight of a given halogen, acid, or salt was then dissolved in the water, and the electromotive force again measured; a second quantity of stronger solution was then taken, and a second measurement made; and so on until the degrees of electromotive force of about twenty different strengths of solution had been obtained. The results were then plotted on equally divided scales, with the electromotive forces as ordinates to the quantities of substance as abscissæ, and a curve of the degrees of electromotive force for equal variations of strength of solution was thus obtained. The electromotive force obtained with water was =1.127 volts, and the curve graphically given of each substance in the above publication, except in one instance, commences at that number. Curves of electromotive force were also obtained by several other methods, viz., *b*, by varying the strength of the solution at one metal only; *c*, by varying the temperature of the solution at both metals; and *d*, by varying the temperature at one metal only.

The thermo-electric pile employed was one formed of about 300 pairs of iron and german silver wires (see *Proc. Birm. Phil. Soc.*, vol. iv., p. 130; *The Electrician*, 1884, vol. xii., p. 414), and the galvanometer was an ordinary astatic torsion one of 100 ohms resistance.

In consequence of the following circumstances, very little error or inconvenience was caused by polarisation:—1. All the measurements were made at the null point when no perceptible current was passing; 2. By experience in working, the null point could be almost instantly attained; 3. The metals were immersed only a very short period of time; 4. The zinc was cleaned each time before immersion; 5. The platinum was washed each time, and heated to redness occasionally; 6. To test whether the couple remained unchanged it was occasionally balanced in distilled water by a similar one in distilled water.

Suitable strengths of solution were employed; the range of strength varied according to the degree of chemical and voltaic energy of the substances, and the strength was smaller in proportion as the substance was more energetic. The accompanying table gives the ranges of strength used with the different substances; in each case in section "a" the quantity of water employed was 155 grains.

The curves obtained with chlorine, bromine, and iodine show:—1. An increase generally of electromotive force attending increased strength of solution. 2. A much greater increase caused by the first amount of substance added than by the subsequent additions. 3. A gradation of degree, both of first increase and of maximum electro-

a. Strength of solution varied at both metals:—

	Grains of substance.
Cl, Br, and I	0.001 to 0.01
HCl, HBr, HI (<i>weak</i>)	0.001 " 0.01
HNO ₃ , H ₂ SO ₄ (<i>weak</i>)	0.001 " 0.01
H ₂ SO ₄ , at 60° C.	0.001 " 0.01
HCl, HBr, HI (<i>strong</i>)	0.1 " 1.0
HCl, with Cd as positive metal	0.1 " 1.0
KCl, KBr, KI	0.1 " 1.0
KBr, at 60° C.	0.1 " 1.0
NaCl, NaBr, NaI	0.1 " 1.0
KClO ₃ , KBrO ₃ , KIO ₃	0.7 " 1.7
K ₂ SO ₄ , Na ₂ SO ₄	0.1 " 1.0
KCl+KI, KCl+NaCl	0.1 " 1.0
Isomeric solutions	0.01 " 0.1

In each of the sections "*b*" and "*c*" the quantity of water employed was 465 grains.

b. Strength of solution varied at one metal only:—

KBr, NaCl, KCl 0.1 grain.

c. Temperature of solution varied at both metals:—

HCl, from 10° to 100° C. .. 0.03 grain.

d. Temperature of solution varied at one metal only:—

Cold Zn and hot Pt from 17°
to 100° C. 39 grains of KCl.
Cold Pt and hot Zn from 15°
to 100° C. 39 " "

motive force in the three curves, varying inversely as the magnitudes of the atomic weights of the substances. 4. A general similarity of form, sufficient to show a graduated degree of likeness. 5. A sufficient degree of difference of form to characterise each individual substance.

Those given by the weak solutions of hydrochloric, hydrobromic, and hydriodic acid show:—1. That the union of hydrogen with the halogens greatly diminished the electromotive force. 2. A feeble increase of electromotive force, greatest at the commencement, especially with hydrochloric and hydrobromic acids, attending increased strength of the solution. 3. A less degree of family likeness than in the curves of the halogens. 4. The substance of largest molecular weight gave the smallest increase of electromotive force. 5. Each substance gave a characteristic curve. The solutions were too weak to fully develop the characteristic forms of the curves.

The curves given by weak solutions of nitric and sulphuric acid are:—1. Very different from those of the halogens, and show very much smaller degrees of electromotive force. 2. Their differences from those of hydrochloric, hydrobromic, and hydriodic acid of the same range of strength are also quite conspicuous. 3. They are sufficiently unlike to be characteristic of each substance and to be clearly distinguishable from each other. The solutions were, however, too dilute to fully show the characteristic forms.

By comparing the curve given by dilute sulphuric acid at 60° C. with that given by the same range of strengths of the solution at 14° C., we find that a rise of temperature caused a general increase of electromotive force, greatest at the commencement, and quite sufficient to distinguish the one curve from the other. The difference would probably be much greater with stronger solutions, as was subsequently found with solutions of potassium bromide at 18° C. and 60° C.

The curves given by the strong solutions of hydrochloric, hydrobromic, and hydriodic acids show:—1. A general increase of electromotive force attending gradually increased strength of liquids. 2. A much larger increase produced by the first amount of substance added than by the succeeding ones. 3. A gradation of degree of general increase of such force varying inversely as the magnitudes of the molecular weights of the substances. 4. A family likeness of the curves with sufficient difference of form to

characterise each individual substance. By comparing these curves with those obtained with the solutions of one-hundredth the degree of strength, we find with the stronger solutions:—1. A much greater increase of electromotive force, both on the addition of the first amount of the substances and by the subsequent additions. 2. A more distinct relation of those increases to the magnitudes of the molecular weights of the substances. 3. Much more characteristic curves. 4. A much greater irregularity of form; this greater irregularity of form was a genuine effect.

By comparing the curve obtained with cadmium as a positive metal with that obtained with zinc in the same series of solutions of hydrochloric acid, we find:—1. Quite a different form of curve. 2. A smaller increase of electromotive force on adding the first portion of acid. 3. A general decrease of that force by the further addition of acid. 4. A curve characteristic of the metal and acid.

The curves obtained with zinc in solutions of chloride, bromide, and iodide of potassium show:—1. A much greater increase of electromotive force caused by the first amount of substance added than by the subsequent ones. 2. A gradation of degree of first increase and of maximum electromotive force, varying inversely as the magnitudes of molecular weight of the substances. 3. Large differences of form, characteristic of each individual substance. 4. The substitution of potassium for hydrogen in the corresponding acids lowered the electromotive force in all three cases, and the amount of this reduction varied inversely as the magnitudes of the molecular weights of the substances; the union of potassium with the halogens had similar effects, but in much greater degree.

By comparing the curves given by the same series of solutions of potassium bromide at 18° C. and 60° C., we find considerable differences:—1. A greater unlikeness of general form. 2. A general and large diminution of electromotive force at the higher temperatures. 3. A much smaller increase of that force on the addition of the first portion of the substance. The results support the conclusion that potassium bromide behaves to a certain extent like a different substance at such different temperature.

The curves obtained with chloride, bromide, and iodide of sodium show:—1. A general increase of electromotive force by increase of dissolved substance. 2. A great difference of form, and a strongly characteristic curve in each case. 3. The substitution of sodium for potassium in each salt considerably diminished the degree of electromotive force produced by the first addition of the substance, and the amount of this reduction varied inversely as the molecular weights of the salts. The curves are widely different in form from those of the corresponding salts of potassium, and this is, no doubt, due to the difference of metallic base; in each group, however, the curve of the chloride intersects that of the bromide.

The curves yielded by the chlorate, bromate, and iodate of potassium were very feeble, and very different from those given by the chloride, bromide, and iodide, and show:—1. A striking similarity of general form, probably due in a large degree to the general feebleness of the action as well as to analogy of chemical composition. 2. A very small increase of electromotive force in each case on adding the first portion of substance, and on subsequent additions, and the amounts of these increases varied directly as the magnitudes of the molecular weights of the salts. 3. A sufficient degree of difference to characterise each substance. 4. The chemical union of oxygen with the three corresponding halogen salts to form these compounds, greatly reduced the electromotive force in each case. Increased complexity of composition was attended by decreased voltaic energy (see "Loss of Voltaic Energy of Electrolytes by Chemical Union" (*Proc. Birm. Phil. Soc.*, vi., p. 225; *CHEMICAL NEWS*, 1889, lix., p. 183); this is a general result.

The curves yielded by the solutions of sulphate of po-

tassium and sulphate of sodium were much alike, due to their being those of closely allied salts of the same acid; but were also different in consequence of difference of their metallic bases. They are each considerably unlike those of the halogen salts of the same metals.

Comparisons of the curves obtained with solutions of mixtures of equivalent weights of KCl+KI and of KCl+NaCl showed:—

1. That each curve was strikingly unlike in general form each of those of the constituent salts of the mixtures, and the form is not in either case an average of that of the two.

2. Each of them shows a great reduction of electromotive force, due to the chemical union of the two dissolved salts (*Ibid.*; also "Examples of Solution Compounds," *Proc. Birm. Phil. Soc.*, vii., p. 33; *CHEMICAL NEWS*, lxi., p. 172; *Proc. Roy. Soc.*, xlv., p. 265).

3. In each case an increase of strength of solution is attended by an increase of electromotive force.

4. The two curves are each characteristic of the particular dissolved "solution compound."

The relative amounts of voltaic energy, as tested by the "voltaic balance," separately before chemical union, were KCl=699,803, NaCl=207,589, and KI=16,361; and after the union those of the compounds were KCl+KI=7,571 and KCl+NaCl=5,959 (see "Relative Amounts of Voltaic Energy of Aqueous Solutions," *Proc. Roy. Soc.*, xlv., p. 442; *Proc. Birm. Phil. Soc.*, vii., p. 42).

In a research "On the Molecular Constitution of Isomeric Solutions" (*Phil. Mag.*, Oct., 1889, p. 289) the author has shown that aqueous isomeric electrolytes yield different amounts of voltaic energy with a zinc-platinum couple. In the present case was employed an unstable solution "A," having a composition represented by the formula $\text{Na}_2\text{SO}_4 + 2\text{HNO}_3$, and yielding by the "voltaic balance" method, an average voltaic energy of 77.446; and its stable isomer, "B," represented by $2\text{NaNO}_3 + \text{H}_2\text{SO}_4$, and yielding 32.722. The curves given by the two series of strengths of these mixtures were largely different in form; they showed the considerable differences of molecular and chemical constitution of the two liquids, and enabled the two mixtures to be readily distinguished. As the unstable liquid "A" is easily changed into the stable one, "B," by heating it to nearly 100° C. in a stoppered glass flask during fifteen minutes, and then would give the curve of "B," it is evident that the method of examining aqueous solutions by means of their curves of electromotive force is applicable for detecting and measuring chemical and molecular changes in them (see "A Method of Examining the Rate of Chemical Change in Aqueous Solutions" (*Proc. Roy. Soc.*, xlv., p. 440).

The curves obtained in solutions of potassium bromide or sodium chloride, by varying the strength of the liquid at one metal only of the voltaic couple, showed:—

1. That the variation produced a large and irregular effect upon the electromotive force at the surface of the zinc, but scarcely any such effect at that of the platinum.

2. That when such variation of strength is made at both metals simultaneously, the effect upon the electromotive force, and consequently upon the form of the curves, is nearly wholly due to changes occurring at the surface of the zinc, and but little to such changes at the platinum.

The curves which resulted from gradually raising the temperature of dilute hydrochloric acid from 10° to 100° C. at both metals simultaneously showed that a regular variation of temperature produced an irregular change of electromotive force. It is probable that the curve thus obtained is characteristic of the substance, and would be different with every different substance and degree of strength of its solution.

By raising the temperature of the solution of potassium chloride from 15° to 100° C. at each metal separately, two curves of quite different forms were obtained. The greatest variation of electromotive force was at the zinc,

and was = 0.103 volt, whilst that of the platinum was only = 0.04 volt. Each of these curves would probably be characteristic of the particular dissolved substance and degree of strength of its solution.

General and Theoretical Considerations.

The evidence obtained by this research shows:—

1. That every different electrolytic substance, when in aqueous solution, gives, by varying the degree of strength of its solution (or by varying its temperature), a different curve of electromotive force.
2. That this curve is characteristic of the substance.
3. That under these conditions, substances which constitute a recognised chemical group yield a series of curves which usually exhibit a gradation of likeness of form.
4. That the degrees of electromotive force of such a group usually vary in magnitude inversely as the amounts of the atomic or molecular weights of the substances.
5. That a much greater increase of electromotive force is usually caused by the first amount of substance added to the water than by the subsequent amounts.
6. That the chemical union of two substances to form a soluble salt is attended by a definite decrease of electromotive force and a definite change of form of curve.
7. That the substitution of one halogen acid or metallic base for another in the composition of a soluble electrolytic salt, is accompanied by a definite amount of change of that force and of the form of its curve; and it will probably be possible to trace, by means of these changes, the presence of each halogen acid and metal in the various solutions of its salts.
8. That isomeric solutions of electrolytic substances give different curves under the same conditions, and may thus be distinguished from each other.
9. That molecular and chemical changes and their rates, in electrolytes, may be examined and measured by this method.
10. That if the solutions of the substances are too weak the characteristic forms and differences of the curves are not fully developed, and if they are too strong the measurements of electromotive force are more difficult to make. As the measurements were made at the null point when no current was passing, the curves represent the electromotive forces and molecular motions which exist under that condition; when the current passes the molecular movements are greatly altered.

The changes of electromotive force and form of curve obtained:—1st, by the same variations of strength of the same solution at two different temperatures; 2nd, by varying the temperature of a solution without changing its strength; and 3rd, by varying its temperature at the positive metal only, or at the negative one only, support the general view that each substance becomes more or less a different substance at each different temperature, and that the degrees of property of each substance at different temperatures are practically infinite in number.

The results in general support the kinetic theory that the most fundamental attribute of matter is motion, that a mass of matter is a mass of motion, that each substance consists essentially of a collection of molecular motions, and that the chief properties of bodies are consequences of such motions. Changes of volta electromotive force are now generally recognised as being due to those motions, and as being disturbances of the universal ether which pervades all bodies and all space. Each degree of such force may also be regarded as a concrete result of an extensive series of molecular vibrations of extremely varied degrees of amplitude; this series being characteristic of the particular material combination producing it, analogous to the collection of vibrations producing a beam of light of a particular burning substance. The curves represent, in addition, the changes in amount of these collective motions; and by observing these changes

in a single substance under a sufficient variety of conditions, a more or less complete graphic delineation of them as representing that particular substance might be obtained. When we are able to fully interpret the language or meaning of these curves we shall learn a very great deal respecting the internal motions and changes of substances, and the conditions of conversion of potential into kinetic energy.

As each curve is a geometrical and quantitative representation of a series of such changes, a complete collection of such curves, yielded by all kinds of aqueous solutions, would constitute an extensive system of representations of the molecular motions of substances somewhat like that of the luminous spectra of bodies; and the magnitudes and harmonic relations of the degrees of electromotive force represented by the curves will form a very large basis of study for mathematicians, something like the spectra of bodies now afford. The entire subject appears to be nearly as large as that of spectrum analysis, and is not altogether unlike it.

The whole system of curves may be viewed as being in some respects analogous to the absorption spectra of liquids, and in a less degree to the spectra of gases. The relations between the different curves are probably more complex than those between the spectra of liquids, because the electrodes take part in the action; and still more complex than those between the spectra of gases, because of the influences of the solvent and of the electrodes, and because each dissolved substance is in the liquid state, and under the influence of cohesion.

As the magnitudes and forms of the curves are manifestly related to the atomic and molecular weights of the dissolved substances, they are doubtless also related to the periodic series, and in this direction a study of them by mathematicians will lead to the acquisition of new knowledge. And as they reveal the kinetic changes which isomeric and other substances undergo when they pass from one state of chemical equilibrium to another in cases of chemical union, substitution, decomposition, &c., they are evidently related very intimately to Newton's third law of motion.

With regard to the latter suggestion, in several researches (see "Relative Amounts of Voltaic Energy of Electrolytes," *Roy. Soc. Proc.*, 1888, xlv., p. 266; *Proc. Birm. Phil. Soc.*, vii., p. 43; "On Loss of Voltaic Energy of Electrolytes by Chemical Union," *Ibid.*, vi., p. 225; "Examples of Solution Compounds," *Ibid.*, vii., p. 33; *CHEMICAL NEWS*, lxi., 172), the author has largely shown, by means of the "voltaic balance" method, that chemical union in definite proportions by weight of substances whilst in aqueous solution together is apparently universal; that elements unite with elements, with all kinds of acids, and with all classes of acid, neutral, and basic salts; that acids unite with acids, each with every other one, and each acid with every salt; and salts with each other in almost endless variety; and apparently that all kinds of dissolved chemical compounds, with but few, if any exceptions, unite together more or less distinctly in those definite proportions indiscriminately and without limit of kind, provided no separation of substance by precipitation or otherwise occurs. Also, by repeatedly doubling the molecular weight of a "solution compound" by successive additions to it of other dissolved substances of equal chemical value, each addition producing a new state of chemical equilibrium, in which chemical action and reaction are equal, he has by the same method shown that chemical union of substances whilst in aqueous solution extends to large aggregates of molecules of the most varied kind and of considerable degrees of complexity (*Proc. Birm. Phil. Soc.*, vi., p. 225; *CHEMICAL NEWS*, lxi., p. 183). This universality of chemical union of substances whilst in solution together indicates the existence of an equally general cause of such union, and that cause must be a molecular one.

"The theory most consistent with these facts is a

kinetic one, viz., that metals and electrolytes are throughout their masses in a state of molecular movement. That the molecules of these substances, being frictionless bodies in a frictionless medium" (viz., the universal ether), "and their motion not being dissipated by conduction or otherwise, continue in motion until some cause arises to prevent them. That every different metal and electrolyte has a different class of motions, and that the molecular motion of each substance varies at a different rate by rise of temperature." This theory has been employed by the author to explain certain phenomena in electrolytes (see *Roy. Soc. Proc.*, 1883, xxxvi., pp. 54, 55). "In accordance with this theory, chemical action is an effect of molecular motion, and is one of the modes by which that motion is converted into electric current." "Those statements are also consistent with the view that the elementary substances lose a portion of their molecular activity when they unite to form acids or salts, and that electrolytes have usually a less degree of molecular motion than the elements of which they are composed" (*Ibid.*).

A kinetic theory must agree with mechanical laws; we cannot create motion or energy; all motion arises from pre-existing motion, every efficient cause of kinetic change is a kinetic one; the immediate source of all chemical change is the latent molecular motion of the combining or mutually acting substances. As neither mere difference of substance, nor union in definite proportions by weight, is in itself an active influence, neither can it be the immediate kinetic cause of chemical change; but as both these circumstances invariably attend chemical union, and no such union occurs without them, we may conclude that they are necessary conditions of the union.

By adopting the above theory, "that electrolytes are throughout their masses in a state of molecular movement, that the molecules of these substances, being frictionless bodies in a frictionless medium, and their motion not being dissipated by conduction or otherwise, they continue incessantly in movement until some cause arises to prevent them," and associating it with Newton's third law of motion, viz., that "the actions of bodies upon one another are always equal and in opposite directions," we are driven to the inference that what we term "chemical affinity," or the immediate active cause of chemical union, is latent or potential molecular motion and the mutual impact and momentum of the molecules of the uniting substances. When two dissolved substances are brought by admixture of their solutions into mutual contact, a portion of the molecular motion of the one substance is neutralised by an equal amount of opposite motion of the other, and the two portions are converted into free heat, electric current, or other form of energy, and the molecules thus brought into nearer proximity retain their new positions and distances; this agrees with the usual evolution of heat, loss of voltaic energy, depression of electromotive force, and frequent increase of density, which occur during chemical union. According to this view, every dissolved chemical compound is an instance of balanced molecular motion, and it is the neutralised portions of motion which escape as heat and electric current. How far there is any originality in these ideas the author leaves to other persons to decide.

Many of the facts evolved by the several researches referred to point towards the conclusion that measurements of volta electromotive force and voltaic energy are essentially measurements of "chemical affinity" between the negative dissolved substance and the positive metal. An analogous idea has already been suggested by other investigators. E. F. Herroun, adopting a view of Helmholtz's, has inferred that "the electromotive force of a voltaic cell is a measure of the actual transformation of free energy," and concluded that it "furnishes a more accurate measurement of the free energy, and therefore of true chemical affinity, than data derived from calorimetric observations" (*Phil. Mag.*, 1888, vol. xxvii., p. 230).

The amounts of voltaic energy lost by two substances during their act of chemical union clearly indicate to a large extent the quantities of opposite molecular motion neutralised by their union. For instance, a much larger amount of such motion is neutralised by the union of sodium with chlorine to form sodic chloride than by that of hydrogen with chlorine to form hydrochloric acid, and, no doubt, by investigating the losses of electromotive force and voltaic energy attending the chemical union of substances in aqueous solution, we may learn a very great deal respecting the quantitative relations of "chemical affinity" between metals and electrolytes; but a great obstacle to making accurate measurements of such "affinity" by this method is the unmeasured portion of energy lost by "local action." It may be further remarked that, disregarding "local action," this chemical union and neutralisation of opposite molecular motions only occurs whilst the circuit is closed, and that at the instant of closing the circuit, potential energy is converted into kinetic energy, and a multitude of electromagnetic waves of varied lengths are generated and radiated into space; the conversion of energy, therefore, in this kind of case, depends upon closing of the circuit.

The results obtained by varying the strength or the temperature of the liquid at each metal separately support the conclusion that, in an ordinary voltaic cell, nearly the whole of the energy is due to action at the zinc, and but little to that at the platinum; and that the latter metal acts nearly wholly by obviating the greater counter electromotive force which would occur by using a more corrodible metal, and by diminishing the resistance which a less conducting substance would offer. The mere absence of an obstacle to a change cannot be an active cause of that change, and any substance which takes an essential part in any physical or chemical action, and (like the platinum plate) remains exactly the same in every respect after the action as it was immediately previous to it, cannot have been a real cause of that action, or of any loss or gain of energy attending it. The presence of the negative metal is only a static permitting condition; it enables, without any expenditure of energy on its own part, the opposite potential molecular motions of the positive metal and the negative constituent of the liquid to neutralise each other and be converted into voltaic current.

The method described in the paper is not merely a technical one of detecting substances, nor is it specially fitted for such a purpose; but it is an extensive new department of chemical and molecular research, and a general system of representation by means of geometrical curves, not only of individual substances, but of some of the fundamental changes of molecular motion of substances which are inseparably related to their chief chemical properties, and it will in this way supply mathematicians with a new and extensive series of facts, representing in terms of electromotive force, the degrees of voltaic chemical action of metals and electrolytes upon each other. Some of the chief uses of it as a method of research will be to examine the molecular structure and chemical composition of substances, to detect differences and changes in them caused by heat, light, chemical union, substitution, decomposition, &c., and to detect and measure molecular and chemical differences in isomeric liquids. It may be used to detect and measure the changes gradually produced by light and heat in chlorine-water and bromine-water, the influence of light upon nitric acid, the degrees of retarding effect of coloured glass screens, &c., upon various chemical changes caused by light, the gradual oxidation of a solution of sulphurous anhydride by exposure to air, the spontaneous decomposition of aqua regia, the rate of decomposition of a solution of potassic iodide by chlorine-water, the speed of displacement of one acid by another, &c. The examples given and researches suggested are sufficient to indicate the extensive applicability of the method.

CHEMICAL COMPOSITION OF THE OILS OF WINTERGREEN AND BIRCH, AND THE CHARACTERS OF THE SYNTHETIC OIL OF WINTERGREEN.

By Prof. Dr. FREDERICK B. POWER,
University of Wisconsin.

(Concluded from p. 77).

III. *Artificial or Synthetic Oil of Wintergreen.*—The physical properties of this oil, as manufactured by Messrs. Schimmel and Co., of Leipzig, and kindly furnished me by Messrs. Fritzsche Bros. of New York, have already been described. In connection with its chemical composition it therefore only remained to determine whether it contained any benzoic acid, since Messrs. Trimble and Schröter have made the statement, which has become widely circulated, that the salicylic acid separated from "a representative sample" of the artificial oil of wintergreen examined by them was contaminated with about 15 per cent of benzoic acid. On the basis of this assertion they take occasion to condemn the artificial oil of wintergreen, and to discountenance its recognition by the Pharmacopœia, which the writer in a former paper* had suggested, by the following expression of opinion:—

"In view of the fact that the oil of birch has in part displaced that of wintergreen, Dr. Squibb (*Ephemeris*, Oct., 1887, p. 954) nearly two years ago made some remarks about the similarity of the three, suggesting that oil of birch should be called by its correct name, and that the Pharmacopœia, by its present definition, is lending its authority to perpetuate the error. These statements have since called forth from others the recommendation that the artificial oil should be made official at the next revision of the Pharmacopœia. How far this would be undesirable may appear on examining the following analysis of a representative sample of the commercial artificial product, and reflecting on the present difference between this and either of the natural oils, and the still greater difference that would naturally follow the recommendation of the artificial methyl salicylate by the Pharmacopœia. If it is not a pure compound now, when it is competing for recognition, what would it degenerate to if it should become established by the recommendation of the Pharmacopœia?"†

Although Messrs. Trimble and Schröter have been very careful not to mention the name of the manufacturer of what they term a "representative sample" of this product, it is well known that it is included among the specialties of Messrs. Schimmel and Co., who are the largest producers of it, and whose products have not only always been without reproach, but, on account of their known purity, have served as the basis of the most extended investigations in this line by the chemists of both continents.

The above assertions of Messrs. Trimble and Schröter, so far as they might be construed to apply to the product of Messrs. Schimmel and Co.'s manufacture, have naturally not failed to evoke a prompt repudiation, and the expression of their opinion on this subject, as contained in their October *Berichte*, 1889, p. 50, is in such plain and forcible language that I take the liberty of presenting a translation of the same.

"In consideration of the rare occurrence of true gaultheria oil, the proposition made some time ago in America, that the Pharmacopœia should recognise the artificial methyl salicylate in place of the natural oil, which is subject to so much adulteration, has resulted in the opposition of the American chemists, Messrs. Trimble and Schröter. These gentlemen have not only published their motives for this in American journals, but by means

of a special pamphlet, have sought to give the same the widest possible circulation."

"We can congratulate them that they have left their readers in the dark with regard to the origin of the synthetic oil of wintergreen examined by them, for if by the disguised designation 'representative sample of the commercial artificial product' they should have meant that of our manufacture, as imported and sold by our New York house, the statement of having found about 15 per cent of benzoic acid in it would have subjected them to lasting censure."

"With regard to our product, we are in the position to furnish the assurance that it does not contain the slightest trace of benzoic acid, for the salicylic acid used in its manufacture is absolutely free from benzoic acid. We have made inquiries concerning this of Dr. Kolbe, of the firm of F. von Heyden, Nachfolger, in Dresden, who supplies us with salicylic acid, and have received from him the most convincing assurance that the occurrence of benzoic acid in his salicylic acid is absolutely out of question, and also that the formation of this acid in its manufacture is impossible."

"Although the assurance from this source should really have sufficed, nevertheless, in order to ward off any possible reflection upon the character of our oil, we have taken the pains to examine the salicylic acid of our oil of wintergreen for benzoic acid, the more especially to anticipate any assertion that benzoic acid might be formed in the manufacture of the oil. We are also thus able, from our own inspection, to confirm the statement that no trace of benzoic acid exists in our oil of wintergreen."

"Every unprejudiced person will certainly agree with us when we present an energetic front against the style and method of procedure of these gentlemen. It is generally known that the synthetic oil of wintergreen has hitherto been exclusively imported by our New York house. There can therefore scarcely be a doubt but that with the designation 'representative sample of the commercial artificial product' our product was intended. We will assume, in favour of Messrs. Trimble and Schröter, that in the suppression of our name they have believed to have shown an act of consideration. If this should have been the case, we will remark that it was quite out of place. We do not need to shun the light, and shall always be capable of defending the products of our manufacture."

From a careful examination which I have recently made of the synthetic oil of wintergreen of Messrs. Schimmel and Co.'s manufacture, I can not only fully corroborate their statement that it does not contain any trace of benzoic acid, but would unhesitatingly designate it as one of the finest products of modern chemical synthesis. Why Messrs. Trimble and Schröter should designate such a compound as that examined by them as a "representative sample" of this oil, when according to their own examination of it, it must have been evident that it was a base sophistication, is perfectly incomprehensible. Their opposition to the recognition by the United States Pharmacopœia of the artificial oil on any such grounds would seem to be no more reasonable than that the Pharmacopœia should exclude all other valuable medicinal agents which are liable to adulteration or sophistication.

The benzoic acid which Trimble and Schröter state to have been found in the artificial oil of wintergreen, as also in small amounts in the natural oils of wintergreen and birch, was separated by them from the salicylic acid by treating the latter with petroleum ether, and further purifying the last crystallisations.

In my examination of the salicylic acid from the artificial oil of wintergreen and the natural oils of wintergreen and birch it seemed desirable in the first place to ascertain the relative solubility of benzoic and salicylic acids in petroleum ether. The latter was freshly rectified, and only that portion employed which distilled over between 25° and 45° C. The solubility of salicylic acid in this

* *Pharm. Rundschau*, 1888, p. 210.

† *Amer. Journ. Pharm.*, 1889, p. 403.

liquid was found to be 1 part in 935 parts at 15° C., and the acid separates from the solution on spontaneous evaporation in small colourless needles.

The solubility of benzoic acid in this liquid was found to be 1 part in 106.3 parts at 15° C., and the acid separates from the solution on spontaneous evaporation in bright pearly scales.

Not only the difference in solubility of these acids, but also their complete dissimilarity in crystalline form, as separated from the petroleum ether, therefore, prove the latter to be well adapted for the detection of benzoic acid. But since both acids are so sparingly soluble in this liquid, I sought, if possible, to bring any benzoic acid present into a smaller compass by taking advantage of the greater solubility of the latter in chloroform, which is stated to be 1 part in 6 of chloroform, while salicylic acid requires 80 parts of chloroform for solution. The acids obtained from the oils were therefore first extracted with hot chloroform, and the portion of acid crystallised from chloroform was then treated with petroleum ether. By this method, as previously stated, not a trace of benzoic acid could be detected in the artificial oil of wintergreen, and I have been equally unsuccessful in detecting it in either a pure natural oil of wintergreen or in the specimen of oil of birch which served for this examination.

Messrs. Trimble and Schroeter also announce the presence of small amounts of ethyl alcohol in the natural oils of wintergreen and birch, as based upon the iodoform reaction afforded by the methyl alcohol separated from the oils. In this connection the fact should not be overlooked that oil of turpentine, and presumably other bodies belonging to the class of terpenes, are also capable of affording iodoform. If, for example, a few drops of pure oil of turpentine be shaken with warm water, and the liquid, after cooling, be filtered through a wet filter, such a clear aqueous solution, which can contain but extremely small amounts of dissolved oil, when treated with iodine and solution of caustic alkali, will afford, on standing, a distinct crystalline precipitate of iodoform. It would therefore not seem impossible but that, in the case of the natural oil of wintergreen at least, so small an amount of a terpene might still remain associated with the methyl alcohol as would suffice to produce this reaction. I would state, however, that I have not been able to obtain any crystals of iodoform from a filtered aqueous solution of the terpene separated from the natural oil of wintergreen, nor is iodoform afforded by the hydrocarbons of ordinary petroleum.

In summing up the results of this investigation, my conclusions, as contrasted with those of Messrs. Trimble and Schroeter, may be presented as follows:—

I. The natural oil of wintergreen consists of methyl salicylate, with small amounts (0.3 per cent or less) of a terpene. The latter is a slightly yellowish, somewhat viscid liquid, having an odour, as described by Cahours, resembling that of black pepper, a specific gravity of approximately 0.940, and does not solidify or separate any solid substance at a temperature of -10° C. It deviates the ray of polarised light to the left, and cannot be vapourised without decomposition.

II. The oil of birch, when pure, consists simply of methyl salicylate, and is without action on polarised light.

III. The natural oils of wintergreen and birch are therefore neither physically nor chemically identical, although the differences are practically very slight.

IV. In the natural oils of wintergreen and birch examined by me no trace of benzoic acid could be detected, nor has sufficient evidence as yet been afforded to establish beyond doubt the presence of ethyl alcohol in these oils.

V. The artificial or synthetic oil of wintergreen, as manufactured by Messrs. Schimmel and Co., of Leipzig, and which to the writer's knowledge is at present the only commercial synthetic oil that is entitled to be design-

ated as a representative product, does not contain any trace of benzoic acid.

VI. The pure synthetic oil of wintergreen can not be distinguished from either the natural oil of wintergreen or the oil of birch by the addition of an excess of a cold solution of potassium hydrate, nor is any "disagreeable phenol-like odour" produced, as affirmed by Messrs. Trimble and Schroeter. In the case of the artificial oil the odour of wintergreen does not disappear to any greater extent than with the natural oils. On heating either of these oils with a caustic alkali the wintergreen odour is naturally destroyed, since the chemical compound to which the odour is due becomes thereby decomposed.

VII. With regard to the adoption of the title Methyl Salicylate, and the recognition of the artificial oil of wintergreen by the Pharmacopœia, as I had suggested in a former paper, no reasonable objection can be urged. It remains, however, for the pharmacists and physicians of this country to decide, whether under the title of *Olum Gaultheria*, the Pharmacopœia should recognise the oil of birch, which is prepared chiefly in a crude manner by farmers and itinerant distillers, and is subject to adulteration with kerosene oil, or whether at least equal recognition should not be given to a pure methyl salicylate, possessing definite physical and chemical characters, and which can always be readily procured.

If any special medicinal virtues reside in kerosene oil, medical practitioners would unquestionably prefer to employ it under its proper name, and in definite or known quantities and combinations.

THE DRY ASSAY OF TIN ORES.*

PART I.

By HEINRICH O. HOFFMANN,
Assistant Professor of Mining and Metallurgy.

(Continued from p. 79).

TABLE III. shows that the loss in tin increases if the crucibles are left too long in a very hot fire; the buttons, however, remaining free from iron.

Although the results in the naked crucible were entirely satisfactory with normal conditions of temperature and time, the chalk-lined crucible was now used to see what effect would be produced upon the assay. Assays Nos. 11, 12, 13 were made in the same way as Nos. 1 to 6, keeping the temperature reasonably low. No difference could be perceived in examining the crucible, slags, and button, except that the upper part of the crucible was more tarnished than with the naked one.

Table IV. shows an average result which does not differ much from that obtained in the naked crucible, but the assays vary as much as 0.6 per cent.

If time and temperature are increased, the difference from the results with the naked crucible becomes much greater (see Table V.).

With the exception of No. 22, all the buttons contained iron, some of the results being even then too low (Nos. 20 and 21), and others too high (Nos. 14 to 19). Apparently the lime, by entering the slag, assisted in carrying the iron into the tin. That nevertheless some tin was slagged is to be accounted for by the fact that there was not enough iron to prevent it; for metallic iron,† although if present in sufficient quantity it will precipitate the tin completely, if in too small amount will only reduce the stannic oxide to stannous oxide, which of course enters the slag.

Kerl‡ mentions the fact that by first heating with char-

coal alone in the crucible and then adding the fluxes, the scorification of tin will be lessened. The reason of this is apparent. If the stannic oxide be reduced to the metallic state, the fluxes then added will, upon fusion, simply assist to collect the fine particles of metallic tin into a button, and the danger that stannic or stannous oxide may be carried off in the slag is excluded. But other more powerful causes counteract the good results which might be expected from this modification of the German assay. The most important is the presence of iron in the metal. Although tin is reduced sooner than iron to the metallic state, there is no direct indication by which the assayer can know when to stop with the reduction and when to add the fluxes. If the reduction is carried too far, the iron also will be reduced and will enter the button; if not carried far enough, so that tin still remains unreduced, the main advantage of the modified method is lost. Another drawback is that the fluxes are added to the hot reduced ore in the crucible. This creates a liability to loss of ore by dusting.

In carrying out the experiments the proportions used were the same as with the regular method. The crucibles were placed in the hot fire, and, counting from the time that the ore appeared dark red, it was exposed for a quarter of an hour to a strong heat; then the fluxes were added in their regular order, and the charge heated for one hour.

The behaviour in the crucible and the general appearance of crucible and slags were not different from that with the regular method. The colour of the salt slag, however, was light green instead of dark purple; that of the borax slag dark olive-green instead of the usual lighter shade. The tin buttons did not separate well from the slag, as their surface was very uneven. In some places were slight depressions or even cavities; in others, the button was covered with small beads of metal, adhering partly to it and partly to the borax slag. Some of the buttons were bright, and more or less malleable, and free from iron; others, however, contained so much iron that they had not the usual white colour and bright appearance, and cracked when hammered flat to the size of a dime.

Two double sets of experiments were carried out, the one in a naked crucible at a normal and then at a high temperature, the other in a chalk-lined crucible under the same conditions. The results obtained in the naked crucible are given in Table VI.

The average result of assays Nos. 23, 24, 25, carried out at a normal heat, is over 1 per cent lower than that obtained by the regular method, and there is a difference of 2.6 per cent between the highest and the lowest of the results. The buttons, however, were all free from iron. Those from assays Nos. 26, 27, 28, carried out at a high temperature, show the presence of iron in quite a marked degree. There was no regularity whatever; No. 26 took up so much iron that the button weighed more than the tin obtained by chemical analysis; Nos. 27 and 28 also took up iron, and at the same time gave some tin to the slag.

The results obtained by this modified method are therefore unsatisfactory. They become still more so if the assay is carried on in the chalk-lined crucible. This can be seen from Table VII.

Of Nos. 29, 30, 31, made at a low temperature, one assay (No. 29) contained iron, and between the other two there is a difference of 7.4 per cent. This discrepancy was probably caused by the large amount of tin carried off in the slag of No. 31. Under the caption "Siftings" there is a blank. As siftings there remained in the pan a heavy brown-black slag, which, when examined in the wet way, proved to be rich in tin. The assays Nos. 32, 33, 34, carried on at a high temperature, gave buttons which were all strongly ferruginous; they also showed great irregularity. Judging from the results obtained by the modified method—Nos. 23 to 32—the preference must be given to the regular German method, although, as above

stated, it would seem rational to suppose that the loss in tin would be smaller if the black tin were reduced to the metallic state before the flux is added and the fusion begins.

Mitchell* gives a method which may be mentioned in connection with the German assay. He mixes 400 grains ore, 100 argol, 300 sodium carbonate, 50 lime, and charges in a crucible so large that it need only be half filled, then gives a cover of sodium carbonate and 200 grains of borax; heats gently, and keeps for at least twenty minutes at a dull red heat, increasing the temperature until tranquil fusion takes place.

The experiments were carried out as directed. A beautiful bottle-green slag resulted. It was as glassy as obsidian, and covered with a thin slag of a lighter green colour. The results from three consecutive assays were so discouraging that no further attempts were made in that direction. Nearly all the tin had been taken up by the slag, the only apparent reason being the intimate mixing of ore and flux.

(To be continued).

THE FIXATION OF ATMOSPHERIC NITROGEN.†

By A. A. BRENNEMAN, S.B.‡

(Continued from p. 84.)

The Formation of Metallic Nitrides.

R. WAGNER in 1857 (*Jsb. chem. Tech.*, 1857, 121) had suggested that nitrides of boron and silicon in the interior of the earth might be the source of the ammonia found in combination with boric acid in the lagoons of Tuscany, and as sal-ammoniac in volcanic exhalations. This ammonia may be a product of the action of water at high temperatures upon the above nitrides. Bunsen, however, and Rainer (*loc. cit.*) regard volcanic ammonia as of organic origin, resulting from action of subterranean heat upon fossil vegetable matter, coal, lignite, &c.

Briegleb and Geuther in 1862 (*J. pr. Ch.*, cxxiii, 228) investigated the question of the metallic nitrides. The close relation of these bodies to the cyanides renders a knowledge of them of much interest in this connection. Nitrides of magnesium, aluminium, and chromium were obtained by simply heating the metals in pure nitrogen. The temperature of combination of nitrogen with the metal seems to be near the melting-point of the latter. Magnesium nitride is a greenish yellow, amorphous mass which yields ammonia in contact with water or caustic alkalis, and yields cyanogen when heated in an atmosphere of carbonic oxide or carbon dioxide. It has the composition Mg_3N_2 .

Tessie de Motay in 1872 (*Jsb. chem. Tech.*, 1873, 279; *Ber.*, 1872, 395) announced that titanium nitride could be made to yield ammonia by the action of steam, and could then be regenerated by submitting it to a current of nitrogen and the action thus alternated successively.

Mallet in 1876 (*Proc. Am. Chem. Soc.*, i., 17) obtained magnesium nitride by the combustion of magnesium powder in a crucible with insufficient admission of air. Other nitrides, of boron, titanium, silicon, &c., have been investigated by Ufer, Uhrlaub, Wohler, Deville, and Caron (*J. pr. Ch.*, ci., 359; ciii., 230; cv., 69; cx., 248.)

Cyanogen from Oxides of Nitrogen.

Binks (R. W., vol. i., Pt. v., p. 60. Eng. Pat. No. 10,911, Nov. 3, 1845) proposed to use oxides of nitrogen or vapour of nitric acid for production of cyanides. The

† *Journal of the American Chemical Society*, vol. xi., Nos. 1-2.

‡ The substance of this article was prepared as an appendix to a commercial report, but has not been printed heretofore in any scientific journal.—A. A. B.

gases were brought in contact with vapours of hydrocarbons in passing through a highly heated cylinder filled with firebrick. When the nitrogen compounds are in excess ammonia is chiefly produced, but with hydrocarbons in excess cyanides are the principal products. Crane and Jullion (*loc. cit.*) used a somewhat similar process, using, however, an excess of water-gas (hydrogen and carbonic oxide) mixed with the oxides of nitrogen and hydrocarbon vapours, and passing the mixture over a hot catalytic substance (platinised asbestos) at a temperature of 600° F.

Firman (*loc. cit.*, p. 65), and others have proposed the use of waste gases of the sulphuric acid chamber (nitrogen, oxides of nitrogen, &c.), for the same purpose.

A process suggested by Roussin in 1858 (*Comptes Rend.*, lxxvii., 875; *J. pr. Ch.*, lxxviii., 375) uses oxides of nitrogen in a different way and recalls the very early methods of Diesbach and Woodward (*ante*). With the object of converting nitrates into cyanides he made the following experiment:—Four equivalents of crude potassium acetate were mixed with three of potassium nitrate (nitre) and five of potassium hydrate or carbonate, and heated in a porcelain crucible to 350° C. The mass burned briskly, leaving a black residue, which, on lixiviation, yielded potassium cyanide and carbonate. By addition of coal powder, to make up for the deficiency of carbon in the organic acid, an increased yield of cyanide was obtained, but still short of the theoretical result. Previous reductions of the nitrate to nitrite yielded better results, and a mixture of potassium acetate and nitrite with lampblack gave 2.6 parts of Berlin blue (dried at 100° C.) to 13 parts of acetate, and an ammoniacal odour during the operation showed a loss of nitrogen. Potassium tartrate yielded little cyanide when used to replace the acetate, a fact already announced by Guibourd. Roussin suggested that a commercial process could be based on the use of crude sodium nitrate and acetate.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, June 19th, 1890.

Dr. W. J. RUSSELL, F.R.S., President, in the Chair.

CERTIFICATES were read for the first time in favour of Messrs. J. Caird, 20, Springfield, Dundee; D. G. Clark, 44, St. John's Wood Park, N.W.; Walter Henry Coleman, 41, Poyning's Road, Junction Road, N.; Thomas Rhymer Marshall, 4, East Castle Road, Edinburgh; William Alexander McCubbin, Mill Bank House, West Derby, Liverpool; William Stagg, 52, Seymour Road, Bristol.

Of the following papers, those marked * were read:—

*51. "Invertase: a Contribution to the History of an Enzyme or Unorganised Ferment." By C. O'SULLIVAN, F.R.S., and FRED. W. TOMPSON.

The substance present in yeast, &c., known as *invertase*, which possesses the power, under suitable conditions, of inducing the hydrolysis of cane-sugar, has been studied by the authors with the object of determining the precise manner in which it acts and its constitution.

The method adopted in determining the functions of invertase is essentially that developed by Vernon Harcourt in his paper "On the Observation of the Course of Chemical Change." A solution of cane-sugar was mixed with a measured amount of invertase, and the action was allowed to take place at a known temperature during a definite time; action was then stopped by the addition of alkali, and its extent determined.

The authors arrive at the following conclusions:—

1. The rate of hydrolysis of cane-sugar by means of invertase may always be expressed by a definite time-curve; this curve is practically that given by Harcourt as expressing a chemical change "of which no condition varies excepting the diminution of the changing substance." There are, however, some slight and apparently constant variations from the theoretical curve.

2. Whatever the conditions may be under which hydrolysis is taking place, as long as these conditions remain unchanged, this curve is adhered to.

3. When the degree of acidity is that most favourable for the action of invertase, the rapidity of the action is in proportion to the amount of invertase present.

4. The most favourable concentration of the sugar solution at a temperature of 54° C. is about 20 per cent. Below that there is a rapid decline in the speed of hydrolysis. Greater concentrations are only slightly less favourable until about 40 grms. per 100 c.c. is reached. In saturated solutions hydrolysis only proceeds with extreme slowness.

5. The speed of hydrolysis increases rapidly with the temperature until 55–60° C. is reached. At 65° C. the invertase is slowly destroyed, and at 75° C. it is immediately destroyed. At the lower temperatures the speed of the action increases with rise of temperature in accordance with Harcourt's law: the rate being about doubled for 10° rise; but above 30° C. the increase is not nearly so rapid.

6. Elevated temperatures have no permanent effect on the activity of the invertase so long as they are not sufficiently high to destroy it.

7. The caustic alkalis, even in very small proportions, are instantly and irretrievably destructive of invertase.

8. Minute quantities of sulphuric acid are exceedingly favourable to the action, but a slight increase of acidity beyond the most favourable point is very detrimental. The most favourable amount of acid increases to some extent with the proportion of invertase, and decreases with rise of temperature, but the authors have not been able to discover on what it depends.

9. In studying the action of invertase it is of the utmost importance that the most favourable amount of acid should be employed; otherwise, correct results cannot be obtained. At a temperature of 60° C. the action is almost stopped unless exactly the right amount of acid is used, whilst if this factor is properly adjusted hydrolysis proceeds at (probably) the maximum speed.

10. The influence of alcohol varies in direct proportion with the amount present. 5 per cent of alcohol decreases the speed of the action by about one-half.

11. The dextrose formed by the action of invertase is initially in the birotatory state.

12. The optical activity of a solution undergoing hydrolysis is no guide to the amount of hydrolysis that has taken place.

13. If a caustic alkali be added to a solution undergoing hydrolysis, and the optical activity be allowed sufficient time to become constant, it is a true indicator of the amount of inversion that had taken place at the moment of adding the alkali.

14. A sample of invertase which had induced hydrolysis of 100,000 times its own weight of cane-sugar was still active.

15. Invertase itself is not injured or destroyed during its action on cane-sugar.

16. There is no limit to the amount of sugar which can be hydrolysed with the aid of invertase.

17. The hydrolysis of cane-sugar by means of invertase is a simple chemical change differing in no important way from those which inorganic substances undergo.

18. The products of hydrolysis have no influence on the rate of the action.

19. A solution of invertase will withstand a temperature 25° C. higher in the presence of cane-sugar than in its absence.

20. The authors are of opinion that when invertase in-

verts cane-sugar combination takes place between the two substances, and that the invertase remains in combination with the invert sugar. This combination breaks up in the presence of molecules of cane-sugar.

21. A means of estimating the activity of a material containing invertase has been devised which consists in recording the result by means of the time factor $\pm 0 = x$ min. In this equation $\pm 0 =$ a certain definite amount of work, and $x =$ the time necessary to perform it. The expression means that the given inverting material takes x minutes to invert a standard amount of cane-sugar under standard conditions. The number x varies in inverse proportion to the actual amount of invertase contained in the material or materials under examination.

22. If sound brewers' yeast be pressed and then kept at the ordinary temperature for a month or two, it does not undergo putrefaction, but changes into a heavy yellow liquid; the product possesses no power of fermentation, but an apparent increase takes place in the invertive power.

23. From such liquefied yeast it is easy to filter off a bright solution of high hydrolytic power. It is shown that all the invertase of the yeast is in this solution, which is termed yeast liquor.

24. Yeast liquor has a relative density of about 1.080. It will remain for a long time unaltered, excepting that the colour darkens. If exposed to the air it may slowly become covered with mould.

25. If spirit be added to the yeast liquor until the mixture contains 47 per cent of alcohol, the whole of the invertase separates with only a slight loss of power. This precipitated invertase may be washed with spirit of the same strength and then the residue either dehydrated with strong alcohol and dried *in vacuo*, or else it may be extracted by means of 10 to 20 per cent alcohol and then filtered. The filtrate contains the invertase. On one occasion the extent of the loss involved by this process was determined, and it was found that all the invertase of the yeast liquor was present in the filtrate except 12.3 per cent.

26. The authors have not succeeded in further purifying invertase preparations carefully made in this manner. The slightest attempt at purification destroys the invertase.

27. They have prepared invertase almost free from ash.

28. The inverting power of pressed English yeast varies from $0 = 1000''$ to $\pm 0 = \pm 3000''$, or about $\frac{1}{3}$ of these amounts if calculated on the dry solid matter of the yeast.

29. The inverting power of the most active invertase preparation made was $\pm 0 = 25.1$ on the dry solid matter. It is believed that pure invertase would approximately have $\pm 0 = 22.5$ min.

30. The dry solid matter of yeast contains from 2 to 6 per cent of invertase. 5.8 per cent of invertase was separated from one sample of yeast.

31. During the preparation of invertase from yeast liquor an albumenoid is obtained, which is not redissolved by water. This is termed yeast albumenoid.

32. Invertase when it approaches a pure state is a very unstable substance. The products of its decomposition have been carefully examined and are found to constitute a new series of substances belonging to the *invertan series*.

33. The invertan series is a homologous series of substances which on analysis yield numbers which may be expressed in terms of an albumenoid and a carbohydrate. Seven members of the series are described.

34. The authors consider that invertase itself is a member of the invertan series and call it β -invertan.

35. If the products of the decomposition of β -invertan are examined, it is usually found that they consist of α - and δ -invertan. The former contains more, and the latter less, nitrogen than invertase.

36. α -Invertan is insoluble in water, and in all its other properties seems to resemble yeast albumenoid. It contains 8.35 per cent N. It is a very stable substance.

37. β -Invertan or invertase is soluble in water, and is the only member of the series which has the power of inverting cane-sugar. It contains about 3.69 per cent N, and its optical activity is $[\alpha]_D = +80^\circ$ (?).

38. γ - and δ -invertan are the products of the simplification of invertase. One or other of these two substances seems invariably to be formed. They both contain less nitrogen than invertase, and are always accompanied by α -invertan. Both are readily soluble in water. They contain respectively 3.15 and 2.43 per cent N, and their optical activity is $[\alpha]_D = +45^\circ$ and $+54^\circ$.

39. ϵ -Invertan is formed from the slow breaking down of δ -invertan. At the same time an insoluble substance, resembling α -invertan, is formed. This probably consists of another member of the series coming between α - and β -invertan. ϵ -Invertan is soluble in water, and has $[\alpha]_D = +65^\circ$. It contains 2.07 per cent N.

40. ζ -Invertan results from the splitting up of ϵ -invertan in the same way that the latter is formed from δ -invertan. Its optical activity is $[\alpha]_D = +75^\circ$, and it yields 1.61 per cent N.

41. η -Invertan is formed by the action of boiling sulphuric acid on ζ -invertan. It contains less nitrogen than the latter substance, but the substance has not yet been sufficiently investigated to give reliable figures.

42. The further products of the action of sulphuric acid on ζ -invertan are two soluble substances, one containing a considerable amount of nitrogen, and the other with little or no nitrogen, a high cupric reducing power, and a low (dextrorotatory) optical activity.

43. The properties of all the members of the series, except α -invertan, are very similar. They are all soluble in water forming bright solutions, which do not cloud on boiling. They are all readily thrown out of solution by alcohol, provided a little acid is present; the precipitates so formed are transparent colourless syrups, miscible with water in all proportions. The solutions are all dextrorotatory.

44. All the members of the invertan series, except η -invertan, yield a pink colouration on boiling with Millon's reagent.

45. All the members of the invertan series, except α -invertan, when submitted to the action of an alkaline copper solution, readily yield a very characteristic copper compound, from which the invertan (except β -invertan) may be separated unaltered. Invertan can probably form several such copper compounds, all having a similar appearance but affording different percentages of copper oxide.

46. In the presence of a very large excess of alkali, a copper compound is also formed from α -invertan, but on examination it is found that the α -invertan has been split up into an albumenoid and ζ -invertan, the copper compound being that of ζ -invertan.

47. It is believed that the members of the invertan series are combinations of yeast albumenoid with η -invertan, and that yeast albumenoid itself is probably a combination of yeast albumenoid with a carbohydrate.

48. According to this theory the composition of the carbohydrate present in the invertan series, calculated from the average of all the analyses, would be C = 43.22 per cent and H = 6.28 per cent. These numbers agree very closely with those required by a hypothetical carbohydrate coming midway between the *in* and the *on* groups.

49. It is thought that η -invertan contains 18 parts by weight of this carbohydrate to 1 of albumenoid, and that α -invertan contains 3 parts of the carbohydrate to 4 of albumenoid.

50. The other members of the series are formed by the union of these two substances according to the general formula $\eta + a\alpha$, where η represents η -invertan and α represents α -invertan. In this way we look upon invertase (β -invertan) as $\eta\alpha$. This splits up into α - and γ -invertan according to the formula $\eta\alpha = \eta\alpha_1 + \alpha$. $\eta\alpha_1$

represents γ -invertan, and this may be further transformed by elimination of α into $\eta\alpha$, or δ -invertan.

60. The numbers calculated for the constitution of the above theoretical homologous series agree with considerable closeness with those obtained from the analysis of members of the invertan series.

61. The number obtained from a single determination by Raoult's freezing process for the molecular weight of ζ -invertan is considerably less than the possible molecular weight of ζ -invertan, according to the authors' theory of its constitution.

*52. "The Action of Carbon Monoxide on Nickel." By LUDWIG MOND, C. LANGER, Ph.D., and F. QUINCKE, Ph.D.

When carbon monoxide is passed over finely divided nickel, such as is obtained by reducing nickel oxide by hydrogen at about 400° , at a temperature between 350° and 450° , carbon dioxide is formed, and the nickel is gradually converted into a black amorphous powder, consisting of carbon and nickel; the composition of this deposit varies widely with temperature and time. A small quantity of nickel can thus change a very large amount of carbon monoxide, the action being complete and rapid at first, and continuing, although at a diminished rate for several weeks. A product containing as much as 85 parts carbon to 15 parts nickel has been obtained. Acids only partially remove the nickel; the carbon is very readily acted on by steam, carbon dioxide, and hydrogen without a trace of carbon monoxide being formed at a temperature of 350° .

On allowing the substance to cool in a current of carbon monoxide, it was noticed that the flame of a Bunsen burner into which the escaping gas was introduced became luminous, and when the tube through which the gas passed was heated, a deposit of nickel, mixed with a small quantity of carbon, was obtained. The authors were thus led to discover the existence of a volatile nickel compound.

To prepare this compound, a combustion tube is filled with nickel oxide, and this is reduced by hydrogen at about 400° ; after cooling the nickel to about 100° , pure dry carbon monoxide is passed over it without further heating, and the issuing gas is led through a tube placed in a freezing mixture: the major portion of the nickel compound condenses as a colourless liquid, but the gas retains about 5 per cent, and is therefore collected, dried, and again passed over the metal. When no more liquid condenses, the nickel is again heated to about 400° in a slow current of pure carbon monoxide; it is then cooled to about 100° , and again submitted to the action of the gas.

Nickel carbon oxide thus prepared is a colourless liquid which boils at 43° under 751 m.m. pressure; its relative density at 17° is 1.3185. It solidifies at -25° to a mass of needle shaped crystals. Its composition is represented by the formula $\text{Ni}(\text{CO})_4$. It dissolves in alcohol, and more readily in benzene and chloroform; dilute acids and alkalis have no action on it, but it is oxidised by concentrated nitric acid. It reduces an ammoniacal solution of cupric chloride, and it also causes the separation of silver from an ammoniacal solution of silver chloride. It interacts with chlorine, forming nickel chloride and carbon oxychloride. It is decomposed at 180° (in boiling aniline vapour) into nickel and carbon monoxide. The atomic weight of the deposited metal was found in three experiments to be 58.52—58.64, a result closely corresponding with Russell's value, 58.74.

Numerous experiments to obtain similar compounds with other metals, notably with cobalt, iron, copper, and platinum, led to negative results. On experimenting with specially purified cobalt, in the beginning a slight coloration of the Bunsen flame into which the gas was led was noticed, but after a time this was no longer observed. Commercial cobalt afforded a gas which deposited a mirror of pure nickel, it being possible, in fact, to purify cobalt from nickel by carbonic oxide. The nickel mirrors

obtained by heating the carbonic oxide compound do not appear to contain any trace of cobalt.

*53. "The Interaction of Iodine, Water, and Potassium Chlorate." By HENRY BASSETT.

The author finds that the usual statement that the chlorine in potassium chlorate is directly displaced by iodine when subjected to treatment in accordance with Millon's directions is incorrect; he considers that the evolution of chlorine observed by Millon is due to a secondary interaction, $\text{HIO}_3 + 5\text{HCl} = 3\text{H}_2\text{O} + \text{ICl} + 2\text{Cl}_2$, which takes place when the iodine is added all at once, and is due doubtless to the rapid formation of iodic acid and hydrogen chloride within the dense mass of iodine. His experiments show that the iodate is formed in accordance with the equation—

and that on evaporating the solution to dryness on the water-bath, decomposition of a portion of the biniodate takes place:—

*54. "The Milk of the Gamoose." By A. PAPPEL and H. D. RICHMOND, Khedival Laboratory, Cairo.

The milk of the Egyptian gamoose or buffalo (*Bos Bubalus*) is distinguished from that of the cow by its white colour and peculiar musk-like smell. The authors find the average composition to be as follows:—

Water	84.10		
Fat	5.56		
Sugar	5.41		
Casein	3.26	containing N	0.511
Albumen	0.60	"	0.094
Nitrogen bases ..	0.09	"	0.035
Salts	1.03		

The fat was found to vary from 7.35 to 5.15 per cent, and the solids not fat from 10.67 to 10.07 per cent. The average relative density at 15.5° was 1.0354; the increase in eight hours after milking was 0.0006, and in twenty-four hours 0.0007. Gamoose milk, therefore, differs from that of the cow, both in the high percentage of fat and of solids not fat, the increase in the latter being largely due to the sugar.

Comparing the fat with that of cows' milk, the chief differences noted by the authors are, (1) the presence of small quantities of sulphur and phosphorus; (2) the presence of fatty acids soluble in boiling water, but not volatile in much larger amount than in cows' milk; (3) the presence of fatty acids giving lead salts soluble in ether but not members of the oleic series; (4) the difference in the ratio between caproic and butyric acid—4:1 instead of 2:1. Other alcohols than glycerol do not appear to be present.

The sugar appears not only to be different from milk sugar, but novel, its rotatory power being $[\alpha]_D = 48.7$, and its cupric-reducing power $\kappa = 73.7$; it yields only dextrose on hydrolysis. It is proposed to name it *temphose*.

The authors also state that the milk contains a small amount of citric acid.

(To be continued).

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 5, August 4, 1890.

The Exhaustion of Soils by Cultivation without Manures. Second Memoir: Study of Drainage Water.—P. P. Dohérain.—The author has studied the cultivation of the experimental fields of Grignon, which

have been kept without manure since 1875. The fields still yield good crops of oats; the yield of wheat is tolerable, but the cultivation of beets and of clover has become impossible. On proceeding to a comparative analysis of the exhausted soils and of some neighbouring soils which have been well manured he found that the respective quantities of nitrogen, phosphoric acid, and potassa differed very little, but the carbon in the organic matter varied from a single to a double proportion; in the unmanured lands there were only 7 grms. of organic carbon per kilo. of soil as against 15 to 16 grms. in the manured soils. Hence he resolved to ascertain whether (1) the decrease of the organic matter occasioned their more rapid desiccation, i.e., a less aptitude to retain moisture, and (2) whether the organic matter of the exhausted soils had lost the power of producing nitrates. In the experiments carried on from November, 1888, to November, 1889, the author found that the differences in humidity were very slight. He now examines the second question: if the organic matter of the exhausted soils was capable or incapable of producing a sufficient quantity of nitrates for the demands of good crop. He now finds, by gauging and analysing the drainage waters respectively from the manured and the unmanured lands, that in their aptitude for the production of nitrates there is no difference sufficient to explain why the one soil is fertile and the other barren.

The Density of Nitrogen and Oxygen according to Regnault, and the Composition of Air according to Dumas and Boussingault.—A. Leduc.—The author finds a discrepancy between the results of Regnault and the composition of the atmosphere as given by Dumas and Boussingault, which he thinks can be accounted for only by an error on the part of Regnault.

Reactions of the Salts of the Alkaloids.—Albert Colson.—In studying the action of bases upon dissolved salts, the author finds some endothermic reactions both within and outside of liquids at low and sensibly constant temperatures. In these reactions the laws of Berthollet seem to predominate over the thermic laws. For bases of the same order the laws of Berthollet are applicable, whatever is the direction of the heats liberated.

Division of Hydrogen Sulphide between the Metals of Two Dissolved Salts.—G. Chesneau.—The author's experiments show that in the incomplete precipitation of copper and lead nitrates dissolved in equal equivalents by hydrogen sulphide, the division of the hydrogen sulphide between the two metals takes place in the direction indicated by the formation-heats of the sulphides, and varies progressively with the quantity of H_2S . The proportion of the copper to the lead precipitated by H_2S varies with the time; it decreases at first, reaches a minimum after a few minutes, and then slowly increases.

Some Derivatives of Acetyl-acetone.—A. Combes.—The author has obtained and studied the cupric derivative of monochloroacetylacetone.

Combinations of Hæmoglobine with Carbonic Acid and with a Mixture of Carbonic Acid and Oxygen.—Christian Bohr.—The following combinations of hæmoglobine and carbonic acid have been observed:—(1) a hæmoglobine which, at a pressure of $CO_2 = 60$ m.m. at a temperature of 18° fixes about 3 c.c. of CO_2 . This the author designates carbohæmoglobine γ ; (2) a hæmoglobine which, at the same pressure and the same temperature, fixes about 6 c.c. of CO_2 (carbohæmoglobine δ); (3) a hæmoglobine observed by Jobin which, under the same conditions, fixes 1.5 c.c. CO_2 (carbohæmoglobine β). If a solution of hæmoglobine is shaken up with a mixture of oxygen and carbonic acid, the hæmoglobine absorbs both, forming with them an unstable compound, and this as if each gas were alone. As the carbonic acid and the oxygen are absorbed independently of each other, we may admit that they are fixed by different parts of the hæmoglobine.

Colouration of Silk by the Food of the Silkworm.—Louis Blanc.—Only some very soluble and very diffusible dyes, such as magenta, are capable of being absorbed by the intestinal epithelium of the silkworm; such substances may then colour the cellulose of the organs which secrete silk, but they do not colour the product secreted. The coloured silks which have been obtained by submitting silkworms to some special diet are very probably merely charged externally with coloured dust.

Société Nationale d'Encouragement pour l'Industrie.
Session of July 25, 1890.

M. de Luynes presented, on behalf of M. Reimer, specimens of synthetic phenic acid prepared at Neuville-sur-Saône at the branch works of the Baden Aniline Company. This acid is quite colourless; it melts at 41° , boils at 178° , and yields limpid solutions. Its slight odour differs from that of the purest phenols of commerce. On account of its properties and its low price it is likely to supersede ordinary phenol in its applications to medicine, to the preservation of putrescible articles, and in the manufacture of chemical products.

M. Le Chatelier made a communication on the measurement of high temperatures developed in furnaces. The indications of Wedgwood are not comparable among themselves; the air-thermometer has to be rejected on account of its fragility and its complicated nature. Very commonly industrialists judge of temperatures by the colour of the radiations emitted. This process may be improved by the use of a cobalt glass, or better, of an optical system consisting of quartz between two Nicols, which renders it possible to arrest at will one of the mean radiations of the spectrum. The most exact of the pyrometers proposed is the thermo-electric apparatus devised in 1832 by Becquerel, and now rendered practicable by the removal of certain difficulties of detail.

M. Lion presented a photometric balance, depending on the destructive action which light exerts on nitrogen iodide. If obtained by allowing ammonia at 25° to act upon iodine, this substance may be managed without the slightest danger if it is kept in the liquid, and it yields a supply of nitrogen which varies with the intensity of the illumination. The liberation of nitrogen begins and ceases instantly with the luminous impression.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale. Series 4, Vol. v., No. 54.

Raffinose.—L. Lindet.—It is disputed whether raffinose pre-exists in beets or if it is formed under the influence of weak alkalies. According to MM. Tollens and Richbeil it is identical with the gossypose from cotton-seed. It cannot be confounded, as Schiebler and Tollens pretend, with Berthelot's melitose. This substance can be split up into raffinose and eucalyne. Its taste is but slightly sweet. Its composition is $C_{36}H_{52}O_{21}$.

THE MASON COLLEGE, BIRMINGHAM.

SESSION 1890-gr.

Faculties of Arts and Science.

The next SESSION commences on Tuesday, September, 30, 1890. A SYLLABUS containing full information as to the various Courses of Instruction, Lecture Days and hours, Fees, Scholarships, &c., is published by Messrs. Cornish, New Street, Birmingham, price 6d., post free, 6d.

Further particulars may be obtained on application to the Secretary, at the College.

R. S. HEATH, Principal.
GEO. H. MORLEY, Secretary.

FOR SALE.—THE CHEMICAL GAZETTE.

Complete Set (unbound and uncut), 17 volumes; from November, 1842, to December, 1859.—Address, "Publisher," CHEMICAL News Office, Boy Court, Ludgate Hill, London, E.C.

AMMONIA FORMED BY BURNING METALLIC MAGNESIUM IN CONTACT WITH ATMOSPHERIC AIR.

By P. L. ASLANOGLU.

We all know that by burning metallic magnesium in contact with atmospheric air it burns with a bright white light rich in chemically active rays, forming magnesium oxide (MgO), the only oxide as yet known, which is liberated from the metallic magnesium as a fine white powder. But there is still a portion of burnt magnesium remaining in the dish, and this is magnesium hydrate—Mg(OH)₂.

In November last (1889) I was experimenting with magnesium. I was burning an ounce of magnesium dust (superior quality) in an iron dish by setting fire directly to the powder; it burnt as usual, and on cooling I examined what remained and found that a strong smell of ammonia proceeded from the remaining powder, magnesium hydrate; I have repeated the same experiment several times with all the different qualities or specimens of magnesium dust I could get, and they all gave the same result; I have also burnt magnesium wire, which likewise gave the same result.

From results obtained I have concluded that magnesium burns in contact with the oxygen of the air, forming magnesium oxide; and that it also burns with the nitrogen and forms ammonia and magnesium hydrate, absorbing at the same time the aqueous vapour of the atmosphere.

It is evident, therefore, that the quantitative amount of nitrogen and aqueous vapour contained in this magnesium hydrate will vary with the different atmosphere found in different towns, countries, districts, &c.

I should think that by this experiment we could estimate the composition of the atmosphere, as its constituents are present in this magnesium mixture.

I have not yet made the quantitative analysis of the above experiment for the estimation of nitrogen, but the best way of estimating it would seem to be the following:—

By passing steam through the powder to collect the ammonia hydrate and receive it in a well-closed flask, then to precipitate it with platinum chloride, and estimate the ammonium platino-chloride precipitated. This will be sufficient to estimate the ammonia, and consequently also the nitrogen present, thus:—

Suppose, for instance, we get by analysis 45 grms. of ammonium platino-chloride; then the amount of NH₃ contained will be—

$$446.5 : 34 :: 45 : x.$$

Six months after this experiment I was informed by an eminent authority on the science, to whom

I imparted my observations, that this phenomenon had been previously observed by an American. Consequently I have hitherto doubted whether to insert it in the CHEMICAL NEWS or not; but, however, on second thoughts I decided to send the above to the editor of the CHEMICAL NEWS, asking him to judge of my work and to publish it or not, as he thinks advisable.

I myself have not yet seen a notice of the experiment in question in any English chemical paper, but I may have missed it, and thus have been anticipated in this record without my knowledge.

Gower Street, W.C.

A SUMMARY OF FOOD ANALYSES, SHOWING THE MORE IMPORTANT ADULTERATIONS THAT MAY BE SUSPECTED TO BE PRESENT.

By H. N. WARREN, Research Analyst.

THE accompanying details, which comprise examination of some of our more important articles of consumption, are intended not so much to enter into the more lengthy or direct means of analysis, but to state as briefly as possible the numerous adulterants that have from time to time been met with by myself.

In the first instance I would mention a few of the worst cases of adulteration that are to be met with in the manufacture of sweetmeats. A compound known by the name of chewing gum has for years been sold by confectioners, which consists of about 80 per cent of paraffin, a small quantity of sugar, and various flavouring matters. As regards the composition of lozenges, inorganic elements play a considerable part; for out of an average of twelve samples, ten contained nothing but a trace of saccharine, the remaining ingredients comprising chalk and silica. Several samples of cheap Spanish liquorice contained 25 per cent of clay, and two samples entirely placed these out of sunlight by being composed of raw sugar and ground coke. Chocolate contains frequently quantities of sand, fuller's earth, and iron ore; as a colouring agent chromic acid is frequently resorted to, and introduced in the form of potassium chromate, whereas a fine blue is also frequently imitated by means of cupric sulphate, and that of nickel sulphate when green is desired; and lastly, but by no means least injurious, may be mentioned the practice of coating sweets with metallic tin, not as a wrapper only, but to create a metallic surface in several instances. I have met with samples of this description where of every half-dozen sweets that were consumed upwards of two grains of metallic tin would thus be introduced into the system.

RECOVERY OF ABSORBED MORPHINE FROM THE URINE, THE BLOOD, AND THE TISSUES.*

By THEODORE G. WORMLEY, M.D., LL.D.,
Professor of Chemistry and Toxicology, Medical Department,
University of Pennsylvania.

(Concluded from p. 81).

CASE IV.—Administered subcutaneously to a dog weighing 14 kilos. 0.1 grm. morphine, dissolved as acetate in 10 c.c. water. Symptoms of the poison soon appeared.

a. Two hours after the injection obtained 14 c.c. very turbid, strongly alkaline urine. The final residue from

* From the *University Medical Magazine*.

this urine readily indicated, under the action of several tests, the presence of morphine in quite decided quantity.

b. Sixteen c.c. urine withdrawn at the end of four and a half hours also showed the presence of the alkaloid in diminished quantity.

c. Fifty-five c.c. urine withdrawn at the end of twenty-eight hours distinctly indicated the presence of morphine in very minute quantity.

CASE V.—A man habituated to the use of morphine in large quantity took daily for some time six grains (0.389 gm.) morphine sulphate. While taking this quantity the urine passed December 28, 1889, during twenty-four hours measured 440 c.c., was about neutral in reaction, and of sp. gr. 1012. For this case I am indebted to my colleague, Professor H. C. Wood.

Two hundred and twenty c.c. of the urine, acidulated with acetic acid, were concentrated to 75 c.c., rendered alkaline by ammonia, and extracted with about two volumes hot amyl alcohol. The residue obtained on the evaporation of the alcohol readily showed the presence of morphine. After further purification the residue, under the action of several tests, indicated the presence of morphine in very marked quantity, the reactions being about as well-marked as with the pure alkaloid, but repeated attempts failed to obtain it in the form of well-defined crystals.

CASE VI.—A man affected with polyuria, accustomed for some years to the use of large quantities of crude opium, was, at the time of this examination, taking daily 60 grains (3.9 grms.) of the drug in 20-grain doses three times a day.

The urine voided during twenty-four hours, January 4, 1890, measured 4040 c.c., had a distinctly alkaline reaction, and sp. gr. 1007.

One thousand c.c. of the urine reduced to 100 c.c. and extracted with amyl alcohol in the usual manner furnished, under the various tests, very satisfactory evidence of the presence of morphine in quite notable quantity.

An attempt was made to also ascertain the presence of meconic acid, but on account of the presence of the phosphates and other interfering substances the results were not satisfactory.

CASE VII.—Dr. W. H. Price, of the University Hospital, kindly furnished me the following case:—A coachman, aged 50, greatly depressed in spirits, swallowed, February 13, 1890, a fluid ounce of ordinary laudanum. When seen by Dr. J. Daland, thirty-five minutes afterwards, the patient was in a comatose state; the pupils were contracted to a point, and the respirations four per minute.

Under the use of strychnine and atropine hypodermically, electricity, and other active measures, at the end of thirty hours the patient was quite himself again.

Eight hours after the poison had been taken about 250 c.c. urine was withdrawn from the bladder by catheterisation; 160 c.c. of this urine, reduced to 75 c.c., was extracted by amyl alcohol; and this extract purified by a second, and then a third, extraction by the alcohol, and finally by ether.

The final residue, when examined by Frøehde, Husemann's, the nitric acid, and iron tests, very clearly showed the presence of morphine. The urine in this case was not examined until the third day after its withdrawal.

CASE VIII.—A man with suicidal intent, took at 10 p.m., March 10, 1890, ten fluid drachms of laudanum. When seen ten hours thereafter by Dr. J. Daland, who kindly furnished me the particulars of the case, the patient was in a state of great stupor, from which he could be partially aroused. Under moderate treatment he soon recovered. The first urine voided by the patient was lost.

About twenty hours after the poison had been taken 120 c.c. of very turbid urine, of slightly acid reaction and sp. gr. 1022, was collected. This, after addition of acetic

acid, was filtered, then reduced to 50 c.c., and extracted in the usual manner by hot amyl alcohol.

The residue obtained on evaporating the alcohol was extracted by ether, and this liquid allowed to evaporate spontaneously. The ether residue very clearly showed the presence of morphine, but only in very minute quantity.

It should be added that the only evidence that ten drachms of laudanum had been taken in this case is the statement of the patient himself; nor is anything known in regard to the quality of the drug taken.

CASE IX.—A gentleman on retiring at night took, by way of experiment, a pellet containing $\frac{1}{2}$ grain (16 m.g.) morphine sulphate. The following morning he voided 185 c.c. urine of light colour and slightly acid reaction.

This, after concentration, was extracted by amyl alcohol in the usual manner. The residue from this alcohol was again extracted by the alcohol, and the operation repeated a third time with a fresh portion of the alcohol.

The residue from the third alcohol extract, when examined by Frøehde's reagent, promptly gave a colouration very similar at least to that of morphine, but the results were not fully satisfactory. Other portions of the residue very promptly reduced solutions of iodic acid and of potassium ferricyanide; but, under the conditions, these reactions have no positive value.

A urine extract of this kind, even in the absence of morphine, will frequently yield, with Frøehde's reagent, a colouration which might be mistaken for that of a minute quantity of morphine, due to the reduction of the molybdenum compound. Moreover, this reducing action may entirely prevent or mask the normal reaction of morphine, even when the alkaloid is added to the residue in very notable quantity, as we have seen in repeated experiments.

For the purification of a mixture or residue of this kind it may be treated with a little water and a drop of acetic acid. The liquid is then filtered, and, while still acid, extracted with several volumes of pure strong ether.

The ether being decanted, the aqueous liquid is again covered with several volumes of fresh ether, and a drop of ammonia, or sufficient to neutralise the acid added. The mixture is then quickly and thoroughly agitated. The ether will now take up any morphine present, in part at least, and at most only a trace of urea, if present, the extractive matters and greater portion of urea being retained by the aqueous fluid. The ether is then decanted and allowed to evaporate spontaneously. Since morphine is only very sparingly soluble in ether, this method of purification is applicable only for the recovery of minute quantities of the alkaloid.

The above residue, from the third amyl alcohol extract, when extracted by ether after the foregoing method, gave a very minute, about colourless residue, which, when examined in several portions by Frøehde's reagent, gave purple colourations which seemed to leave no doubt of the presence of morphine.

CASE X.—This was a repetition of the foregoing case, only that $\frac{1}{2}$ grain morphine sulphate was taken, and the next morning 350 c.c. of urine, of faintly acid reaction and sp. gr. 1012, was obtained.

After concentration the urine was extracted by amyl alcohol and finally by ether, in the same manner as in the previous case.

The very minute final ether residue, when examined in three or four portions by Frøehde's reagent, gave well-marked purplish or violet colourations. These results were quite in contrast with those obtained by the reagent from an exceedingly minute residue obtained in the same manner from urine known to be free from morphine.

General Considerations.

In the use of amyl alcohol for the extraction of morphine from the urine, the urea taken up with the morphine interferes more or less with the purification of the alkaloid. In a residue consisting of a mixture of this kind,

the urea, as such, may, as we have found, be decomposed by heating the mixture in an air oven for a few hours at 135° C., without any appreciable loss of the morphine. But the presence of the products of the decomposition of the urea prove about as objectionable as that of the urea itself. Since urea is freely soluble in water, whilst morphine is only sparingly soluble, it might be inferred that these substances could thus be readily separated. This is true in regard to pure mixtures, and also when the morphine has assumed the crystalline state; but when present in only minute quantity the alkaloid seems to be so closely adherent with the urea and colouring-matter that these substances are largely dissolved together.

Some experiments were made in regard to the adaptability of *isobutyl alcohol* for the extraction of morphine from complex mixtures, especially from the urine. For this purpose, Schuchardt's alcohol, apparently pure, was employed. If a small quantity of this alcohol be agitated with large excess of water, it is dissolved by the water in the proportion of one volume of the alcohol in about 10.5 volumes of water, as generally stated by writers.

If, however, equal volumes of the alcohol and water, say 100 volumes of each, be mixed and agitated, after repose the alcoholic liquid will measure 103 volumes, the aqueous fluid being reduced to 97 volumes—that is, 100 volumes of the alcohol will take up 3 volumes of water. On treating excess of finely powdered morphine with hot *isobutyl alcohol*, and allowing the mixture to stand sixteen hours, it was found that one part of morphine was held in solution by 110 parts by weight of the alcohol. Under the same conditions one part of urea was retained in solution by 49.8 parts by weight of the alcohol.

It would thus appear that morphine, while rather freely soluble in *isobutyl alcohol*, is slightly less soluble in this liquid than in *amyl alcohol*; whereas urea, on the other hand, is somewhat more freely soluble in *isobutyl alcohol* than in *amyl alcohol*.

THE FIXATION OF ATMOSPHERIC NITROGEN.*

By A. A. BRENNEMAN, S.B.†
(Continued from p. 95.)

Production of Cyanides from Ammonia.

THE reactions by which ammonia is converted into cyanides are so closely related to the direct production of cyanides from nitrogen, and offer so many points of suggestion in connection with the same, regarded as an industrial problem, that the history of them cannot be omitted from this summary.

The original experiment, ascribed by Langlois (*Ann. ch. phys.*, [3] i., 117) to Scheele, of heating together sal-ammoniac, potash, and charcoal and obtaining potassium cyanide, may be regarded as the starting point.

Liebig attributes to Scheele (1750—80?) the statement, that ammonia passed over hot charcoal yields hydrocyanic acid, but Langlois does not find this in Scheele's writings. What Scheele does say is that when sal-ammoniac is heated with vegetable charcoal and potash the mass yielded on lixivation "*la lessive du sang*."‡ (*Langlois, loc. cit.*)

* *Journal of the American Chemical Society*, vol. xi., Nos. 1—2.

† The substance of this article was prepared as an appendix to a commercial report, but has not been printed heretofore in any scientific journal.—A. A. B.

‡ That is, potassium ferrocyanide, yellow prussiate of potash, called also in German "*blutlaugensalz*." The iron must have come from impurities in the materials. In the "*Life of Scheele*," given in *Crell's Journal*, vol. i., p. 12, 1897, the author says: "His experiments on the colouring matter of prussian blue, the methods of separating it, its properties, and in short the discovery of its artificial composition from charcoal, fixed alkali, and sal-ammoniac, may be mentioned amongst the most valuable of the performances with which he has presented us." The biographer also refers to fuller accounts of this work in *The New Transactions of the Royal Stockholm Academy*, vol. iii., p. 256, and vol. iv., p. 32. These sources of information are not accessible to me.—B.

Clouet in 1791* mentioned that ammonia gas passed over hot charcoal yields hydrocyanic acid. He states that Thenard had noticed that a soluble substance having the odour of bitter almonds was formed under the same conditions. Bonjour, Vauquelin, Buchholz, Schroder, and Ittner (*J. pr. Ch.*, xxvi., 409) all refer to the same fact as based upon experiments in which ammonia or ammonium chloride was heated with charcoal or with mixtures of charcoal and lime or oxide of lead. The product was probably ammonium cyanide, as in later repetitions of similar experiments, but the constitution of the cyanides was not then understood, as this was before the date of Gay-Lussac's discovery (1814). Clouet reported that hydrocarbons, carbonic acid, and nitrogen were set free at the same time, while Bonjour showed that hydrogen was the only by-product, an observation that was fully confirmed by Langlois in 1841. Trommsdorff (*Ibid.*) however, was first to recognise ammonium cyanide in the products of this experiment.

Kuhlmann (*Ibid.*, *Ann. Chem. (Liebig)*, xxxviii., 62; *J. pr. Ch.*, xvi., 482) found that volatile nitrogen compounds containing all hydrogen or mixed with volatile hydrocarbons, when passed together with carbonic oxide over hot platinum sponge, yielded ammonia. He refers to Clouet's experiment, and shows, by a repetition of the same, that no hydrocyanic acid, but only ammonium cyanide, is produced. Marsh-gas (CH_4) is separated at the same time. He regards the process of preparing alkaline cyanides as involving first the formation of ammonia, which, in presence of alkali and excess of carbon, is converted into cyanogen and carbonic oxide. Langlois (*Ann. ch. phys.*, [3], i., 117) repeated Scheele's experiment with sal-ammoniac, but obtained no cyanide. He also obtained ammonium cyanide by passing ammonia over hot charcoal, and called attention to the remarkable way in which ammonium cyanide resists decomposition at high temperatures.

The processes of Jacquemyn and Berry in this direction have already been mentioned (*ante*).

Graeger (*Jsb. chem. Tech.*, 1853, 184) passed vapour of ammonium carbonate through alkaline charcoal contained in narrow iron cylinders 1½ inches in diameter, and obtained 93 to 95 per cent of the theoretical yield of ferrocyanide. When large and wide cylinders were used the results were much inferior, only 15 to 30 per cent being obtained.

Brunquill (*Preuss. Verhandlungen*, 1856, 30; *Jsb. chem. Tech.*, 1856, 102; *Dingl. pol. J.*, cxl., 374, 452), in 1856, proposed to apply the same principle to the production of cyanides and prussiates. Ammonia, or the vapours from distillation of bones, &c., are passed over hot firebrick and then over hot wood charcoal in pieces of the size of a chestnut. The volatile ammonium cyanide is absorbed by solution of ferrous sulphate in an apparatus of peculiar construction. A portion of the ammonia is recovered as sulphate, and used anew in the process. The precipitated cyanides of iron are converted by potash or soda into prussiates. The advantages of this method are the prevention of waste of potash and of nitrogen. Only moderate temperatures being employed, there is no loss of potash by volatilisation, by absorption, or by formation of unavailable salts of potash, all of which occur in the old process. The cost of the ammonia is defrayed by the increased value of the residue when bones are used. The author hoped also to obtain ammonia for the first stage of the process by passing air and steam over coal.

Levoir, in 1859 (*J. pr. Ch.*, lxxvi., 447; *Dingl. pol. J.*, cliii., 466), noticed that a flame of ammoniacal gas yielded cyanogen (ammonium cyanide) in burning. Fischer (*Dingl. pol. J.*, clvii., 466) questioned this statement, saying that he had repeated Levoir's experiment with an

* *Ann. ch. phys.*, xi., 30; *J. pr. Ch.*, xxvi., 408. *Crell's Annalen*, 1796. This latter reference, which is probably the original source, I have not had access to.—B.

argand burner, and obtained no cyanogen. The fact was verified, however, a few years later by Romily.

H. Johnson (*Dingl. pol. J.*, clvi., 212; *Jsb. chem. Tech.*, 1860, 221, with diagram), in 1860, obtained in England a patent for a method, devised by J. V. Lucas in Paris, for preparation of prussiates, which consists simply in saturating wood charcoal with potash solution, drying and heating it to redness in a retort, and passing ammonia over it. The charcoal is mixed also with 5 per cent of iron filings.

J. Webster, in 1860 (Eng. Pat., No. 1913, Aug. 8, 1860), patented in England a process for manufacture of prussiates by charring or burning a mixture of sawdust or spent bark and oxide of iron, charging the mixture with potash and passing ammonia through it.

Fleck (*Polyt. Centralbl.*, 1863, 717; *Dingl. pol. J.*, clxix., 209; *Jsb. chem. Tech.*, 1863, 323), in 1863, proposed to make cyanides as follows:—A hot mixture of charcoal or coal, sulphur, and potash is treated with a definite quantity of ammonium sulphate. Potassium sulphocyanate is formed. Ammonia in part escapes, but is absorbed and utilised. The sulphocyanate is decomposed by metallic iron, yielding potassium cyanide and ferrous sulphide. It was claimed by the author that 94.42 per cent of the ammonium salts used were ultimately converted into cyanides. This process is referred to by Meyer ten years later, 1874, as not being successful in practice.

Gelis (*Annales du Conservatoire des Arts Metiers*, 1862, 37; *Jsb. chem. Tech.*, 1862, 283), in 1862, manufactured prussiates in Paris after a new method of his own invention, for which a medal was awarded at the London Exhibition of 1862. It consists in mixing, in the cold, a solution of ammonium sulphate (NH_4HS), obtained from gas liquor, with carbon disulphide; ammonium sulpho-carbonate, $(\text{NH}_4)_2\text{SCS}_2$, is formed and sulphuretted hydrogen. The addition of potassium sulphide to the sulphocarbonate results in the production of potassium sulphocyanate, which by action of iron can be converted into cyanide or prussiate. The by-products, ammonium sulphate and sulphuretted hydrogen, are again used. The process is carried on in a retort, and these products are readily recovered. The cost by this process was said by Payen to be within 1.6 francs per kilo. (about 15 cents per pound) for potassium ferrocyanide.

Meyer, in 1874 (*ante*), remarks that the conversion of potassium sulphocyanate into cyanide by iron is wasteful of nitrogen when fusion is resorted to and incomplete in the cold. The process of Gelis was finally abandoned.

Romily (*Compt. Rend.*, lxi., 320; lxi., 865; *Jsb. chem. Tech.*, 1867, 761), in 1867, repeated the experiment of Levoir (*ante*), and improved upon it. Illuminating gas was made to bubble through ammonia and then burned from a jet, and the flame was made to impinge upon a surface of water containing caustic potash in solution. Potassium cyanide was found after a time in the solution. Solutions of sodium and calcium hydrates gave corresponding results. When distilled water was used ammonium cyanide was found in the liquid. The effect was produced only when the flame was luminous or smoky; the flame of a Bunsen lamp yielded no cyanides. Vapours of oils or hydrocarbon gases containing ammonia gave similar results. Vapour of water in the mixture of gases did not prevent the formation of cyanides. When iron in fine powder was suspended in the alkaline solution ferrocyanide was formed.*

An apparatus was devised to apply the principle industrially. A cylinder of iron revolving on a horizontal axis, dipped into a tank containing an alkaline solution. A pipe, parallel with the cylinder and pierced with holes,

supplied ammoniacal illuminating gas, burning in a line of jets which impinged upon the face of the cylinder. The cyanides were absorbed by the film of alkaline liquid, which was continually renewed as the cylinder revolved.

Schwarz (*Bull. Soc. Chim.*, 1869, 167; *Dingl. pol. J.*, cxc., 399; *Jsb. chem. Tech.*, 1869, 269), in 1869, obtained ammonium cyanide by passing vapour of carbon disulphide mixed with ammonia over hot iron or copper in an iron tube. Sulphide of the metal is simultaneously formed. The vapours are passed into a mixture of solutions of caustic potash, ferrous sulphate, and ferric chloride, and the resulting mass is converted into prussian blue by hydrochloric acid, and then by potash into yellow prussiate. Schwarz also confirmed the conclusions of Levoir and Romily (*ante*) as to the production of ammonium cyanide during the combustion of ammoniacal illuminating gas, and he suggests that the purification of such gas from ammonia is, on this account, a matter of the greatest importance.

Frohde remarks ("Watt's Dict. Supp." I., 537) that the fumes from burning coal may be noxious, not merely because of oxides of carbon in them, but also because of cyanogen. He claims to have detected cyanogen by its odour where coal was incompletely burned.

E. Meyer (*Jsb. chem. Tech.*, 1874, 442), in 1874, published a review of the cyanogen industry up to the year of the Vienna Exhibition (1873). He found the old method still the only important one. The problem of making cyanides from nitrogen of the air was still unsolved, and the earlier efforts of Possoz and Boissiere (*ante*) had not been even equalled in its results by the later one of Margueritte and Sourdeval, from which much was at first expected. The methods using ammonia as a source of nitrogen for the manufacture of cyanides had not replaced the old method, through dry distillation of animal matters (Karmrodt, and others)—which are treated by fusion in the old process—nor by substitution of ammonia salts as a source of nitrogen for these substances (Fleck, *ante*). Neither had the methods based upon formation of sulphocyanate (Gelís) marked any great success. The production of sulphocyanate is readily brought about by Gelís's method, and the process is, so far, a success; but the conversion of this salt into cyanide or ferrocyanide is difficult. It does not stand sufficiently above the usual raw materials (animal matters) used for this purpose, in its proportion of nitrogen, to counterbalance the disadvantage which it offers in comparison with them from its high proportion of sulphur.

F. Maxwell-Lyte (U.S. Pat. 161, 137, March 23, 1875) patented, in 1875, a process for manufacture of ammonia by bringing nitrogen in contact with nascent hydrogen liberated in the presence of a triad or pentad element.

Tscherniak and Gunsberg (*Ber.*, 1879, 140; *Dingl. pol. J.*, ccxxii., 80; *Jsb. chem. Tech.*, 1879, 471; 1882, 570), in 1878, patented a method, in Germany (D. R. Pat. 3,199, April 9, 1878), for the manufacture of cyanides similar in principle to that of Schwarz (*ante*). Two parts of ammonia water of 85 per cent and one of carbon disulphide are put into a tight vessel, heated to 110° C. below and cooled above, so that a continuous distillation of the volatile substances occurs. After three or four hours the mixture is found to be converted into ammonium sulphocyanate and sulphuretted hydrogen. The ammonium salt is converted into calcium sulphocyanate, which, by action of an alkaline sulphate or carbonate, yields the corresponding alkaline salt, and this, by heating with coal, lime, and iron, yields cyanides or prussiates. The ammonia is recovered and used again.

Graham Young, in a process for the manufacture of ammonia patented in England in 1880, has suggested the use of electricity to effect the union of nitrogen and hydrogen. The principle had also been mentioned in an English patent issued to Chisholm and Kent in 1860. No practical result has as yet come from these suggestions.

* The discoveries of Levoir and Romily recall the early observations of Kuhlmann, who showed that ammonia and all volatile compounds of nitrogen yielded ammonium cyanide when mixed with hydrocarbons (or even with carbonic oxide in the case of ammonia), and passed over platinum sponge, at a temperature of 600° F.—B.

The Decomposition of Alkaline Hydrates by Metals in Presence of Air to Produce Ammonia.

Dufrené (Eng. Pat. No. 5478, Dec. 29th, 1880), in 1880, patented a process in England for the manufacture of ammonia by combustion of zinc in air, in presence of an alkaline hydrate. Hydrogen and nitrogen are both set free and combine to form ammonia under the influence of a porous solid, such as iron or platinum sponge in a heated state.

Twinch (Eng. Pat. No. 3712, Aug. 25th, 1881), in 1881, proposed to manufacture ammonia by using oxide of nitrogen (nitric oxide?—B.) to remove oxygen from air; the resulting nitrogen (which is said to be nascent and peculiarly active?—B.) is brought in contact with nascent hydrogen from the decomposition of steam or of alkaline hydrates by metals, to produce ammonia.

(To be continued).

THE DRY ASSAY OF TIN ORES.*

PART I.

By HEINRICH O. HOFFMANN,
Assistant Professor of Mining and Metallurgy.

(Continued from p. 94).

2. *Fusion with Calcium Fluoride.*—There are three methods described under this head, in all of which fluor-spar is used as the only or principal flux. They are recommended for ores containing silica only.

Fluor-spar is not readily fusible; in fact, it cannot be melted at temperatures produced in a muffle-furnace. Assays requiring it as a flux must therefore be carried on in a pot-furnace. While difficult of fusion, it is liquid when melted, and assists to liquefy compounds which have a refractory character by holding in suspension the particles which cannot be completely melted. It is therefore very satisfactory if a high temperature is required. Berthier† was the first to suggest that a loss in weight takes place if calcium fluoride and silica are heated together. In later publications‡ the formula—

is found with the statement that part of the silica escaped as silicon fluoride. Percy§ has shown by experiments that, while a loss in weight does take place, the formula is wrong, as it expresses more than three times the actual amount lost. It would seem, therefore, that the basis on which these methods are founded is not a correct one. Owing to the high temperature there is always danger of losing tin through volatilisation, although|| in a charcoal-lined crucible this may be prevented by entirely excluding the air. In regard to scorification it seems doubtful whether it can be avoided so as to give satisfactory results.

(1). Ricketts¶ recommends mixing 10 grms. of ore with 10 to 20 grms. of fluor-spar or cryolite. He then says: "Charge in a charcoal-lined crucible, which is first covered with charcoal and then luted with clay, heat strongly for about one hour, remove carefully from the fire, and tap gently. Treat the button as an alloy afterwards." These instructions were closely followed, fluor-spar being used and the time of exposure to heat lengthened, as previous experiments in charcoal-lined crucibles had shown that considerable time is required for the heat to penetrate the lining.

Three experiments were made, resulting in a grey, slightly fritted mass, which contained white tin and black

tin mixed with fluor-spar. This gave, when crushed in a porcelain mortar and treated with water, grey slimes and, as residue, the mixture of white and black tin. The complete reduction of the stannic oxide was probably prevented by the intimate admixture of fluor-spar. It could scarcely have been caused by insufficient heat. A hot anthracite fire was used; the furnace was 12×12 inches, the crucible resting on 3 inches of coal, and being covered by 3 inches of coal (to the lower edge of the flue). The draught was strong, the total time of exposure to heat two hours.

(2). Rickett.* gives a similar charge for a chalk-lined crucible—ore 10 grms., fluor-spar 10 grms., powdered charcoal 2 grms., a salt and charcoal cover, and recommends a hot fire.

This method produced negative results. The charge at the bottom and sides of the crucible was fused; it was grey, showing a crystalline structure. At the bottom the fused rim was $\frac{1}{2}$ inch thick, decreasing to $\frac{1}{4}$ inch higher up. Inside this shell was a fritted mass of a colour from dark grey to black, consisting apparently of charcoal and fluor-spar, with fine particles of tin dispersed through it, and covered by a pumice-like grey slag, probably a mixture of salt and fluor-spar.

(3). Balling† recommends mixing 5 grms. of ore with 2.5 grms. of fluor-spar and 2.5 grms. of lime, charging the mixture in a charcoal-lined crucible, and treating as in the old German method of assaying iron ores in the dry way—that is, heating for an hour and a half, the last fifteen or twenty minutes at a white heat.

The result of several fusions was a slightly sintered mass of a greyish white colour collected into a button. Through it were distributed prills of metallic tin of different sizes, the largest being about the size of a small pin-head. Another negative result.

No pains was spared to make these experiments with fluor-spar as thorough as possible, and the failure to obtain satisfactory results must have been due to one of two things; either the ore used was not suited to that mode of treatment, or important particulars were omitted from the directions given.

3. *Fusion with Potassium Cyanide.*—This very valuable method of assaying tin ores is given by Mitchell.‡ In describing his manner of operating, he says he uses a 3-ounce Hessian crucible, rams into its bottom a $\frac{1}{4}$ -inch layer of potassium cyanide, adds the charge, consisting of 100 grains of ore mixed with from four to five times its weight of powdered potassium cyanide, and gives a cover of the same flux. He then heats at a moderate temperature for ten minutes, removes the crucible, taps it gently, and allows it to cool. He dissolves the slag in water to see if any reduced metal or heavy particles of the original ore are present, and says that, with ordinary care, the results are accurate to 0.5 per cent.

The basis on which the process rests can be expressed by the formula $\text{SnO}_2 + 2\text{KCy} = \text{Sn} + 2\text{KOCy}$. Potassium cyanide, being more powerful than any other reagent, acts more quickly, and also at a lower temperature, thus reducing the volatilisation of tin to a minimum. The disadvantages are its cost and its very poisonous character. The extra expense need hardly be taken into consideration, as it is very nearly counterbalanced by the saving in time, the difference being fully made up by the superiority of the results obtained. Its poisonous character requires that special care should be taken in handling it. The mortar ought to be covered with a wooden lid, having a hole through which the handle of the pestle passes, and a cloth placed over this to avoid dusting. A sponge or handkerchief should protect nose and mouth while pulverising, weighing, and mixing the reagent with the ore. The crucible should be placed to cool under a good draught, and care taken to finish the

breaking of crucibles and handling of cyanide slags before the fingers have occasion to become moist. If these precautions are observed, there is no danger whatever, as the writer can testify from repeated experience.

In the experiments the ordinary chemically pure potassium cyanide—98 per cent KCy and 2 per cent KOcy—was first used; then the effects produced by the different impurities that are apt to be found in commercial cyanides are studied; and lastly, the commercial cyanides themselves were tested. The regular method given by Mitchell was varied in different ways to see what effect modifications from other methods would have on the reagent.

In regard to temperature and time required for the assay, Mitchell says "a moderate fire," which will keep the charge at a "steady fusion" for "ten minutes." It was found that a charge can be kept at a steady continuous fusion for twenty minutes, and the temperature be too low to complete the chemical reaction. Small globules of tin can be seen floating about in the slag, and these will not be collected into one button when the crucible is broken. On the other hand, the temperature may be raised so high that the charge will boil, and the fusion still be steady and continuous. The tin will be reduced, but will not collect into one button, and the assay will again be imperfect. The best way to regulate the temperature would seem to be the following. Begin with a hot fire, and keep it at the highest point to which potassium cyanide can be heated without beginning to boil and evolve heavy fumes. This temperature is easily recognisable after a few assays. Ten minutes is a very good average for the time, beginning when the charge is liquid and brown-red. An assay may be considered finished when the pure upper slag has become so transparent that the impurities contained at the bottom of the crucible are visible through it. The tin will then have collected into one button beneath the lower slag, and very few, if any, prills will be found.

The experiments with potassium cyanide were as follows (1 to 11):—

(1). 5 grms. of ore mixed with 20 grms. of potassium cyanide were charged in a Battersea crucible, size F, into the bottom of which had been rammed 5 grms. of cyanide; the charge was covered with 5 grms. of cyanide; time given, ten minutes.

The slag was as liquid as water. When cold, its surface was smooth, and had the shining lustre of porcelain. The crucible was not corroded, and the upper part was free from tin. On breaking the crucible, it was found that the potassium cyanide had filtered through nearly the entire bottom and blackened it, the blackness diminishing on the sides and disappearing near the top. The fracture of the upper slag was coarsely granular; it was opaque, milk-white, brittle, and soluble in water. On the bottom of the crucible was an amorphous, uneven slag; it had a resinous lustre, was subtranslucent, of light green colour, harder than the white slag, and insoluble in water. It was charged with the impurities contained in the ore. The button separated well from the slag, was white, bright, easily cut, malleable, and free from iron.

To examine the slags and lower part of the crucible for prills of tin, they were placed in hot water. The white slag dissolved readily, and the green, as a rule, separated easily from the crucible. The solution of potassium cyanide and cyanate was removed by decanting, and the

pieces of crucible taken out and dried apart from the residue in the dish. Both were then crushed separately, and passed through a 60-mesh sieve. The resulting fine pulp was panned, and the siftings weighed with their scales, the slags and crucibles of one series of assays being worked up together, as the weights of the resulting buttons were close enough to justify the proceeding.

Table VIII. shows that the average result is 0'54 per cent lower than that found by chemical analysis, and the percentage of tin in slags and crucible—1'10 per cent—rather higher than would have been expected. The greatest discrepancy, however, in the total weights is only 0'03 grm., but expressed in percentage it amounts to 0'6 per cent. It seemed, therefore, more advisable to use 10 grms. of ore, as in the next experiments.

(2). The charge consisted of ore, 10 grms.; potassium cyanide, 40 grms.; 5 grms. cyanide for bottom of crucible, and 5 grms. cyanide for cover; crucible, size F; time, fifteen minutes.

The only difference between the first and second assays is, that in the latter the bottom was covered with a larger quantity of green slag, showing (as the crucibles were of the same size as before) a thicker layer. In assays Nos. 35 to 38 this heavy green slag had collected around the button, filling the space between it and the crucible, and not quite reaching the top of the button, which was covered by the pure white slag. It would, therefore, seem advisable to use for a 10-grm. assay a crucible having a larger base than the size F of the Battersea make. The button could then lie on the bottom and be surrounded by the impure slag, the top being covered by pure white slag, which helps reduction and the successful collecting of the metal in one button. If the assays are made in the muffle, the 10 and 20-grm. (or Colorado A and B) crucibles, used for lead and assays, might be very suitable for the purpose.

The total average differs here only 0'35 per cent from the chemical analysis; three assays agree perfectly, and the fourth shows only 0'01 grm., or 0'1 per cent difference, which is very close. The percentage of tin in slags and crucible is half as much as that in the previous assays (Table VIII.), suggesting that the first assays, Nos. 35 to 38, might have been benefited by a longer exposure to the heat.

(To be continued).

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING JULY 31ST, 1890.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;

and C. MEYMOTT TIDY, M.B., F.C.S., Barrister-at-Law,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, *Metropolis Water Act, 1871.*

London, August 4th, 1890.

SIR,—We submit herewith the results of our analyses of the 189 samples of water collected by us during the past

month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from July 1st to July 31st inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 189 samples examined, 14 were found to be "very slightly turbid," the remainder being clear, bright, and well filtered.

During the first three weeks of the month of July the condition of the water supply to the Metropolis continued to be, as it had been for months previously, entirely satisfactory; but during the last ten days of the month there was manifested an appreciable deterioration, especially in respect to degree of colour-tint upon examination in bulk, consequent on the exceptional heavy rainfall of the 17th and 18th. This deterioration was noticeable to some extent in the supply of all the seven Companies, but more especially, as shown by the Tables, in the case of four out of the five Companies taking their supply from the Thames.

That the deterioration was associated with but an insignificant increase in the proportion of organic matter present in the water—and that inferred on good grounds to be mainly of a vegetable nature—is shown by a comparison of the determinations of organic carbon present in the water-supply of the earlier and later portions of the month, with the determinations of the degree of colour-tint manifested during the same periods respectively. Thus, in the case of the five Companies deriving their supply from the Thames, while the mean ratio of brown to blue tint of the water during the first three weeks of the month was as 13 : 20, during the last ten days of the month it was as 22 : 20. But as regards organic carbon, the mean proportion for the first three weeks of the month being 0.143 part in 100,000 parts of the water, with a maximum of 0.161 part in any single sample examined, the mean proportion for the last week of the month was but 0.165 part in 100,000 parts of the water, with a maximum of 0.185 part in any single sample examined. Altogether, the mean proportion of organic carbon for the entire month of July was but 0.152 part, as against a mean of 0.150 part for the month of June.

As regards the heavy rainfall of the month and consequent unfavourable condition of the rivers, it is to be noticed that on 28 out of the 31 days of the month there was an appreciable rainfall in the Thames and Lea Valleys, and on one or two of the early days of the month a decidedly heavy rainfall, followed up by the remarkable rainfall of the 17th, and very considerable rainfall of the following day. Mr. G. J. Symons, F.R.S., has informed us that the mean rainfall for the month in the Thames and Lea watersheds was 3.73 inches, of which 1.92, or nearly two inches, fell on the 17th and 18th.

Mr. Symons further writes us word: "The rain of the 17th was a very exceptional if not unprecedented one, not on account of the absolute totals (though one gauge, Lord Ebury's, at Moor Park, Rickmansworth, collected 4.19 inches, and another at Hillingdon, Uxbridge, collected 4.00 and then ran over) as because of the very large area with upwards of two inches, and the considerable area with more than three." Speaking of these high returns, he has elsewhere observed, "It is perhaps noteworthy that they are all from stations either actually on the banks of the Thames, or within three miles of it," in view of the really unprecedented amount of the rain-

fall—in regard to the wide area of heavy fall, more considerable even than that of July 26th, 1867—it is only to be wondered at that the water supply to the Metropolis should have been so inconsiderably affected.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES.

WILLIAM ODLING.

C. MEYMOTT TIDY.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, June 19th, 1890.

Dr. W. J. RUSSELL, F.R.S., President, in the Chair.

(Continued from p. 97).

55. "*The Action of Heat on the Chlorides and Hydroxides of mixed Quaternary Ammonium Compounds.*" By N. COLLIE, Ph.D., and S. B. SCHRYVER, B.Sc.

The object of the authors' experiments has been to devise, if possible, a general method for preparing mixed tertiary amines. One of them (Collie, *Chem. Soc. Trans.*, 1888, 714—726) has shown that mixed tertiary phosphines could be prepared by heating the quaternary phosphonium compounds, and the following results show distinctly a marked analogy between the compounds of nitrogen and those of phosphorus.

Hofmann has already pointed out that when the hydroxides of mixed quaternary ammonium compounds containing ethyl are heated, one of the ethyl groups is invariably eliminated in the form of ethylene, e.g.,—

and Lossen has obtained similar results. But none of the mixed tertiary amines were thus prepared in a state of purity; both Hofmann and Lossen were content to reconvert the products into quaternary ammonium chlorides and analyse the platinum salts. The authors have used trimethylamine and triethylamine, and from these tertiary amines have prepared the quaternary ammonium compounds by heating the alcoholic solution of the amine with the iodide or chloride of primary, secondary, or tertiary hydrocarbon radicles of the C_nH_{2n+1} series. The action of heat on the quaternary ammonium compounds containing the radicles allyl, benzyl, and phenyl has also been studied. The mixed tertiary amines which have thus been prepared for the first time in the pure condition are:—

Dimethylethylamine, b. p.		45—46° C.
Diethylmethylamine, "		66—67° C.
Dimethylamylamine, "		113—114° C.
Dimethylbenzylamine, "		178—179° C.

56. "*Action of Phosphoric Anhydride on Fatty Acids.*" By F. STANLEY KIPPING, Ph.D., D.Sc.

The investigation of the action of phosphoric anhydride on fatty acids has now been extended to palmitic acid and lauric acid, and some preliminary experiments have also been made with caproic acid. These compounds, like stearic acid and heptylic acid, are decomposed by phosphoric anhydride at a moderately high temperature in accordance with the equation—

As the ketone produced can easily be obtained in a pure condition and the yield is also good, this method may be conveniently employed for the preparation of the compounds in question.

Palmitone, $(C_{15}H_{31})_2CO$, can be prepared by heating palmitic acid at 200—210° and gradually adding a slight

excess of the theoretical quantity of phosphoric anhydride. The dark brown mass is allowed to cool, treated first with water and then with soda to free it from phosphoric acid, and the residue extracted several times with boiling alcohol; on cooling, the ketone separates from the alcoholic extracts as a yellowish powder, and can be obtained in a pure condition by re-crystallising it from boiling alcohol. The yield of the pure product is more than 50 per cent of the theoretical. It is a colourless crystalline powder melting at 82–83°. The *hydroxime*, $(C_{15}H_{31})_2C:N\cdot OH$, forms peculiar fern-like crystals and melts at about 64–65°.

Dipalmitylcarbinol, $(C_{15}H_{31})_2CH\cdot OH$, is obtained by reducing palmitone with sodium in boiling alcoholic solution; it crystallises from alcohol in silky plates and melts at 84–85°. When boiled with acetic anhydride for several hours, it is converted into a colourless crystalline acetyl-derivative, $(C_{15}H_{31})_2CH\cdot OAc$, melting at 49–50°.

Laurons, $(C_{11}H_{23})_2CO$, can be easily prepared by heating lauric acid at 220–230°, with a slight excess of the theoretical quantity of phosphoric anhydride; at a lower temperature the acid is not readily decomposed. The product is purified as described in the case of palmitone; the yield is about 40 per cent of the theoretical. The *hydroxime*, $(C_{11}H_{23})_2C:N\cdot OH$, is formed when the ketone is heated with hydroxylamine hydrochloride and excess of potash in dilute alcoholic solution; it crystallises from alcohol in slender needles and melts at 39–40°.

Dilaurylcarbinol, $(C_{11}H_{23})_2CH\cdot OH$, is obtained when the ketone is reduced with sodium and water in ethereal solution; it crystallises in colourless waxy plates and melts at 75–76°. The acetyl derivative,—

is formed when the alcohol is boiled with acetic anhydride for some hours; it crystallises from methyl alcohol in colourless plates melting at 34–35°.

Caproic acid, at its boiling-point, is decomposed by phosphoric anhydride, giving the ketone $(C_5H_{11})_2CO$; the product can be isolated by distillation with steam. The yield seems so be fairly good.

57. "*aa'-Dimethyl-aa'-diacetylpentane*." By F. STANLEY KIPPING, Ph.D., D.Sc., and J. E. MACKENZIE, B.Sc.

The conversion of *aa'*-diacetylpentane into dimethyl-dihydroxyheptamethylene on reduction (Kipping and Perkin, *Proc. Chem. Soc.*, 1889, 145) being an action to which much interest attaches, the authors have instituted experiments with a view to ascertain whether other diketones of analogous constitution can be converted into heptamethylene derivatives in a similar manner. The investigation is not yet completed, but *aa'*-dimethyl-*aa'*-diacetylpentane and various other compounds have already been prepared.

Ethyl-aa'-dimethyl-aa'-diacetylpimelate,—

can be obtained by treating ethylic methylacetoacetate with trimethylene bromide and sodium ethoxide in absolute alcoholic solution; a considerable quantity of compounds of lower boiling-point is also formed, so that the yield of ethylic dimethyldiacetylpimelate is only 50–60 per cent of the theoretical. It is a colourless oil boiling at about 250° under a pressure of 60 m.m. On hydrolysis with alcoholic potash the ethereal salt is decomposed into dimethyldiacetylpentane, dimethylacetylcaproic acid, and dimethylpimelic acid, the relative quantity of each of these three compounds depending to a considerable extent on the concentration of the alcoholic potash, and on the manner in which the hydrolysis is carried out.

aa'-Dimethyl-aa'-diacetylpentane,—

is a colourless oil boiling at 198–201° under a pressure of 112 m.m.; it shows no signs of crystallising even when cooled to 0°. The *dihydroxime*,—

crystallises from a mixture of benzene and light petroleum in colourless needles melting at 95–95°.

aa'-Dimethylpimelic acid,—

separates from light petroleum in compact colourless crystals, and melts at 74–75°; it is readily soluble in water and most organic solvents. The *silver* salt, $C_9H_{14}O_4Ag_2$, is a colourless, seemingly amorphous compound, only sparingly soluble in boiling water.

Ethyl-aa'-dimethylpimelate, $C_9H_{14}O_4Et_2$, is formed in large quantities when ethylicmethylacetoacetate is treated with sodium ethoxide and trimethylene bromide in alcoholic solution in presence of a small quantity of water; under these conditions the ethylic dimethyldiacetylpimelate which is produced in the first case seems to be completely converted into the ethylic dimethylpimelate. It is a colourless oil boiling at 190–191°. On hydrolysis with alcoholic potash it is converted into dimethylpimelic acid.

aa'-Dimethyl-ω-acetylcaproic acid,—

is a thick colourless oil boiling at about 218–220° under a pressure of 60 m.m.; it cannot easily be obtained in a pure condition.

58. "*Berberine*." Part II. By W. H. PERKIN, jun. Ph.D., F.R.S.

In Part I. of this research (*cf. Chem. Soc. Trans.*, 1889, 63) the results of preliminary experiments on the oxidation of berberine with varying quantities of potassium permanganate were briefly described, and a short account of some new substances obtained during these experiments appended. In the further prosecution of this research very large quantities of the alkaloid have been oxidised. The amounts used in the experiments varied considerably, but some of the best results were obtained where, in each operation, 7 grms. of berberine, 9 grms. of potassium permanganate, and about 1 gm. of potassium carbonate were used. The product from a number of such operations was treated with sulphur dioxide until the whole of the manganese precipitate had been brought into solution; the resulting yellow precipitate was then separated from the yellow solution (A) by filtration, washed with water, and warmed to 40° with a dilute sodium carbonate solution, by which means about one-half of the precipitate was dissolved (B).

The insoluble residue contains, besides two substances—berberilic anhydride, $C_{20}H_{17}NO_8$ (m. p. 236–237°), and berberal, $C_{20}H_{17}NO_7$ (m. p. 150°)—which have been already described, a new base, $C_{20}H_{19}NO_9$, which is very sparingly soluble in water, and crystallises in flat yellow plates, and small quantities of two other substances.

The alkaline solution (B) contains, as principal product, α -berberilic acid, $C_{20}H_{19}NO_9$, which was described in the former paper. This acid, when heated to 180°, is converted into berberilic anhydride; in other respects it shows great similarity to β -berberilic acid, which is described below.

The solution (A) was evaporated in large flat basins to about half its bulk, filtered from the precipitate (C) which separates and then evaporated to a small bulk (D). The precipitate (C) was warmed with dilute chlorhydric acid till free from inorganic matter, the residue washed with water, dried, and extracted with hot acetic acid, by which means a quantity of berberilic anhydride was removed. The insoluble residue was dried and dissolved in a small quantity of boiling aniline, from which solution it was deposited, on cooling, in glittering yellow plates, having the composition $C_{20}H_{17}NO_6$.

This substance, which is formed in very small quantities, has only been superficially examined. It is characterised by its insolubility in the usual solvents, and by the fact that it yields a beautifully crystalline potassium salt when dissolved in alcoholic potash.

The highly concentrated liquors (D) were extracted 30

times with ether, the ether evaporated and the semi-solid residue boiled with water until the greater part had dissolved (E). The residue dissolved almost entirely in dilute sodium carbonate solution (P), leaving a dark brown pasty residue, from which, by treatment with glacial acetic acid, a substance crystallising in long brown needles can be isolated. This substance melts at 167°, and has the formula $C_{20}H_{15}O_5$, and dissolves in alkali with formation of an acid, which crystallises from water in long glittering needles, m. p. 147°.

The alkaline solution (F) acidified with chlorhydric acid, deposits a brown amorphous precipitate, which crystallises from glacial acetic acid in glittering colourless plates, which melt at 200° with decomposition and charring.

This substance, which has the composition $C_{20}H_{15}NO_7$, is a monobasic acid, yielding highly characteristic salts, of which the silver salt, $C_{20}H_{14}NO_7Ag$, was analysed. The calcium, lead, and zinc salts are sparingly soluble, but beautifully crystalline.

The solution (F) was next examined. This was heated to boiling, rendered slightly alkaline with sodium carbonate, and allowed to stand twenty-four hours. At the end of this time the liquid is found to be filled with a mass of glittering plates of a new base, $C_{10}H_9NO_3$, which will be described in detail later on. These are filtered off, the alkaline solution neutralised with chlorhydric acid, and mixed with an excess of strong solution of calcium chloride. No precipitate is produced in the cold, but on boiling, a crystalline calcium salt separates. This is collected, washed with a little water, dissolved in hot dilute hydrochloric acid, from which solution, on standing, a quantity of crystals separate. These crystals are a mixture of two acids, which both melt at 18°, and which can be separated by re-crystallisation from water. The more soluble acid is hemipinic acid. The second acid crystallises from water, without water of crystallisation, in colourless plates, which, on analysis, give numbers agreeing with the formula $C_6H_6O_6$. The silver salt has the composition $C_6H_4O_6Ag_2$. This acid is most probably identical with hydrastric acid,—

which Freund and Lachmann (*Berichte*, xxii., 2324) obtained from hydrastrinine, and which melts at 175°.

The following are the results of the examination of the principal products described above:—

1. *Berberilic anhydride*, $C_{20}H_{17}NO_8$, m. p. 236—237°, does not combine with phenyl hydrazine. When boiled with acetic anhydride for some hours it is converted into an acetate, $C_{20}H_{16}NO_7(C_2H_3O_2)$, which crystallises from acetic anhydride in hard light yellow prisms melting at 140°. Boiling dilute sulphuric acid decomposes this acetate quantitatively into berberilic anhydride and acetic acid. Pentachloride of phosphorus converts berberilic anhydride into a chloride, $C_{20}H_{16}NClO_7$, which crystallises from benzene in hard garnet-red prisms melting at 167°. This substance is readily acted on by water and re-converted into berberilic anhydride. Berberilic anhydride dissolves readily in warm dilute caustic soda solution, with formation of β -berberilic acid, which is precipitated on the addition of acids as a white sticky mass, which becomes hard on standing.

This new acid crystallises from dilute alcohol in warty masses, and melts at 180°, being at this temperature re-converted into its anhydride. Its composition is—

and it is isomeric with α -berberilic acid, which melts at about 140°.

A number of salts were prepared by precipitating a neutral solution of the ammonium salt with various agents. These salts, however, are not derived from berberilic acid, $C_{20}H_{19}NO_9$, but all contain one molecule of water less, and are therefore derivatives of the anhydride $C_{20}H_{17}NO_8$. The silver salt, $C_{20}H_{16}AgNO_8$, is a white

amorphous mass. The methylic salt, $C_{20}H_{16}(CH_3)NO_8$, prepared by the action of methyl iodide on the silver salt, crystallises from acetic acid in glittering plates, which melt at 178—179°. As it was thought possible that the methyl group might be attached to nitrogen, the action of hydrogen iodide on this methyl salt was investigated, and it was found that three methoxy-groups were present, two belonging to the berberine molecule. The substance is therefore a true methylic salt.

The most important reaction of β -berberilic acid is the change which this substance undergoes on hydrolysis. When boiled with dilute sulphuric acid (5 per cent), it dissolves completely, being converted quantitatively into hemipinic acid and a new base:—

small quantities of berberilic anhydride being always re-generated during the decomposition.

After extracting the hemipinic acid by ether, the sulphuric acid liquors are evaporated to a small bulk, and then allowed to stand forty-eight hours, when the sulphate of the base separates in large slightly brownish coloured tablets. These are collected, dissolved in water, treated by the calculated quantity of baryta-water, and the solution gently evaporated. The concentrated solution deposits the base in large flat monoclinic plates which melt at 180—182°, and contain 1 mol. of water. The platinumchloride, $(C_{10}H_{11}NO_4HCl)_2PtCl_4$, crystallises from water in dark yellow needles which melt at about 220°. Nitrous acid converts the base into a substance of the formula $C_{10}H_8O_4$, which will be described later on.

When heated to 180°, or digested with strong potash solution, or even simply boiled with water for some time, the base loses the elements of a molecule of water, and is converted into another base, $C_{10}H_9NO_3$.

This important substance crystallises from water in magnificent colourless glittering plates which melt at 182°. It is feebly basic, its salts being only stable in the presence of large quantities of acid. It is a very stable substance, and when boiled with dilute nitric acid is principally converted into a nitro-derivative,—

which crystallises from water in yellow plates, m. p. 175—180°. If the base be dissolved in a large quantity of dilute chlorhydric acid (HCl to $2H_2O$), well cooled, and the calculated quantity of sodium nitrite (1 mol. prop.) added, an immediate precipitate of a yellow nitroso-compound, $C_{10}H_8(NO)NO_3$, is produced. This crystallises from alcohol in glittering yellow needles which melt at 195—196° with decomposition. When boiled with dilute caustic soda, this nitroso-compound rapidly dissolves with evolution of nitrogen,—

The new substance melts at 146°, and is readily soluble in hot water and most of the usual solvents. It is an acid, the salts of which are fairly characteristic. The silver salt, $C_{10}H_9AgO_5$, is crystalline, and soluble in hot water. When heated to 150°, or boiled with water, this substance readily loses 1 mol. of water, and is converted into its anhydride, $C_{10}H_8O_4$.

This substance crystallises from water in large flat plates which melt at 126°, and distils almost without decomposition. It is re-converted by dissolution in alkalies into the acid $C_{10}H_{10}O_5$. Nitric acid produces a light yellow mononitro-compound, $C_{10}H_7(NO_2)O_4$, which melts at 197°. A number of experiments were tried with the object of oxidising the molecule to some well known acid, but without success, the substance being either unacted on or else completely destroyed by the oxidising agents employed. Gently fused with potash, the substance yields a mixture of pyrocatechol and protocatechuic acid.

When heated with hydriodic acid in Zeisel's apparatus, no trace of methyl iodide was evolved, a proof that the molecule contains no methoxyl-groups; chlorhydric acid (HCl to $4H_2O$) at 170—175° decomposes the substance,

however, and apparently quantitatively, with deposition of carbon and formation of a new compound,—

This compound crystallises from water, in which it is very soluble, in warty masses which melt at about 220–225°. Its aqueous solution shows with ferric chloride the most intense pyrocatechol reaction; it gives a white precipitate with acetate of lead, and reduces both Fehling's solution and ammoniacal nitrate of silver.

The result shows that all these derivatives contain the piperonyl-group,—

the constitution and proposed nomenclature of these substances being apparent from the following table:—

Freund and Will (*Berichte*, xx., 2400), in their researches on hydrastine, describe a substance, oxyhydrastine, obtained by the action of caustic potash on hydrastine, which they subsequently prove to have the constitution—

If the formulæ assigned to the compounds above be correct, this oxyhydrastine must be a methyl-derivative of the compound $C_{10}H_9NO_3$, and in order to confirm these formulæ every effort was made to convert the substance $C_{10}H_9NO_3$ into oxyhydrastine.

The experiments first made in this direction are the following:—

1. $C_{10}H_9NO_3$ and $C_{10}H_{11}NO_4$ were treated with methyl iodide under various conditions, with and without the addition of alkali.

2. $C_{10}H_8O_4$ was heated with methylamine and with methylamine acetate in a sealed tube.

3. $C_{10}H_{10}O_5$ was converted into the methylamine salt, and this was distilled.

But all these experiments failed to produce the change desired. The transformation was, however, ultimately accomplished in the following way:—The compound $C_{10}H_8O_4$ is converted by phosphorus pentachloride into the chloride $C_{10}H_7O_4Cl$, which crystallises from chloroform in glittering needles melting at 159°. This substance is remarkable for the ease with which it loses hydrogen chloride, and is re-converted into $C_{10}H_8O_4$. This change takes place on heating to 150°, or on heating with alkalis, or reducing with zinc-dust and acetic acid, and also on heating with methylamine in alcoholic solution in a sealed tube.

In order to prevent this, the carboxyl-group was protected by converting the chloride into its methylic salt. For this purpose, $C_{10}H_7O_4Cl$ was treated in chloroform

solution with an excess of pentachloride of phosphorus, the chloroform distilled off, and the residue poured into methyl alcohol. The methylic salt was thus obtained as a white powder, which crystallised from dilute methyl alcohol in beautiful woolly tufts of needles melting at 83°.

When this was heated with methylamine in alcoholic solution at 130° for six hours and the product was boiled with alcoholic potash, oxyhydrastine was almost quantitatively obtained, thus:—

The substance obtained in this way melted at 98°, and showed all the properties of oxyhydrastine.

2. *Berberal*, $C_{20}H_{17}NO_7$, m. p. 150°.—When in a finely divided state and very pure, berberal is moderately readily hydrolysed by boiling dilute sulphuric acid (containing 20 per cent H_2SO_4), a clear slightly brownish coloured solution resulting. Ether extracts from this solution a colourless crystalline mass, which, when treated with dilute sodium carbonate, is separated into the base $C_{10}H_9NO_3$, described above, and a new acid. This latter substance crystallises from water in beautiful long satiny needles which melt at 121°, and on analysis give numbers agreeing with the formula $C_{10}H_{10}O_5$. The analysis of the silver salt, $C_{10}H_9AgO_5$, showed the acid to be monobasic. When treated with hydrogen iodide in Zeisel's apparatus, results were obtained which proved that the acid contained two methoxyl groups. Fusion with potash converts the acid into protocatechuic acid; but if caustic potash solution (sp. gr. 1.4) be employed and the acid simply digested with this on a reflux apparatus, an almost quantitative yield of veratric acid, $(CH_3O)_2C_6H_3COOH$ (m. p. 177–178°), is obtained.

When subjected to the action of hydroxylamine in alkaline solution at ordinary temperatures, a hydroxime, $C_{10}H_{11}NO_5$, is produced. This crystallises in fine needles, which, when heated, melt at 124°, but at once become solid again, and then do not again melt till the temperature is raised to 213°. In order to investigate this decomposition, the pure hydroxime was heated to 180° for fifteen minutes and the residue re-crystallised from alcohol. Beautiful needles were thus obtained which melted at 224–226°, and were readily identified as hemipinimide.

The acid $C_{10}H_{10}O_5$ is readily reduced by sodium amalgam, being converted into an acid which, when precipitated from its alkaline solution by the addition of an acid, at once loses water with formation of pseudomekonin,—

This substance crystallised from water in long needles melting at 122–123°, and possessed all the properties ascribed to pseudomekonin by Solomon (*Ber.*, xx., 884). These experiments prove conclusively that the acid $C_{10}H_{10}O_5$ has the constitution represented by the formula—

and it thus bears a very close relationship to opianic acid,—

which is brought out in a most interesting way by a parallel study of the reactions of the two substances; thus, for instance, on reduction both yield mekonins, and with hydroxylamine both yield hydroximes, which, when gently warmed, are converted into hemipinimide. The acid $C_{10}H_{10}O_5$ may therefore be called *pseudopianic acid*.

These experiments throw considerable light on the constitution of *berberal*. This substance on hydrolysis yields pseudopianic acid and the base—

its constitution is therefore probably represented by the formula—

Berberilic anhydride, $C_{20}H_{17}NO_8$, yields on hydrolysis hemipinic acid and the base—

it has, therefore, possibly the following constitution:—

These experiments also show:—

1. The nature of all the oxygen atoms in the molecule of berberine, $C_{20}H_{17}NO_4$, thus precluding the hypothesis that berberine owes its colour and tintorial power to the presence of a quinone-group.

2. That berberine is an isoquinoline-derivative.

3. That berberine is closely related to hydrastine, narcotine, and papaverine.

Further experiments must decide the question of the exact constitution of berberine; but the author is of the opinion that the following formula explains well all the reactions of this alkaloid which have hitherto been investigated:—

The discussion of this formula will be attempted in the detailed paper.

(To be continued).

ROYAL INSTITUTION OF GREAT BRITAIN.

General Monthly Meeting, July 7, 1890.

SIR JAMES CRICHTON-BROWNE, M.D., LL.D., F.R.S.,
Treasurer and Vice-President, in the Chair.

THE following were elected Members of the Royal Institution:—Thomas Townsend Bucknill, Q.C.; Edward A. Harvey; Malcolm Morris, F.R.C.S.; and William Thomas Rabbits, F.L.S.

The Presents received since the last Meeting were laid on the table, and the thanks of the Members returned for the same.

NOTICES OF BOOKS.

The Gas and Water Companies Directory, 1890. Edited by C. W. HASTINGS. London: Hazell, Watson, and Viney, Limited.

THIS work is of less interest from a technical or a sanitary point of view than are its companion volumes. But it is certain to be of great value to persons investing in gas and water undertakings, or, as the editor puts it, "to all interested in the great question of supplying light and water for the public benefit." It might here well be asked

how many promoters, directors, or shareholders of such undertakings think of the "public benefit" at all, or of anything save the great question of dividends.

Several new features have been added to the work which will increase its value. It appears that enquiries have often been made by secretaries, managers, &c., as to the amount paid by gas and water undertakings for taxation, local and national. Whether such officials think that their respective companies are too heavily taxed is a point upon which we cannot enter.

Another feature is a directory of firms supplying articles likely to be needed by gas and water undertakings.

The third, and we must say the most important, novelty is an "Electric Lighting Section." If we take a page of this section we find it divided into the following columns: Name of town; name and address of company (if not municipal); date of formation; capital; system; capacity; price per unit; name of secretary; name of electrician in charge; and area of supply, with remarks. Fifty-six towns or municipal districts are already provided with electric lights or the necessary installations are in a very advanced state.

Gas Works Statistics, 1890. Edited by C. W. HASTINGS.

London: Hazell, Watson, and Viney, Limited.

COMPANIES and towns have responded much more generally to the editor's request for information concerning their gas-production than touching their water supplies. Many of the returns are made up only to a rather remote date; thus Castleford, Chertsey, and Chigwell only carry their accounts down to 1884, whilst Dartford and Grant-ham go merely to 1883.

Some towns have worked very neatly, consuming exactly as much gas as they made in the year. Chatteris does better still; it made 3161 thousand feet of gas and sold 3486. Whether the extra 325 thousands were gas remaining in stock from a former season or air which had leaked in it does not appear.

The general illuminating power of gas has improved of late years. Berwick heads the list with 30 candle-power, followed by Liverpool with 21½, and Mallock Bridge with 21, and twenty towns dispense 20 candle gas, whilst 19 and 18 are fairly common. Nevertheless not a few places keep to the good old rule of 14 candles.

In Scotland the quality of the gas is much higher than in England. Highest comes Colinsburgh with its 65 candle gas, made from oil. In 27 towns the standard is 30 or upwards, in no case does it fall as low as 20. With the single exception of Berwick the best English gas falls short of the poorest in Scotland.

In Ireland the quality of the gas is equal, on the average, to that of England. Larne takes the lead with 22 candle gas; 14, the lowest figure, occurs very rarely.

It does not appear that in any of the three kingdoms the price of gas is a function of its illuminating power.

The Water Works Statistics, 1890. Edited by C. W. HASTINGS. London: Hazell, Watson, and Viney.

As in former years certain towns still neglect or decline to furnish information to this publication. Among the defaulting places are Aylesbury, Tring, Durham, and Kingston-on-Thames. Two new columns have been added, showing "storage capacity" and "daily consumption per head," but on these points a majority of the towns are silent. The latter piece of information, when procurable, would be very useful in calculating the dry-weather flow of sewage. Concerning the value of the column "Death rate," we are not free from doubts. No one, of course, questions the danger of polluted water. But the factors which affect the sanitary condition of a community are so many and so varied that we do not feel free to argue from the death-rate to the comparative merits of hard and soft waters.

The information concerning the water-supplies of Scottish, Irish, and Welsh towns is somewhat meagre, and is mixed up with returns from foreign parts, but only, it would appear, from towns which are supplied by English water companies.

A foot-note on p. 6 is a curiosity. We are told that a certain water "requires to be hardened," but we cannot trace to what town this note refers. We are inclined to say that no water requires to be hardened except it contains free alkali, and to harden such a water usefully would be a difficult matter.

The information under the head "Source of Supply" is still somewhat promiscuous. Some towns tell us, sensibly enough, that their wells or springs are in the chalk, the greensand, the new red, or the millstone grit, as the case may be. Others curtly say "springs," "gathering grounds," "wells," &c., without stating the geological formation. Such answers are not of the slightest value.

We are still of opinion that the statistics might be exceedingly valuable if municipalities and companies would loyally coöperate with the editor.

Might we suggest that statistics of sewage treatment—whether irrigation, filtration, or precipitation, and in the two latter cases by what process—would form a very useful companion pamphlet.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 6, August 11, 1890.

Equilibria and Reciprocal Displacements of the Volatile Alkalies.—M. Berthelot.—If the initial bodies or products undergo no dissociation, and if they are in conditions favourable for setting the reactions on foot, the magnitude of the heats liberated alone determines the phenomena. But if certain of the initial bodies or products are capable of dissociation, the existence and the degree of this dissociation must be taken into account. If we have, e.g., a salt in solution but in part dissociated into free base and a free acid, the whole forming a system in equilibrium; if we add another base then, whatever may be its relative strength, it will necessarily tend to seize the fraction of free acid resulting from the dissociation of the antagonistic salt. In consequence, the primitive equilibrium will be disturbed and a new dose of the initial salt will be dissociated, reproducing some proportion of acid, which in turn will be taken up by the second base. If the salt of the second base is capable of being eliminated by insolubility or volatility the laws of Berthelot come into action.

Death of M. Chancel.—The Secretary announced to the Academy the decease of M. Chancel, Correspondent of the Section of Chemistry, which took place at Montpellier, August 5, 1890.

Certain Novel Hydrates of Gas.—M. Villard.—The author has previously indicated the existence of solid hydrates of methane and ethane, and he has now experimented on their higher homologue, propane, which he has prepared by the method of Prof. Schorlemmer. He finds it difficult to obtain a pure hydrate by compression. The compound obtained presents at 0° a dissociation temperature bordering upon one atmosphere, and it may be preserved indefinitely below 8.5° under suitable pressures. An admixture of air has no influence upon the temperature of destruction of this hydrate, which is still 8.5°, even under strong pressures. The critical tem-

perature of the hydrates formed by methane, ethane, and propane, falls if we pass from a carbide to its higher homologue; the compounds are destroyed respectively at 21.5°, 14.5°, and 8.5°. It is sufficiently proved that carbon tetra- and di-fluoride, methylene fluoride, and fluoroform, can yield with water four solid hydrates having the respective destruction temperatures 20.4°, 10.5°, 17.6°, and 21.8°.

A New Fatty Acid.—E. Gérard.—The fatty acid in question is obtained from the seeds of *Datura stramonium*. Its composition answers to the formula $C_{24}H_{48}O_4$. The acid is, in its properties, intermediate between the palmitic and the stearic, though its melting-point is decidedly lower than that of the more fusible of its two homologues. The author proposes for it the name daturic acid.

Researches on the Purple of *Purpura capillus*.—Augustin Letellier.—At the moment when the colouration appears in the coloured band in the body of this mollusc an offensive and penetrating odour is given off which contains sulphur, and behaves with sulphuric acid and with water like allyl sulphide. No ammoniacal salts are present, but there exists a cyanide or a sulphocyanide, and the presence of carbamides or sulphocarbamides may be suspected.

Revue Générale des Sciences Pures et Appliquées.

Vol. i., No. 14, July 30, 1890.

Annual Review of Pure Chemistry.—E. Etard.—In this summary the author calls attention to the revived interest in general or physical chemistry which has characterised the last few years. The questions of dissociation, of thermo-chemistry, of electrolysis, and chemical optics have given scope for much valuable research. A most important development is that chemists now feel it to be unphilosophical to imagine atoms or molecules fixed on a surface without thickness, and enlarging the notion of relative progression, they have come to admit formulæ in space, thus recognising the study of stereochemistry. It is now found that by the simple inspection of a constitutional formula we may foretell whether the body is or is not endowed with a rotatory power. In a chapter on inorganic chemistry the author complains that in a life which is continually becoming harder the brain-working classes have no longer time for trains of research which are of necessity slow. He points out how the groups of the cerium and the yttrium metals tend to dislocate the classification of Prof. Mendeleeff. In organic chemistry M. Etard mentions the numerous transitions which have been effected between the fatty and the aromatic series, and he calls attention to the curious fact that no polygon of more than six sides has been found to exist.

THE MASON COLLEGE, BIRMINGHAM.

SESSION 1890-91.

Faculties of Arts and Science.

The next SESSION commences on Tuesday, September, 30, 1890. A SYLLABUS containing full information as to the various Courses of Instruction, Lecture Days and hours, Fees, Scholarships, &c., is published by Messrs. Cornish, New Street, Birmingham, price 6d., post free, 8d. Further particulars may be obtained on application to the Secretary, at the College.

R. S. HEATH, Principal.
GEO. H. MORLEY, Secretary.

ST. PAUL'S SCHOOL.—An Examination for filling up about Fifteen Vacancies on the Foundation will be held on the 10th September next.—For information apply to the Bursar, St. Paul's School, West Kensington.

FOR SALE.—THE CHEMICAL GAZETTE. Complete Set (unbound and uncut), 17 volumes; from November, 1842, to December, 1859.—Address, "Publisher," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

THE CHEMICAL NEWS.

Vol. LXII. No. 1606.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

LEEDS, 1890.

INAUGURAL ADDRESS OF THE PRESIDENT,

SIR FREDERICK AUGUSTUS ABEL,
C.B., D.C.L. (Oxon.), D.Sc. (Cant.), F.R.S., P.P.C.S.
Hon. M.Inst.C.E.

MANY who had the pleasure of listening last year, at Newcastle, to the interesting and instructive Address of the President to whom I am a most unworthy successor, could not fail, both by the chief subject of his discourse and by the circumstance of the official position which he occupies with so much benefit to science and the public, to have their thoughts directed to the illustrious naturalist whose philosophical Address delighted the members of the Association and the people of Leeds thirty-two years ago.

More than one-half the period of existence of this Association has passed since Richard Owen presided over its meeting in this town. Alas! what gaps have been created in the ranks of those who then were prominent for activity in advancing its work; the then General Secretary, Sir Edward Sabine; the all-popular Assistant-general Secretary, John Phillips; the Treasurer, John Taylor, now live with us only through their works and the enduring esteem which they inspired. But very few of those who held other prominent positions at that meeting have survived to see the Association re-assemble in this town. Whewell, Herschel, Hopkins, the elder Brodie, Murchison, William Fairbairn, all Presidents of Sections in 1858, have long since been removed from among us; and the then President of Section F, Edward Baines, a much-honoured and highly-talented son of the "Franklin of Leeds," whom we had hoped to count among those Vice-Presidents representing the City on this occasion, has recently passed away, in his ninetieth year, after a most honourable and useful career, during which he especially distinguished himself by his successful exertions in the advancement of the great educational movements of his time.

The illustrious President of our last meeting here, concerning whose health the gravest apprehensions were not long since entertained, is happily still preserved to us; still intellectually bright at the ripe age of eighty-six, and still, with the keen pleasure of his early life, following the progress of those branches of scientific research which have constituted the favourite occupations and the arena of many intellectual triumphs of a long career of ardent and successful devotion to the advancement of science.

To not a few of those who have flocked to Leeds to attend the annual gathering of this Association, our present meeting-place is doubtless known chiefly by its proud position as one of the most thriving manufacturing towns of the United Kingdom; of ancient renown, especially in connection with one of the chief industries identified with Great Britain in years past. But this good town of Leeds, whose cloth market was described by Daniel Defoe, one hundred and sixty odd years ago, as "a prodigy of its kind, and not to be equalled in the world," and whose present position in connection with divers of our great industries would have equally excited the enthusiasm of that graphic writer, is famous for other

things than its prominent association with manufactures and commerce.

Not many of our great industrial centres can boast of so goodly an array, upon the scroll of their past history, of names of men eminent in the Sciences, the Arts and Manufactures, in Divinity and Letters, and in heroic achievements such as are identified with Leeds and its immediate vicinity: Thomas, Lord Fairfax, one of the most prominent heroes of the Commonwealth; Smeaton, an intellectual giant among engineers; William Hirst and John Marshall, illustrious examples of the men who by their genius, energy, and perseverance placed Great Britain upon the pinnacle of industrial and commercial greatness which she so long occupied unassailed; Richard Bentley, the eminent classic and divine; John Nicholson, the Airedale poet; John Fowler and Peter Fairbairn, worthy followers in the footsteps of Smeaton; Isaac Milner, weaver and mathematician, afterwards Senior Wrangler, Smith's prizeman, Jacksonian Professor, President of Queen's College, Vice-Chancellor of Cambridge University, Dean of Carlisle, and a most illustrious Fellow of the Royal Society; Thoresby, antiquarian and topographer; Benjamin Wilson, painter, and industrious contributor to the development of electrical science; William Hey, the eminent surgeon, and friend and counsellor of Priestley; Sadler, political economist and philanthropist; the Brothers Sheepshanks—Richard, the astronomer, and John, the accomplished patron of the arts, and munificent contributor to our national art treasures; Edward Baines, whose conspicuous talents and energy developed a small provincial journal into one of the most powerful public organs of the country; his talented sons, of whom not the least conspicuous and highly respected was the late Sir Edward Baines. I might swell this voluminous list by reference to illustrious members of such families as that of Denison, of Beckett, of Lowther, but the men I have referred to fitly illustrate the remarkable array of worthies whose careers have shed lustre upon the town in or near which they were born. Yet that illustration would be altogether incomplete if I failed to speak of one whose career and works alone would suffice to place Leeds in the foremost rank of those English towns which can claim as their own men whose course of life and whose achievements have secured their pre-eminence among our illustrious countrymen. Needless to say that I refer to Joseph Priestley, born within six miles of Leeds, whose name holds rank among the foremost of successful workers in science: who, by brilliant powers of experimental investigation, rapidly achieved a series of discoveries which helped largely to dispel the shroud of mystery surrounding the art of alchemy, and to lay the foundation of true chemical science. An ardent student of the classics, of Eastern languages, and of divinity, a zealous exponent of theological doctrines which marred his career as divine and instructor, he early displayed conspicuous talents for the cultivation of experimental science, which he pursued with ardour under formidable difficulties. His acquaintance with Franklin probably developed the taste for the study of electric science which led him to labour successfully in this direction; and the publication, in 1767, of his valuable work on "The History and Present State of Electricity, with Original Experiments," secured him a prominent position among the working Fellows of the Royal Society. His connection with the Mill Hill Chapel, in 1768, appears to have given rise accidentally to his first embracing the experimental pursuit of what formerly was termed pneumatic chemistry, the foundation of which had been laid by Cavendish's memorable contribution, in 1766, to the *Philosophical Transactions*, on carbonic acid and hydrogen. Priestley's first publication in pneumatic chemistry, on "Impregnating Water with Fixed Air" (carbonic acid), attracted great attention; it was at once translated into French, and the College of Physicians addressed the Lords of the Treasury thereon, pointing out

the advantages which might result from the employment, by men at sea, of water impregnated with carbonic acid gas, as a protective against, or cure for, scurvy.

Six years later, Priestley investigated the chemical effects produced on the air by the burning of candles and the respiration of animals, and, having demonstrated that it was thereby diminished in volume and deteriorated, he showed that living plants possessed the power of rendering air, which had been thus deteriorated, once more capable of supporting the combustion of a candle. At about this time Priestley received very advantageous proposals to accompany Captain Cook upon his second expedition to the South Seas; but when about to prepare for his departure he learned from Sir Joseph Banks that objections against his appointment, on account of the great latitude of his religious principles, had been successfully urged by some ecclesiastical member of the Board of Longitude. In 1773 the Royal Society awarded Priestley the Copley Medal for a remarkable paper entitled "Observations on Different Kinds of Air," and in that year he became librarian and literary companion to the Earl of Shelbourne (afterwards Marquis of Lansdowne), and thereby secured special advantages in the pursuit of his scientific researches.

With respect to his departure from Leeds, he expressed himself as having been very happy there "with a liberal, friendly, and harmonious congregation, to whom my services (of which I was not sparing) were very acceptable. Here I had no unreasonable prejudices to contend with, so that I had full scope for every kind of exertion; and I can truly say that I always considered the office of a Christian minister as the most honourable of any upon earth, and in the studies proper to it I always took the greatest pleasure." During the next five years he published as many volumes describing the results of important experiments on air. After investigating the properties of nitric oxide, and applying it to the analysis of air, Priestley, in 1774, discovered and carefully studied oxygen, which he obtained by the action of heat upon the red oxide of mercury. He was the first to prepare and study sulphurous acid, carbonic oxide, nitrous oxide, hydrochloric acid (*marine acid air*), and the fluoride of silicon, and carried out important researches on the properties of hydrogen, and of other gases previously but little known. His great quickness of perception and power of experiment led him to the achievement of many novel and important results; but one cannot help contrasting his somewhat random search after new discoveries with the close logical reasoning and philosophic spirit which guided and pervaded the remarkable researches of him whose departure from amongst us since the last gathering of this Association is so universally deplored—of the great discoverer of the universal law of the conversion of energy, James Prescott Joule. I could not add to the judicious and graceful reference to his work which Sir Henry Roscoe was privileged to make, in the last year of that philosopher's valuable life, when presiding over the recent meeting of the Association in the town which glorified in numbering Joule among its citizens; but I may, perhaps, be permitted to express the sanguine hope that the desire of the scientific world to secure the establishment of an international memorial fitly commemorative of his great life-work may be realised in the most ample manner.

The wide scope of the admirable discourse delivered by Owen in this town thirty-two years ago affords an interesting illustration of the delight which men whose best energies are devoted to the cultivation of one particular branch of science take in the results of the labours of their fellow workers in other departments, and in their achievements in contributing to the general advancement of our knowledge of Nature's laws and of their operations. It is to this bond of intimate union between all workers in pure science that we owe the instructive reviews of the progress made in different departments of science, with

which we have often been presented at our annual gatherings. On the other hand, those men, from time to time selected to fill the distinguished office of President, whose lives have been mainly devoted to the practical utilisation of the results of scientific research, and to the extension in particular directions of the consequent resources of civilisation, seize with keen pleasure the opportunity afforded them of directing attention to the triumphs achieved in the application, to the purposes of daily life, of the great scientific truths established by such illustrious labourers in the fields of pure science as Newton, Dalton, Faraday, and Joule. The wide and constantly extending domain of applied science presents, even to the superficial observer, a continually varied scene; not a year passes but some great prize falls to the lot of one or other of its explorers, and some apparently insignificant vein of treasure, struck upon but a few years back, is rapidly opened out by cunning explorers, until it leads to a mine of vast wealth, from which branch out in many directions new sources of power and might.

Among the branches of science in the practical applications of which the greatest strides have been made since the Association met at Leeds in 1858, is electricity. That year witnessed the accomplishment of the first great step towards the establishment of electrical communication between Europe and America, by the laying of a telegraph cable connecting Newfoundland with Valencia. Through this cable a message of thirty-one words was shortly afterwards transmitted in thirty-five minutes; an achievement which, though exciting great enthusiasm at the time, scarcely afforded promise of the succession of triumphs of ocean telegraphy which have since surpassed the wildest dreams of the pioneers in the realms of applied electricity.

The development of the electric telegraph constitutes a never-failing subject of the liveliest interest. The experiments made by Stephen Gray, in 1727, of transmitting electrical impulses through a wire 700 feet long; by Watson, twenty years afterwards, of transmitting frictional electricity through many thousand feet of wire, supported by a line of poles, on Shooter's Hill, in Kent; and by Franklin, who carried out a similar experiment at Philadelphia,—although they were followed by many other interesting and philosophical applications of frictional electricity to the transmission of signals—were not productive of really practical results. The work of Galvani and of Volta was more fruitful of an approach to practical telegraphy in the hands of Sömmering and of Coxe, while the researches of Oersted, of Ampère, of Sturgeon, and of Ohm, and especially the discoveries of volta-electric induction and magneto-electricity by Faraday, paved the way for the development of the electric telegraph as a practical reality by Cooke and Wheatstone in 1837. How remarkable the strides have been in the resources and powers of the telegraphist since that time is demonstrated by a few such facts as these; the first needle instrument of Cooke and Wheatstone transmitted messages at the rate of four words per minute, requiring five wires for that purpose; six messages are now conveyed by one single wire, at ten times that speed, and news is dispatched at the rate of 600 words per minute. Duplex working, which more than doubled the transmitting power of a submarine cable, was soon eclipsed by the application of Edison's quadruplex working, which has in its turn been surpassed by the multiplex system, whereby six messages may be sent independently, in either direction, on one wire. When last the British Association met in Leeds, submarine telegraphy had but just started into existence; thirty years later, the accomplished President of the Mechanical Section informed us, at our meeting at Bath, that 110,000 miles of cable had been laid by British ships, and that a fleet of nearly forty ships was occupied in various oceans in maintaining existing cables and laying new ones.

The important practical achievements by which most

formidable difficulties have been surmounted, step by step, in the successive attainment of the marvellous results of our day, have exerted an influence upon the advancement, not merely of electrical science, but also of science generally and of its applications, fully equal to that which they have exercised upon the development of commerce and of the intercourse between the nations of the earth.

Thus, the laying of the earliest submarine cables, between 1851 and 1855, led Sir W. Thomson, in conference with Sir George Stokes, to work out the theory of signalling in such cables, by utilising the mathematical results arrived at by Fourier in his investigation of the propagation of heat-waves. The failure of the first Atlantic cable led to the survey of the bottom of the Atlantic, which was the forerunner of deep-sea explorations, culminating in the work of the *Challenger Expedition*, and opening up new treasures of knowledge scarcely dreamt of when last the British Association met at Leeds. To the difficulties connected with the early attempts at submarine telegraphy, and the determination with which Thomson drove home the lessons learned, we owe the systematic investigations into the causes of the variations in resistance of copper conductors, and the consequent improvements in the metallurgy of copper, which led to the realisation of the high standard of purity of metal essential for the efficient working of telegraphic systems, and also to the extensive utilisation of electricity in the production of pure copper. The rare combination of originality in powers of research and perspicuity in mathematical reasoning, with inventive and constructive genius, for which Thomson has so long been pre-eminent, has placed at the disposal of the investigator of electric science, and of the practical electrician, instruments of measurement and record which have been of incalculable value, and which owe their origin to the theoretical conclusions arrived at by him in his researches into the conditions to be fulfilled for the attainment of practical success in the construction and employment of submarine cables. The mirror galvanometer, the quadrant electrometer, the syphon-recorder, and the divided-ring electrometer, are illustrations of the valuable outcome of Thomson's labours; the combination of the last-named instrument with sliding resistance coils has rendered possible the accurate sub-division of a potential difference into 10,000 equal parts. The general use of condensers in connection with cable signalling, due to Varley's application of them for signalling through submerged cables with induced short waves, was instrumental in establishing the fact that all electro-static phenomena are simply the result of starting an electric current of known short duration round a closed circuit. The practical application of the Wheatstone Bridge led to numerous important mathematical investigations, and induced Clerk Maxwell to devise a new mode of applying determinants to the solution of the complicated electrical problems connected with networks of conductors. The necessity for the universal recognition of an electrical unit of resistance led to the establishment, in 1860, of the Electrical Standards Committee of the British Association, whose long succession of important annual reports was instrumental in most important developments of theoretical electricity, and, indeed, served to open up the whole science of electrical measurement. Matthiessen's important investigations of the electrical behaviour of metals and their alloys, and the preparation and properties of pure iron, were the outcome of the commercial demand for a practically useful standard of electrical resistance, while Latimer Clark's practical standard of electromotive force, the mercurous sulphate cell, became invaluable to the worker in pure electrical research. The unit of resistance established by the British Association Committee received, in 1866, most important scientific application at the hands of Joule, who, by measuring the rate of development of heat in a wire of known resistance by the passage of a known current, obtained a new value of the mechanical equivalent of heat. This value differed

by about 1·3 per cent from the most accurate results arrived at by his experiments on mechanical friction, a difference which eventually proved to be exactly the error in the British Association unit of resistance; so that the true value of the unit of resistance, or ohm, was determined by Joule fifteen years before this result was achieved by electricians. Clerk Maxwell's remarkable electro-magnetic theory of light was put to the test, through the aid of the British Association unit of resistance, by Thomson, in determining the ratio of electro-magnetic unit to the electro-static unit of quantity. Many other most interesting illustrations might be given of the invaluable aid afforded to purely scientific research by the practical results of the development of electrical science, and of the constant co-operation between the science student and the practical worker. No one could, more fitly than the late Sir William Siemens, have maintained, as he did in his admirable Address at our meeting in Southampton, in 1882, that we owe most of the rapid progress of recent times to the man of science who partly devotes his energies to the solution of practical problems, and to the practitioner who finds relaxation in the prosecution of purely scientific inquiries. Most assuredly, both these classes of the world's benefactors may with equal right lay claim to rank the name of Siemens among those whom they count most illustrious!

In that highly interesting and valuable Address, delivered little more than a year before his sudden untimely removal from among us, the numerous important subjects discussed by him included not a few which he had made peculiarly his own in the wide range embraced by his enviable power of combining scientific research with practical work. Prominent among these were the applications of electric energy to lighting and heating purposes, and to the transmission of power, to the future development of which his personal labours very greatly contributed.

Siemens referred to the passing of the first Electric Lighting Bill, in the year of his Presidency, as being designed to facilitate the establishment of electric installations in towns; but the anxiety of the Government of that day to protect the interests of the public through local authorities led to the assignment of such power to these over the property of lighting companies, that the utilisation of electric lighting was actually delayed for a time by those legislative measures. There can now be no doubt, however, that this delay has really been in the interests of intending suppliers and of users of the electric light, as having afforded time for the further development of practical details, connected with generation and distribution, which was vital to the attainment of a fair measure of initial success. The subsequent important modification of legislation on the subject of electric lighting, together with the practical realisation of comparatively economical methods of distribution, the establishment of fairly equitable arrangements between the public and the lighting companies, and the apportionment, so far as the metropolis is concerned, of distinct areas of operation to different competing companies, have combined to place electric lighting in this country at length upon some approach to a really sound footing, and to give the required impetus to its extensive development. Nine companies either are now, or will very shortly be, actually at work supplying, from central stations, districts of London comprising almost the entire western and north-western portions of the metropolis. As regards other parts of England, there are already twenty-seven lighting stations actually at work in different towns, besides others in course of establishment and many more projected. The town of Leeds has not failed to give serious attention to the subject of utilising the electric light, and, although no general scheme has yet been adopted, the electricians who now visit this town will rejoice to see many of its public buildings provided with efficient electric illumination.

While the prediction made by Siemens, eight years ago,

that electric lighting must take its place with us as a public illuminant, has thus been already, in a measure, fulfilled, important progress is being continuously made by the practical electrician in developing and perfecting the arrangements for the generation of the supply, its efficient distribution from centres, and its delivery to the consumer in a form in which it can be safely and conveniently dealt with and applied at an outlay which, even now, does not preclude a considerable section of the public from enjoying the decided advantages presented by electric lighting over illumination by coal-gas. Yet our recent progress in this direction, encouraging though it has been, is insignificant as compared with the strides made in the application of electric lighting in the United States, as may be gauged by the fact that, while in America the number of arc lamps in use, in April of this year, was 235,000, and of glow lamps about three millions, there are at present about one-tenth the number of the latter, and one-hundredth the number of arc lamps, in operation in England.

In some important directions we may, however, lay claim to rank foremost in the application of the electric light; thus, our large passenger ships and our war ships are provided with efficient electrical illumination; to the active operations of our Navy the electric light has become an indispensable adjunct; and our system of coast defence, by artillery and submarine mines, is equally dependent, for its thorough efficiency, upon the applications of electricity in connection with range-finding, with the arrangement and explosion of mines, and with the important auxiliary in attack and defence, the electric light, which, while so arranged, at the operating stations, as to be protected against destruction by artillery fire and difficult of detection by the enemy, is available at any moment for affording invaluable information and important assistance and protection.

Other important applications of the electric light, such as its use as a lighthouse illuminant, for the lighting of main roads in coal mines, where its value is being increasingly appreciated, and even for signalling purposes in mid-air, through the agency of captive balloons, are continually affording fresh demonstrations of the value of this particular branch of applied electric science.

At the Electrical Exhibition at Vienna in 1883, where, not long before the lamented death of Siemens, I had the honour of serving as one of his colleagues in the representation of British interests, the progress which had been made in the construction of electrical measuring instruments since the French Exhibition and the Electrical Congress, two years before, was very considerable. The advance in this direction has been enormous since that time; but although the practical result of Thomson's and of Carlew's important work has been to supply us with trustworthy electrical balances and voltmeters, while efficient instruments have also been made by other well-known practical electricians, we have still to attain results in all respects satisfactory in these indispensable adjuncts to the commercial supply and utilisation of electric energy.

In connection with this important subject the recent completion of the Board of Trade standardising laboratory, established for the purposes of arriving at and maintaining the true values of electrical units, and of securing accuracy and uniformity in the manufacture of instruments supplied by the trade for electrical measurements, may be referred to with much satisfaction as a practical illustration of official recognition of the firm root which the domestic and industrial utilisation of electric energy has taken in this country.

The achievements of the telephone were referred to by Siemens in glowing terms eight years ago; but the results then attained were but indications of the direction in which telephonic inter-communication was destined speedily to become one of the most indispensable of present applications of electricity to the purposes of daily life. Preece, in speaking at Bath, two years ago, of the

advances made in applied electricity, showed that the impediments to telephonic communication between great distances had been entirely overcome; and now, although considerably behind America and France in the use of the telephone, we are rapidly placing ourselves upon speaking terms with our friends throughout the United Kingdom. The operations of the National Telephone Company well illustrate our progress in telephonic inter-communication: that company has now 22,743 exchange lines, besides nearly 5000 private lines, its exchanges number 272, and its call-offices 526. The number of instruments under rental in England has now reached 99,000; but, important as this figure is compared to our use of the telephone a very few years ago, it sinks into insignificance by the side of the number of instruments under rental in America, which at the beginning of the present year had reached 222,430, being an increase of 16,675 over the number in 1889. Only thirteen years have elapsed since the telephone was first exhibited as a practically workable apparatus to members of the British Association at the Plymouth Meeting, and the number of instruments now at work throughout the world may be estimated as considerably exceeding a million.

The successful transmission of the electric current, and the power of control now exercised over the character which electrically-transmitted energy is made to assume, are not alone illustrated by the efficiency of the arrangements already developed for the supply of the electric light from central stations. Siemens dwelt upon this subject at Southampton with the ardent interest of one who had made its development one of the objects of his energetic labours in later years, and also with a prophet's prognostications of its future importance. In speaking of the electric current as having entered the lists in competition with compressed air, the hydraulic accumulator, and the quick-running rope driven by water-power, Siemens pointed out that no further loss of power was involved in the transformation of electrical into mechanical energy than is due to friction, and to the heating of the conducting wires by the resistance they oppose, and showed that this loss, calculated upon data arrived at by Dr. John Hopkinson and by himself, amounted at the outside to 38 per cent. of the total energy. Subsequent careful researches by the Brothers Hopkinson have demonstrated that the actual loss is now much less than it was computed at in 1885, as much as 87 per cent. of the total energy transmitted being realisable at a distance, provided there be no loss in the connecting leads used.

The Paris Electric Exhibition of 1881 already afforded interesting illustrations of the performance of a variety of work by power electrically transmitted, including a short line of railway constructed by the firm of Siemens, which was a further development of the successful result already attained in Berlin by Werner Siemens in the same direction, and was, in its turn, surpassed by the considerably longer line worked by Messrs. Siemens at the Vienna Exhibition two years later. Various short lines which have since then been established by the firm of Siemens are well known, and one of the latest public acts in the valuable life of Siemens was to assist at the opening of the electric tramway at Portrush, in the installation of which he took an active part, and where the idea, so firmly rooted in his mind from the date of his visit to the Falls of Niagara, in 1876, of utilising water-power for electrical transmission—a result first achieved on a small scale by Lord Armstrong—was more practically realised than had yet been the case. Since that time Ireland has witnessed a further application of electricity to traction purposes, and of water-power to the provision of the required energy, in the working of the Bessbrook and Newry tramway, while London at length possesses an electric railway, three miles in length, to be very shortly opened, which will connect the City with one of the southern suburbs through a tram subway, and, although including many sharp curves and steep gradients, will be capable of conveying one hundred passengers at a time, at speeds

varying from thirteen to twenty-four miles per hour. During the past year a regular service of tramcars has been successfully worked, through the agency of secondary batteries, upon part of one of the large tramways of North London, with results which bid fair to lead to an extensive development of this system of working. The application of electricity to traction purposes has, however, received far more important development in the United States; at the commencement of this year there were in operation in different States 200 electrical tram-roads, chiefly worked upon the Thomson-Houston and the Sprague systems, and having a collective length of 1641 miles, with 2346 motor-cars travelling thereon. Further extensions are being rapidly made; thus, one company alone has 39 additional roads, of a collective length of 385 miles, under construction, to be worked through the agency of storage batteries.

The idea cherished by Siemens, and enlarged upon by him in more than one interesting address, of utilising the power of Niagara, appears about to be realised, at any rate in part; as a large tract of land has been recently acquired, by a powerful American Association, about a mile distant from the Falls, with a view to the erection of mills for utilising the power, which it is also proposed to transmit to distant towns; and an International Commission, with Sir William Thomson at its head, and with Mascart, Turretini, Coleman Sellers, and Unwin as members, will carefully consider the problems involved in the execution of this grand scheme.

The application of electric traction to water traffic, first successfully demonstrated in 1883, is receiving gradual development, as illustrated by the considerable number of pleasure boats which may now be seen on the Upper Thames during the boating season, and in connection with which Professor George Forbes proposed, at our meeting last year, that stations for charging the requisite cells, through the agency of water-power, should be established at the many weirs along the river, so as to provide convenient electric coaling stations for the river pleasure fleet.

Electrically-transmitted energy was first applied in Germany to haulage work in mines by the firm of Siemens some years ago, and great progress has since been achieved herein on the Continent and in America. Comparatively little has been accomplished in this direction in England; but it is very interesting to note, on the present occasion, that the first successful practical application of electricity in this country to pumping and underground haulage work was made in 1887, in this neighbourhood, at the St. John's Colliery, at Nornanton, where an extensive installation, carried out by Mr. Immisch, so well known in connection with electric launches, is furnishing very satisfactory results in point of economy and efficiency. The gigantic installations existing for the same purposes in Nevada and California afford remarkable illustrations of the work to be accomplished in the future by electrically-transmitted energy.

Among the many subjects of importance studied by Joule with the originality and thoroughness characteristic of his work, was the application of voltaic electricity to the welding and fusion of metals. Thirty-four years ago he published a most suggestive paper on the subject, in which, after dealing with the difficulties attending the operation of welding, and of the interference of films of oxide, formed upon the highly heated iron surfaces, with the production of perfect welds either under the hammer or by the methods of pressure (of which he then predicted the application to large masses of forged iron), he refers to the possibility of applying the calorific agency of the electric current to the welding of metals, and describes an operation witnessed by him in the laboratory of his fellow labourer, Thomson, of fusing together a bundle of iron wires by transmitting through them, when embedded in charcoal, a powerful voltaic current. Joule afterwards succeeded in fusing together a number of iron wires with the current of a Daniell battery, and of welding together

wires of brass and steel, platinum and iron, &c. In discussing the question of the amount of zinc consumed in a battery for raising a given amount of iron to the temperature of fusion, he points out that the same object would probably be more economically attained by the use of a magneto-electric machine, which would allow the heat to be provided by the expenditure of mechanical force, developed in the first instance by the expenditure of heat; and he indicates the possibility of arranging machinery to produce electric currents which shall evolve one-tenth of the total heat due to the combustion of the coal used, so that 5000 grains of coal applied through that agency would suffice for the fusion of one pound of iron. The successful practical realisation of Joule's predictions in regard to the application of electric currents, thus developed, to the welding of iron and steel, and to analogous operations, through the agency of the efficient machines devised by Professor Elihu Thomson, was demonstrated to the members of the Association by Professor Ayrton at Bath two years ago, and was shown upon a larger scale to visitors at the Paris Exhibition last year, and recently to highly interested audiences in London by our late President, Sir Frederick Bramwell. The latter demonstrated that the production of iron-welds by means of the Thomson machines was accomplished nearly twice as rapidly as by expert craftsmen; the perfection of the welds being proved by the fact that the strength of bars broken by tensile strains at the welds themselves was about 92 per cent of the strength of the solid metal. At the Crewe Works Mr. Webb is successfully applying one of these machines to a variety of welding work. The rapidity with which masses of metal of various dimensions are raised in those machines to welding heat is quite under control; the heat is applied without the advent of any impurities, as from fuel, and the speed of execution of the welding operation reduces to a minimum the time during which the heated surfaces are liable to oxidise. With such practical advantages as these, this system of electric welding bids fair to receive many useful applications.

Another very simple system of electric welding, especially applicable to thin iron and steel sheets, hoops, &c., has been contemporaneously elaborated in Russia by Dr. Bernados, and is already being extensively used. The required heat at the surfaces to be welded is developed by connecting the metal with the negative pole of the dynamo machine, or of a battery of accumulators, the circuit being completed by applying a carbon electrode to the parts to be heated; the reducing power of the carbon is said to preserve the heated metal surfaces from oxidation during the very brief period of heating. This mode of operation appears to have been practised upon a small scale, some years ago, by Sir William Siemens, to whom we also owe the first attempt to practically apply electric energy to the smelting of metals.

In his address in 1882 he referred to some results attained with his small electrical furnace, and pointed out that, although electric energy could, obviously, not compete economically with the direct combustion of fuel for the production of ordinary degrees of heat, the electric furnace would probably receive advantageous application for the attainment of temperatures exceeding the limits (about 1800° C.) beyond which combustion was known to proceed very sluggishly. This prediction appears to have been already realised through the important labours of Messrs. Cowles, who some years ago attacked the subject of the application of electricity to the achievement of metallurgical operations with the characteristic vigour and fertility of resource of our Transatlantic brethren. After very promising preliminary experiments, they succeeded, in 1885, at Cleveland, Ohio, in maturing a method of operation for the production of aluminium-bronze, ferro-aluminium, and silicium-bronze, with results so satisfactory as to lead to the erection of extensive works at Lockport, N.Y., where three dynamo-machines, each supplying a current of about 3000 amperes, are worked by water-power, through the agency of turbines, each of 500

h.-p., eighteen electric furnaces being now in operation for the production of aluminium alloys. These achievements have led to the establishment of similar works in North Staffordshire, where a gigantic dynamo-machine has been erected, furnishing a current of 5000 amperes, with an E.M.F. of 50 to 60 volts. The arrangement of the electrodes in the furnaces, the preparation of the furnace-charges (consisting of mixtures of aluminium ore with charcoal and with the particular granulated metal with which the aluminium is to become alloyed at the moment of its elimination from the ore); the appliances for securing safety in dealing with the current from the huge dynamo-machine, and many other details connected with this new system of metallurgic work, possesses great interest. Various valuable copper and aluminium alloys are now produced by alloying copper itself with definite proportions of the copper alloy, very rich in aluminium, which is the product of the electric furnace. The rapid production in large quantities of ferro-aluminium—which presents the aluminium in a form suitable for addition in definite proportions to fluid cast iron and steel—is another useful outcome of the practical development of the electric furnace by Messrs. Cowles.

The electric process of producing aluminium alloys has, however, to compete commercially with their manufacture by adding to metals, or alloys, pure aluminium produced by processes based upon the method originally indicated by Oersted in 1824, successfully carried out by Wöhler three years later, and developed into a practical process by H. St. Claire Deville in 1854—namely, by eliminating aluminium from the double chloride of sodium and aluminium in the presence of a fluoride, through the agency of sodium. An analogous process, indicated in the first instance by H. Rose—namely, the corresponding action of sodium upon the mineral cryolite, a double fluoride of aluminium and sodium—has also been recently developed at Newcastle, where the first of these methods was applied, upon a somewhat considerable scale, in 1860, by Sir Lowthian Bell, but did not then become a commercial success, mainly owing to the costliness of the requisite sodium. As the cost of this metal chiefly determines the price of the aluminium, technical chemists have devoted their best energies to the perfection and simplification of methods for its production, and the success which has culminated in the admirable Castner process constitutes one of the most interesting of recent illustrations of the progress made in technical chemistry, consequent upon the happy blending of chemical with mechanical science, through the labours of the chemical engineer.

Those who, like myself remember how, between forty and fifty years ago, a few grains of sodium and potassium were treasured up by the chemist, and used with parsimonious care in an occasional lecture experiment, cannot tire of feasting their eyes on the stores of sodium-ingots to be seen at Oldbury as the results of a rapidly and dexterously executed series of chemical and mechanical operations.

The reduction which has been effected in the cost of production of aluminium through this and other processes, and which has certainly not yet reached its limit, can scarcely fail to lead to applications of the valuable chemical and physical properties of this metal so widespread as to render it as indispensable in industries and the purposes of daily life as those well-known metals which may be termed domestic, even although, and, indeed, for the very reason that, its association with many of these, in small proportion only, may suffice to enhance their valuable properties or to impart to them novel characteristics.

The Swedish metallurgist, Wittenström, appears to have been the first to observe that the addition of small quantities of aluminium to fused steel and malleable iron had the effect of rendering them more fluid, and, by thus facilitating the escape of entangled gases, of ensuring the production of sound castings without any prejudicial effect upon the quality of the metal. The excellence of the

so-called Mitis castings, produced in this way, appears thoroughly established, and the results of recent important experiments seem to be opening up a field for the extensive employment of aluminium in this direction, provided its cost becomes sufficiently reduced. The valuable scientific and practical experiments of W. J. Keep, James Riley, R. Hadfield, Stead, and other talented workers in this country and the United States, are rapidly extending our knowledge in regard to the real effects of aluminium upon steel, and their causes. Thus, it appears to be already established that the modifications in some of the physical properties of steel resulting from the addition of that metal, are not merely ascribable to its actual entrance into the composition of the steel, but are due, in part, to the de-oxidation by aluminium of some proportion of iron-oxide which exists distributed through the metal, and prejudicially affects its fluidity when melted. In the latter respect, therefore, the influence exerted by aluminium, when introduced in small proportions into malleable iron and steel, appears to be quite analogous to that of phosphorus, silicon, or lead when these are added in small proportions to copper and certain of its alloys, the de-oxidation of which, through the agency of those substances, results in the production of sound castings of increased strength and uniformity. It is only when present in small proportion in the finished steel, that aluminium increases the breaking strain and elastic limit of the product.

The influence of aluminium, when used in small proportion, upon the properties of grey and white cast iron, is also of considerable interest, especially its effect in promoting the production of sound castings, and of modifying the character of white iron in a similar manner to silicon, causing the carbon to be separated in the graphitic form; with this difference—that the carbon appears to be held in solution until the moment of setting of the liquid metal, when it is instantaneously liberated, with the result that the structure of the cast metal and distribution of the graphite are perfectly uniform throughout.

The probable beneficial connection of aluminium with the industries of iron and steel naturally directs attention to the great practical importance, in the same direction, which has already been acquired, and promises to be in increasing measure attained, by certain other metals which, for long periods succeeding their discovery, have either been only of purely scientific interest and importance, or have acquired practical value in regard to their positions in a few directions quite unconnected with metallurgy. Thus, great interest attaches to the influence of the metals manganese, chromium, and tungsten upon the physical properties of steel and iron.

The name of Mushet is most prominently associated with the history of manganese in its relations to iron and steel. Half-a-century ago David Mushet carried out very instructive experiments on the influence exerted upon the properties of steel by the presence of manganese; and to Robert Mushet we owe the invaluable experiments leading to his suggestion to use manganese in the production of steel by the Bessemer process, which at once smoothed the path to the marvellously rapid and extensive development of the applications of steel produced by that classic method, and subsequently by the open-hearth or Siemens-Martin process—a development which has recently received its crowning illustration in the completion of one of the grandest of existing triumphs of engineering science and constructive skill—the Forth Bridge.

Robert Hadfield has recently contributed importantly to our knowledge of the relations of manganese to iron. His systematic study of the subject has revealed some very remarkable variations in the physical properties of so-called manganese-steel, according to the proportions of manganese which it contains. Thus, while the existence in steel of proportions ranging from 0.1 up to about 2.75 per cent improves its length and malleability, it becomes brittle if that limit is exceeded, the extreme of

brittleness being obtained with between 4 and 5 per cent of manganese; if, however, the percentage is increased to not less than 7, and up to 20, alloys of remarkable strength and toughness are obtained. Castings of high manganese steel, such as wheel-tyres, combine remarkable hardness with toughness. Even if the proportion of manganese is as high as 20 per cent in a steel containing 2 per cent of carbon, it can be forged; whereas it is very difficult to forge a steel of ordinary composition containing as much as 2.75 per cent of carbon. Another remarkable peculiarity of the high manganese steel is its behaviour when quenched in water. Instead of the heated metal being hardened and rendered brittle by the sudden cooling, like carbon steel, its tensile strength and its toughness are increased; so that water-quenching is really a toughening process, as applied to the manganese alloy; and an interesting feature connected with this is that, the colder the bath into which the highly-heated metal is plunged, the tougher is the product. The curious effect of manganese in reducing, and even destroying, the magnetic properties of iron was already noticed by Rinman nearly 120 years ago; one result of Hadfield's important labours has been to place in the hands of such eminent physicists as Thomson, John Hopkinson, and Reinold, materials for the attainment of most interesting information respecting the electrical and other physical characteristics of manganese steel. Hopkinson, from experiments with a sample of steel containing 12 per cent of manganese, estimated that not more than 9 out of the 86 per cent of the iron composing the mass was magnetic, and he considered that the manganese enters into that which must, for magnetic purposes, be regarded as the molecule of iron, completely changing its properties, a fact which must have great significance in any theory regarding the nature of magnetisation. The great hardness of manganese steel, and the consequent difficulty of dealing with it by means of cutting-tools, constitute at present the chief impediments to its technical applications in many directions; but where great accuracy of dimensions is not required, and where great strength is an essential, it is already put to valuable uses.

The importance of manganese in connection with the metallurgy of iron and steel is in a fair way of finding its rival in that of the metal chromium, the employment of which, as an alloy with steel, was first made the subject of experiment in 1821, by Berthier, who was led by the important experiments of Faraday and Stoddart, then just published, to endeavour to alloy chromium with steel, and obtained good results by fusing steel together with a rich alloy of chromium and iron, so as to introduce about 15 per cent of the former into the metal. Further small experiments were made the year following, by Faraday and Stoddart, in the same direction; but chrome steel appears to have been first produced commercially at Brooklyn, N.Y., sixteen years ago. Ten years later its manufacture had become developed in France, and the varieties of chrome steel produced in the Loire district now receive important and continually extending applications, on account of their combining comparative hardness with high tenacity, and only little loss in ductility, and of their acquiring great closeness of structure when tempered.

The influence of chromium upon the character of steel differs in several marked respects from that exercised by manganese; thus, chrome steels weld badly, or not at all, whereas manganese steels weld very readily, and work under the hammer better than ordinary carbon steel. Again, the remarkable influence of manganese upon the magnetic properties of steel and iron is not shared by chromium. Chrome steel has for some time been a formidable rival of the very highest qualities of carbon steel produced for cutting tools, and of the valuable tungsten steel which we owe to Robert Mushet. The great hardness, high tenacity, and exceeding closeness of structure possessed by suitably tempered steel containing hot more than from 1 to 1.5 per cent of chromium, and

from 0.8 to 1 per cent of carbon, renders this material invaluable for war purposes: cast projectiles, when suitably tempered, have penetrated compound steel and iron plates over 9 inches in thickness, such as are used upon armoured ships of war, without even sustaining any important change of form. The proper tempering of these projectiles necessitates their being produced hollow; their cavities or chambers are only of small capacity, but the charge of violent explosive which they can contain, and which can be set into action without the intervention of fuse or detonating appliance, suffices to tear these formidable punching tools into fragments as they force their way irresistibly through the armoured side of a ship, and to violently project those fragments in all directions, with fearfully destructive effects. The employment of chromium as a constituent of steel plates used for the protection of ships of war is already being entered upon, and the influence exerted by the presence of that metal in small quantities in steel employed in the construction of guns is also at present a subject of investigation. At Crewe, Mr. F. Webb has for some time past used chromium, with considerable advantage, in the production of high-quality steels for railway requirements.

The practical results attained by the introduction of copper and of nickel as components of steel have also recently attracted much attention. At the celebrated French Steel Works of M. Schneider, at Creuzot, the addition of a small percentage of copper to steel used for armour plates and projectiles is practised, with the object of imparting hardness to the metal without prejudice to its toughness. James Riley has found that the presence of aluminium in very small quantities facilitates the union of steel with a small proportion of copper, and that the latter increases the strength but does not improve the working qualities of steel. With nickel, Riley has obtained products analogous in many important respects to manganese steel; the remarkable differences in the physical properties of the manganese alloys, according to their richness in that metal, are also shared by the nickel alloys, some of these being possessed of very valuable properties; thus, it has been shown by Riley that a particular variety of nickel-steel presents to the engineer the means of nearly doubling boiler-pressures, without increasing weight or dimensions. He has, moreover, found the co-existence of manganese in small quantity with nickel in the alloy to contribute importantly to the development of valuable physical properties.

The careful study of the alloys of aluminium, chromium, manganese, tungsten, copper, and nickel, with iron and with steel, so far as it has been carried, with especial reference to the influence which they respectively exercise upon the salient physical properties of those materials, even when present in them in only very small proportions, has demonstrated the importance of a more searching or complete application of chemical analysis, than hitherto practised, to the determination of the composition of the varieties of steel which practical experience has shown to be peculiarly adapted to particular uses. It appears, indeed, not improbable that certain properties of these, which have been ascribed to slight variations in the proportion or the condition of the constituent carbon, or in the amounts of silicium, phosphorus, and manganese which they contain, may sometimes have been due to the presence in minute quantities of one or other of such metals as those named, and to the effects which they produce, either directly, or indirectly by modifying or counteracting the effects of the normal constituents of steel. The important part now played by manganese in steel manufacture is an illustration of the comparatively recent results of research, and of practical work based on research, in these directions, and the effects of the presence in steel of only very small quantities of some of the other metals named are already, as I have pointed out, being similarly understood and utilised.

Such systematic researches as those upon which

Osmond, Roberts-Austen, and many other workers have been for some time past engaged, may make us acquainted with the laws which govern the modifications effected in the physical characteristics of metals by alloying these with small proportions of other metals. The suggestion of Roberts-Austen that such modifications may have direct connection with the periodic law of Mendeleeff, which may furnish explanations of the causes of specific variations in the properties of iron and steel, has been followed up energetically by Osmond, who has experimentally investigated the thermal influence upon iron of the elements phosphorus, sulphur, arsenic, boron, silicon, nickel, manganese, chromium, copper, and tungsten. He regards his results as being quite confirmatory of the soundness of Roberts-Austen's suggestion, as they demonstrate that foreign elements having atomic volumes lower than iron tend to make it assume or preserve the particular molecular form in which it has itself the lowest atomic volume, while the converse is the case for the foreign elements of high atomic volume. An analogous influence was found to be exerted by those two groups of elements upon the permanent magnetisation of steel.

Captivating as such deductions are, those who have devoted much attention to the practical investigation of iron, steel, and other metals, cannot but feel that much caution has to be exercised in drawing broad conclusions from the results of such researches as these. Like the investigations recently made with the object of ascertaining the condition in which carbon exists in steel, and the part played by it in determining the modifications in the properties developed in that material by the influence of temperature and of work done upon it, they are surrounded by formidable difficulties, arising from the practical impossibility of altogether eliminating the disturbing influences of minute quantities of foreign elementary bodies, co-existing in the metal operated upon, with those whose effects we desire to study. Certain it is, however, that by acquiring an accurate acquaintance with the composition of varieties of iron and steel exhibiting characteristic properties; by preserving in the all-important work of systematic practical examination of the mechanical and physical peculiarities developed in iron and steel of known composition by their association with one or more of the rarer metals in varied proportions, and by the further prosecution of chemical and physical research in such directions as those which have already been fruitful of most instructive results, such talented labourers as Chernoff, Osmond, Roberts-Austen, Barus and Stroudal, Hadfield, Keepe, James Riley, Stead, Turner, and others, cannot fail to contribute continually to the development of improvements equalling in importance those already attained in the production, treatment, and methods of applying cast iron, malleable iron, and steel, or alloys equivalent to steel in their qualities.

The causes of the variations in the physical properties of steel produced by the so-called hardening, annealing, and tempering processes were for very many years a fruitful subject for experimental inquiry, as well as of theoretical speculation with regard to the condition in which the carbon is distributed in steel, according to whether the metal is hardened or annealed, or in an intermediate, tempered state. Recent researches have made our knowledge in the latter direction fairly precise; as yet, however, we are only on the track of definite information respecting the nature and extent of connection between the physical peculiarities of steel in those different conditions and the established differences in the form and manner in which the carbon is disseminated through it.

The careful systematic study of the modifications developed in certain physical properties of iron and steel by gradual changes of temperature between fusion of the metal and the normal temperature, has shown those modifications to be governed by a constant law, and that at certain critical temperatures special phenomena present

themselves. This important subject, which was so clearly brought before the Association last year in the interesting lecture of Roberts-Austen, has been and is still being pursued by accomplished workers, among whom the most prominent is F. Osmond. The phenomenon of recalcence, or the re-glowing of, or liberation of heat in, iron and steel at certain stages during the cooling process, first noticed by Gore, and examined into by Barrett, appears to be the result of actual chemical combination between the metal and its contained carbon at the particular temperature attained at the time; while the absorption of heat, demonstrated by the arrest in rise of temperature during its continuous application to the metal, is ascribed to the elimination, within the mass, of carbon as an iron carbide perfectly stable at low temperatures. The pursuit of a well-devised system of experimental inquiry into this subject has led Osmond to propound theories of the hardening and tempering of steel, which are at present receiving the careful study of physicists and chemists, and cannot fail to lead to further important advancement of our knowledge of the true nature of the influence of carbon upon the properties of iron.

Another important subject connected with the treatment of masses of steel, and with the influence exercised upon their physical characteristics by the processes of hardening and tempering, and by submitting them to oft-repeated concussion or vibrations, or frequent or long-continued strains, is the development and maintenance, or gradual disappearance, of internal stresses in the masses—one of the many important subjects to which attention was directed by Dr. Anderson, the Director-General of Ordnance Factories, in his very suggestive address to the Mechanical Section last year. This question is one of especial interest to the constructor of steel guns, as the powers of endurance of these do not simply depend upon the quality of the material composing them, but are very largely influenced by the treatment which it receives at the hands of the gunmaker. Indeed, the highest importance attaches to the processes which are applied to the preliminary preparation of the individual parts of which the gun is constructed, and to the putting together of these so as to ensure their being and remaining in the physical condition best calculated to assist each other in securing for the structure the power of so successfully resisting the heavy strains to which it has to be subjected, as to suffer little alteration other than that due to the superficial action of the highly-heated products of explosion of the charges fired in the gun. The development of internal strains in objects of steel, especially by the hardening and tempering processes, or by their exposure to conditions favourable to unequal cooling of different parts of the mass, has long been a subject of much trouble and of experimental inquiry in connection with many applications of steel. Systematic experiments of the kind commenced, about eighteen years ago, by the late Russian general, Kalakoutsky, are now being pursued at Woolwich, with the objects of determining the nature and causes of internal stresses in steel gun-hoops and tubes, and in shells, and of thereby establishing the proper course to be adopted for avoiding, lessening, or counteracting injurious stresses, on the one hand, and for setting up stresses beneficial to the powers of endurance of guns on the other. One method of experiment pursued, with parts of guns, is to cut narrow hoops off the forgings, after a particular treatment, which are then cut right across at one place, it being observed whether, and to what extent, the resulting gaps open or close. This important subject has also been similarly investigated by my talented old friend and fellow worker, the President this year of the Mechanical Section, Captain Andrew Noble, whose name in connection with the science and practice of artillery is familiar to us as household words.

(To be continued).

ADDRESS TO THE CHEMICAL SECTION
OF THE
BRITISH ASSOCIATION.

By Professor T. E. THORPE, B.Sc., Ph.D., F.R.S., Treas.C.S.,
President of the Section.

LEEDS has one most notable association with chemistry of which she is justly proud. In the month of September, 1767, Dr. Joseph Priestley took up his abode in this town. The son of a Yorkshire cloth-dresser, he was born in 1733 at Fieldhead, a village about six miles hence. His relatives, who were strict Calvinists, on discovering his fondness for books, sent him to the Academy at Daventry to be trained for the ministry. In spite of his poverty and of certain natural disadvantages of speech and manner, he gradually acquired, more especially by his controversial and theological writings, a considerable influence in Dissenting circles. A pressing invitation and the offer of one hundred guineas a year, induced him to accept an invitation to take charge of the congregation of Mill Hill Chapel here. He was already known to science by his "History of Electricity," and the effort was made to attach him still more closely to its cause by the offer of an appointment as naturalist to Cook's Second Expedition to the South Seas. But thanks to the intervention of some worthy ecclesiastics on the Board of Longitude who had the direction of the business, and who, as Professor Huxley once put it, "possibly feared that a Socinian might undermine that piety which in the days of Commodore Truncheon so strikingly characterised sailors," he was allowed to remain in Leeds, where, as he tells us in his Memoirs, he continued six years, "very happy with a liberal, friendly, and harmonious congregation," to whom his services (of which he was not sparing) were very acceptable. "In Leeds," he says, "I had no unreasonable prejudices to contend with, and I had full scope for every kind of exertion."*

We have every reason to feel grateful to the "worthy ecclesiastics," since their action indirectly occasioned Priestley to turn his attention to chemistry. The accident of living near a brewery led him to study the properties of "fixed air," or carbonic acid, which is abundantly formed in the process of fermentation, and which at that time was the only gas whose separate and independent existence had been definitely established. From this happy accident sprang that extraordinary succession of discoveries which earned for their author the title of the Father of Pneumatic Chemistry, and which were destined to completely change the aspect of chemical theory and to give it a new and unexpected development.

I have been led to make this allusion to Priestley, not so much on account of his connection with this place as for the reason that, as it seems to me, there has been a disposition to obscure his true relation to the marvellous development of chemical science which made the close of the last century memorable in the history of learning. Our distinguished fellow-worker, M. Berthelot, the Perpetual Secretary of the French Academy, has recently published, under the title of "La Révolution Chimique," a remarkable book, written with great skill, and with all the charm of style and perspicacity which invariably characterises his work, in which he claims for Lavoisier a participation in discoveries which we count among the chief scientific glories of this country. From the eminence of M. Berthelot's position in the world of science, his book is certain to receive in his own country the attention which it merits, and as it is issued as one of the volumes of the Bibliothèque Scientifique Internationale it will probably obtain through the medium of translations a still wider circulation. I trust that I shall not be accused of being unduly actuated by what Mr. Herbert

Spencer terms "the bias of patriotism" in deeming the present a fitting occasion on which to bring these claims to your notice with a view of determining how far they can be substantiated.

All who are in the least degree familiar with the history of chemical science during the last hundred years will recognise, as I proceed, that the claims which M. Berthelot asserts on behalf of his illustrious predecessor are not put forward for the first time. Explicitly made, in fact by Lavoisier himself, they were uniformly and consistently disallowed by his contemporaries. M. Berthelot now seeks to support them by additional evidence, and to strengthen them with new arguments, and asks us thereby to clear the memory of Lavoisier from certain grave charges which lie heavily on it. You have doubtless anticipated that these claims have reference to Lavoisier's position in relation to the discovery of oxygen gas and the determination of the non-elementary nature of water.

The substance we now call oxygen—a name we owe to Lavoisier—was discovered by Priestley on August 1, 1774; he obtained it, as every schoolboy knows, by the action of heat upon the red oxide of mercury. We all remember the characteristically ingenuous account which Priestley gives of the origin of his discovery. M. Berthelot sees in it merely the evidence of the essentially empirical character of his work. "Priestley," he says, "the enemy of all theory and of every hypothesis, draws no general conclusion from his beautiful discoveries, which he is pleased, moreover, not without affectation, to attribute to chance. He describes them in the current phraseology of the period with an admixture of peculiar and incoherent ideas, and he remained obstinately attached to the theory of phlogiston up to his death, which occurred in 1804" (p. 40). Such a statement is calculated to give an erroneous idea of Priestley's merit as a philosopher. That the implication it contains is wholly opposed to the real spirit of his work might be readily shown by numerous quotations from his writings. Perhaps this will suffice. "It is always our endeavour, after making experiments, to generalise the conclusions we draw from them, and by this means to form a *theory* or system of principles to which all the *facts* may be reduced, and by means of which we may be able to foretell the result of future experiments." This quotation is taken from the concluding chapter of his "Experiments and Observations on Different Kinds of Air," in which he actually seeks to draw "general conclusions" concerning the constituent principles of the various gases which he himself made known to us, and to show the bearing of these conclusions on the doctrine of phlogiston. That he was content to rest in the faith of Stahl's great generalisation, even to the end, is true, and the fact is the more remarkable when we recall the absolute sincerity of the man, his extraordinary receptivity, and, as he says of himself, his proneness "to embrace what is generally called the heterodox side of almost every question." If it is argued that this merely shows Priestley's inability to appreciate theory, it must be at least admitted that there is no proof that he was inimical to it. His position is clearly evident from the concluding words of the section of his work from which I have already quoted. "This doctrine of the composition and decomposition of water has been made the basis of an entirely new system of chemistry, and a new set of terms has been invented and appropriated to it. It must be acknowledged that substances possessed of very different properties may, as I have said, be composed of the same elements in different proportions and different modes of combination. It cannot, therefore, be said to be absolutely impossible but that water may be composed of these two elements or any other. But then the supposition should not be admitted without *proof*, and if a former theory will sufficiently account for all the *facts* there is no occasion to have recourse to a new one, attended with no peculiar advantage (*loc. cit.*, p. 543).

I should not feel much reluctance to adopt the *new doctrine*, provided any new and stronger evidence be

* Leeds still enjoys one of the fruits of Priestley's insatiable power of work in her admirable Proprietary Library. He seems to have suggested its formation and was its first honorary secretary.

produced for it. But though I have given all the attention that I can to the experiments of M. Lavoisier, &c., I think that they admit of the easiest explanation on the old system" (*loc. cit.*, p. 563).

The fact that Priestley was the first to consciously isolate oxygen is not contested by M. Berthelot, although he is careful to point out, what is not denied, that the exact date of the discovery depends on Priestley's own statement, and that his first publication of it was made in a work published in London in 1775. It was known before Priestley's famous experiment that the red oxide of mercury, originally formed by heating the metal in contact with air, would again yield mercury by the simple action of heat and without the intervention of any reducing agent. Bayen, six months before the date of Priestley's discovery, had observed that a gas was thus disengaged, but he gave no description of its nature, contenting himself merely by pointing out the analogy which his experiments appeared to possess to those of Lavoisier on the existence of an elastic fluid in certain substances. Afterwards, when the facts were established, Bayen drew attention to his earlier experiments and claimed, not only the discovery of oxygen, but all that Lavoisier deduced from it. "But," says M. Berthelot, in reference to this circumstance, "his contemporaries paid little heed to his pretensions, nor will posterity pay more" ("La Révolution Chimique," p. 60).

M. Berthelot, however, does not dismiss Lavoisier's claims to a participation in the discovery in the same summary fashion. On the contrary, whilst not explicitly claiming for him the actual isolation, in the first instance, of oxygen, the whole tenor of his argument is to extenuate, and even to justify, his demand to be regarded as an independent discoverer of the gas. He begins by asserting that Lavoisier had already a presentiment of its existence in 1774, and he quotes, in support of this assumption, an abstract from Lavoisier's memoir, published in December, 1774, in the *Journal de Physique* of the Abbé Rozier. "This air, deprived of its fixable portion (by metals during calcination), is in some fashion decomposed, and this experiment would seem to afford a method of analysing the fluid which constitutes our atmosphere and of examining the principles of which it is composed. . . . I believe I am in a position to affirm that the air, as pure as it is possible to suppose it, free from moisture and from every foreign substance, far from being a simple body, or element, as is commonly thought, should be placed, on the contrary, . . . in the group of the mixtures, and perhaps even in that of the compounds."

M. Berthelot further asserts that Lavoisier was at this time the first to recognise the true character of air, and he expresses his belief that it is probable that he would himself have succeeded in isolating its constituents if the path of inquiry had been left to him alone. It is no disparagement to Lavoisier's prescience to say that there is nothing in these lines, nor in the memoir of the repetition of Boyle's experiments on the calcination of tin to which they refer, to show that Lavoisier had made any advance beyond the position of Hooke and Mayow. It has been more than once pointed out that the chemists of the seventeenth century understood the true nature of combustion in air much better than their brethren of the last quarter of the eighteenth century. Hooke, in the *Micrographia*, and Mayow, in his "Opera Omnia Medico-physica," indicated that combustion consists in the union of something with the body which is being burnt; and Mayow, both by experiment and inference, demonstrated in the clearest way the analogy between respiration and combustion, and showed that in both processes one constituent only of the air is concerned. He distinctly stated that, not only is there increase of weight attending the calcination of metals, but that this increase is due to the absorption of the same *spiritus* from the air that is necessary to respiration and combustion. Mayow's experiments are so precise, and his facts so incontestable, that, as Chevreul has said, it is surprising that the truth

was not fully recognised until a century after his researches (*Vide* Watts' "Dictionary of Chemistry," by Morley and Muir, art. "Combustion," p. 242).

It is now necessary to examine Lavoisier's claims rather more closely and in the light of M. Berthelot's book. A *résumé* of his work "On the Calcination of Tin" was given by Lavoisier to the Academy in November, 1774, but the complete memoir was not deposited until May, 1777. A careful comparison of an abstract of what was stated to the Academy in November, 1774, contributed by Lavoisier himself, in December, 1774, to the *Journal de Physique* of the Abbé Rozier, makes it evident that very substantial additions were made to the communication before it was finally printed in the *Mémoires de l'Académie des Sciences*. The possibility of this is allowed by M. Berthelot. He says (p. 58):—"A summary communication, often given *vis à vis* to a learned society, such as the Academy of Sciences of Paris or the Royal Society of London, would immediately call forth verifications, ideas, and new experiments, which would develop the range and even the results of such communication. The original author, when printing his memoir, would in return—and for this he is hardly blamable—embody these additional results and later interpretations. It thus becomes most difficult to assign impartially to each his share in a rapid succession of discoveries" (*Loc. cit.*, p. 58).

But although, as we shall see, Lavoisier was certainly aware of Priestley's great discovery, no allusion is made to the gas, nor to Priestley's previous work on the other constituent of air, which is printed in the *Philosophical Transactions* for 1772, and for which he was awarded the Copley Medal by the Royal Society. It is simply impossible to believe that Lavoisier could have been influenced by this work. Indeed, we venture to assert that the full and clear recognition of the non-elementary nature of air which he eventually made was based upon it. It is noteworthy that in the early part of his memoir he states his opinion that the addition, not only of powdered charcoal, but of any phlogistic substance to a metallic calx is attended with the formation of fixed air. It is certain that at this period he had, not only not consciously obtained any gas resembling Priestley's dephlogisticated air from any calx with which he had experimented, but that none of his experiments had afforded him any idea that the gas absorbed during calcination was identical with it.

At Easter, 1775, Lavoisier presented a memoir to the Academy "On the Nature of the Principle which Combines with Metals during Calcination." This was "*reçu le 8 Août, 1778*." To the memoir there is a note stating that the first experiments detailed in it were performed more than a year before; those on the red precipitate were made by means of a *burning glass* in the month of November, 1774, and were repeated in the spring of 1775 at Montigny in conjunction with M. Trudaine. In this paper Lavoisier first distinctly announces that the principle which unites with metals during their calcination, which increases their weight, and which transforms them into calces, is nothing else "than the purest and most salubrious part of the air; so that if that air which has been fixed in a metallic combination again becomes free, it re-appears in a condition in which it is eminently respirable, and better adapted than the air of the atmosphere to support inflammation and the combustion of substances" ("Œuvres de Lavoisier," official edition, vol. ii., p. 123). He then describes the method of preparing oxygen by heating the red oxide of mercury, and compares its properties with those of fixed air. There is, however, no mention of Priestley, nor any reference to his experiments. It can hardly be doubted that in this memoir Lavoisier intended his readers to believe that he was "the true and first discoverer" of the gas which he afterwards named oxygen. This is borne out by certain passages in his subsequent memoir "On the Existence of Air in Nitrous

Acid; *lu le 20 avril, 1776, remis en décembre 1777.*" He had occasion incidentally to prepare the red oxide of mercury by calcining the nitrate, and says that he obtained from it a large quantity of an air "much purer than common air, in which candles burnt with a much larger, broader, and more brilliant flame, and which in no one of its properties differed from that which I had obtained from the calx of mercury, known as *mercurius precipitatus per se*, and which Mr. Priestley had procured from a great number of substances by treating them with nitric acid."

In another part of this memoir he says that "perhaps, strictly speaking, there is nothing in it of which Mr. Priestley would not be able to claim the original idea; but as the same facts have conducted us to diametrically opposite results, I trust that, if I am reproached for having borrowed my proofs from the works of this celebrated philosopher, my right at least to the conclusions will not be contested." M. Berthelot remarks on the irony of this passage: we may infer from it that the friends of the English chemist had not been altogether idle. In his memoir "On the Respiration of Animals," read to the Academy in 1777, he again appears to admit the claim of Priestley to at least a share in the discovery. "It is known from Mr. Priestley's and my experiments that *mercurius precipitatus per se* is nothing but a combination," &c. In several subsequent communications Priestley's name is mentioned in very much the same connection, until we come to the classical memoir "On the Nature of the Acids," when it is said:—"I shall henceforth designate the dephlogisticated air, or the eminently respirable air . . . by the name of the *acidifying principle*, or, if it is preferred to have the same signification under a Greek word, by that of the "*principe oxygene*."

In none of the memoirs after that of Easter 1775 is the claim for participation more than implied; it is made explicitly for the first time in the paper "On a Method of Increasing the Action of Fire," printed in the *Mémoires de l'Académie* for 1782, and in these words:—"It will be remembered that at the meeting of Easter 1775, I announced the discovery, which I had made some months before with M. Trudaine,* in the laboratory of Montigny, of a new kind of air, up to then absolutely unknown, and which we obtained by the reduction of *mercurius precipitatus per se*. This air, which Mr. Priestley discovered at very nearly the same time as I, and I believe even before me, and which he had procured mainly from the combination of minium and of several other substances with nitric acid, has been named by him *dephlogisticated air*."

In the "Traité Élémentaire de Chimie" the claim for participation is again asserted in these words:—"This air, which Mr. Priestley, Mr. Scheele, and I discovered at about the same time . . ."

Now there is no question that Lavoisier knew of the existence of oxygen some months before he made the experiments with the burning glass of M. Trudaine at Montigny for the simple reason that Priestley had already told him of it. Priestley left Leeds in 1773, to become the librarian and literary companion of Lord Shelburne, and in the autumn of 1774 he accompanied his lordship on to the Continent, and spent the month of October in Paris. Lavoisier was famous for his hospitality; his dinners were celebrated; and Priestley, in common with every foreign *savant* of note who visited Paris at that period, was a welcome guest. What followed is best told in Priestley's own words. "Having made the discovery [of oxygen] some time before I was in Paris, in the year 1774, I mentioned it at the table of Mr. Lavoisier, when most of the philosophical people of the city were present, saying that it was a kind of air in which a candle burnt much better than in common air, but I had not then given it any name. At this all the company, and Mr. and Mrs. Lavoisier as much as any, expressed great surprise. I

told them I had gotten it from *precipitate per se* and also from red lead. Speaking French very imperfectly, and being little acquainted with the terms of chemistry, I said *plombe rouge*, which was not understood until Mr. Macquer said I must mean minium."

In his account of his own work on dephlogisticated air, given in his "Observations," &c., 1790 edition, he further says (vol. ii., p. 108):—"Being at Paris in the October following [the August of 1774], and knowing that there were several very eminent chemists in that place, I did not omit the opportunity, by means of my friend Mr. Magellan,* to get an ounce of *mercurius calcinatus* prepared by Mr. Cadet, of the genuineness of which there could not possibly be any suspicion; and, at the same time, I frequently mentioned my surprise at the kind of air which I had got from this preparation to Mr. Lavoisier, Mr. le Roy, and several other philosophers, who honoured me with their notice in that city, and who, I dare say, cannot fail to recollect the circumstance."

If any further evidence is required to prove that Lavoisier was not only not "the true and first discoverer" of oxygen, but that he has absolutely no claim to be regarded even as a later and independent discoverer, it is supplied by M. Berthelot himself. Not the least valuable portion of M. Berthelot's book, as an historical work, is that which he devotes to the analysis of the thirteen laboratory journals of Lavoisier, which have been deposited, by the pious care of M. de Chazelles, his heir, in the archives of the Institute. M. Berthelot has given us a synopsis of the contents of almost every page of these journals, with explanatory remarks and dates when these could be ascertained. As he well says, these journals "are of great interest because they inform us of Lavoisier's methods of work and of the direction of his mind—I mean the successive steps in the evolution of his private thought." On the fly-leaf of the third journal is written, "*du 23 mars, 1774, au 13 février, 1776.*" From p. 30 we glean that Lavoisier visited his friend M. Trudaine at Montigny about ten days after his conversation with Priestley, and repeated the latter's experiments on the marine acid and alkaline airs (hydrochloric acid gas and ammonia). He is again at Montigny some time between the February 28 and the March 31, 1775, and repeats, not only Priestley's experiments on the decomposition of mercuric oxide, presumably by means of M. Trudaine's famous burning glass, but also his observations on the character of the gas. The fly-leaf of the fourth journal informs us that it extends from February 13, 1776, to March 3, 1778. On p. 1 is an account of experiments made February 13 on "*précipité per se* chez M. Baumé, in which the disengaged gas is spoken of as "*l'air déphlogistique de M. Priestley*" (*sic*). Such a phrase in a private note-book is absolutely inconsistent with the idea that at this time Lavoisier considered himself as an independent discoverer of the gas. How he came to regard himself as such we need not enquire. Nor is it necessary to occupy your time by any examination of the arguments by which M. Berthelot, with the skill of a practised advocate, would seem to identify himself with the case of his client. We would do him the justice of recognising the difficulty of his position. He seeks to discharge an obligation, of which the acknowledgment has been too long delayed. The Académie des Sciences a year ago awoke to the sense of its debt of gratitude to the memory of the man who had laboured so zealously for its honour and even for its existence, during the stormy period of which France has just celebrated the centenary, and out of the *éloge* on Lavoisier which M. Berthelot, as Perpetual Secretary, was commissioned to deliver, has grown La Révolution Chimique. To write eulogy, however, is not necessarily to write history. We

* Prof. Grimaux (Lavoisier, p. 51), says: "Un de ses [Lavoisier's] amis qui habitait Londres, Magalhaens ou Magellan, de la famille du célèbre navigateur, lui en voyait tous les mémoires sur les sciences qui paraissaient en Angleterre et le tenait au courant des découvertes de Priestley."

* M. Trudaine de Montigny died in 1777.

cannot but think that M. Berthelot has been hampered by his position, and that his opinion, or at least the free expression of it, has been fettered by the conditions under which he has written. We imagine we discern between the lines the consciousness that, to use Brougham's phrase, the brightness of the illustrious career which he eulogises is dimmed with spots which a regard for historical truth will not permit him wholly to ignore.

Two cardinal facts made the downfall of phlogiston complete—the discovery of oxygen and the determination of the compound nature of water. M. Berthelot's contention is that, not only did Lavoisier effect the overthrow, but he also discovered the facts. In other words, he has, not only a claim to a participation in the discovery of oxygen, but he is also "the true and first discoverer" of the non-elementary nature of water. This second claim is directly and explicitly stated. Although it is supported by a certain ingenuity of argument, we venture to think that we shall be able to show that it has no greater foundation in reality than the first.

Members of the British Association, who are at all familiar with its history, will recall the fact that this is not the first occasion on which the attempt to transfer "those laurels which both time and truth have fixed upon the brow of Cavendish" has had to be resisted. At the Birmingham Meeting of 1839 the Rev. W. Vernon Harcourt, who then presided, devoted a large portion of his Address to an able and eloquent vindication of Cavendish's rights. The attack came then as now from the Perpetual Secretary of the French Academy, and the charges were also formulated then, as now, in an *éloge* read before that learned body. The assailant was M. Arago, who did battle, not for his countryman Lavoisier, whose claims are dismissed as "pretensions," but on behalf of James Watt, the great engineer, who was one of the foreign members of the Institute.

It is not my wish to trouble you at any length with the details of what has come to be known in the history of scientific discovery as the Water Controversy—a controversy which has exercised the minds and pens of Harcourt, Whewell, Peacock, and Brougham in England; of Brewster, Jeffrey, Muirhead, and Wilson in Scotland; of Kopp in Germany; and of Arago and Dumas in France. This controversy, it has been said, takes its place in the history of science side by side with the discussion between Newton and Leibnitz concerning the invention of the Differential Calculus, and that between the friends of Adams and Leverrier in reference to the discovery of the planet Neptune. Up to now it has practically turned upon the relative merits of Cavendish and Watt. M. Berthelot is the first French *savant* of any note who has seriously put forward the claims of Lavoisier, his countryman and predecessor Dumas having deliberately rejected them.

At the risk of wearying you with detail, I am under the necessity of re-stating the facts in order to make the position clear. Some time before April 18, 1781, Priestley made what he called "a random experiment" for the entertainment of a few philosophical friends. It consisted in exploding a mixture of inflammable air (presumably hydrogen) and common air, contained in a closed glass vessel, by the electric spark, in the manner first practised by Volta in 1776. The experiment was witnessed by Mr. John Warltire, a lecturer on natural philosophy and a friend of Priestley, who had rendered him the signal service of giving him the sample of the mercuric oxide from which he had first obtained oxygen. Warltire drew Priestley's attention to the fact that after the explosion the sides of the glass vessel were bedewed with moisture. Neither of the experimenters attached any importance to the circumstance at the time, Priestley being of opinion that the moisture was pre-existent in the gases, as no special pains were taken to dry them. Warltire, however, conceived the notion that the experiment would afford the means of determining whether heat was ponderable or not, and hence he was led to repeat it, firing the mixture in a copper vessel for

greater safety. The results of these observations are contained in Priestley's "Experiments and Observations on Air," vol. v. 1781, App. p. 395.

At this period Cavendish was engaged on a series of experiments "made, as he says, principally with a view to find out the cause of the diminution which common air is well known to suffer by all the various ways in which it is phlogisticated, and to discover what becomes of the air thus lost or condensed" (Cavendish, *Phil. Trans.* 1784, p. 119). On the publication of Priestley's work he repeated Warltire's experiment, for, he says, as it "seemed likely to throw great light on the subject I had in view, I thought it well worth examining more closely." The series of experiments which Cavendish was thus induced to make, and which he made with all his wonted skill in quantitative work, led him some time in the summer of 1781 to the discovery that a mixture of two volumes of the inflammable air from metals (the gas we now call hydrogen) with one volume of the dephlogisticated air of Priestley combine together under the influence of the electric spark, or by burning, to form the same weight of water. If Cavendish had published the results of these observations at or near the time he obtained them, there would have been no Water Controversy. But in the course of the trials he found that the condensed water was sometimes acid, and the search for the cause of the acidity (which incidentally led to the discovery of the composition of nitric acid) occasioned the delay. The main result that a mixture of two volumes of inflammable air and one volume of dephlogisticated air could be converted into the same weight of water was, however, communicated to Priestley, as he relates in a paper in the *Phil. Trans.* for 1783. Priestley was at this time interested in an investigation on the seeming convertibility of water into air, and he was led to repeat Cavendish's experiments, some time in March 1783, on what was apparently the converse problem. Priestley, however, made a fatal blunder in the repetition. With the praiseworthy idea of obviating the possibility of any moisture in the gases, he prepared the dephlogisticated air from nitre, and the inflammable air by heating what he calls "perfectly made charcoal" in an earthenware retort. At this time, it must be remembered, there was no sharp distinction between the various kinds of inflammable air: hydrogen, sulphuretted hydrogen, marsh gas and olefiant gas, coal gas, the vapours of ether and turpentine, and the gas from heated charcoal, consisting of a mixture of carbonic oxide, marsh gas, and carbonic acid, were indifferently termed "inflammable air." Priestley attempted to verify Cavendish's conclusion on the identity of the weight of the gases used with that of the water formed; but his method in this respect, as in his choice of the inflammable air, was wholly defective, and could not possibly have given him accurate results. It consisted in wiping out the water from the explosion vessel by means of a weighed piece of blotting-paper and determining the increase of weight of the paper. He says, however, "I always found, as near as I could judge, the weight of the decomposed air in the moisture acquired by the paper. . . . I wished, however, to have had a nicer balance for this purpose; the result was such as to afford a strong presumption that the air was reconverted into water, and therefore that the origin of it had been water." These results, together with those on the conversion of water into air, were communicated towards the end of March, 1783, by Priestley to Watt, who began to theorise upon them, and then to put his thoughts together in the form of a letter to Priestley, dated April 26, 1783, and which he requested might be read to the Royal Society on the occasion of the presentation of Priestley's memoir. In this letter Watt says:—"Let us now consider what obviously happens in the case of the deflagration of the inflammable and dephlogisticated air. These two kinds of air unite with violence, they become red-hot, and upon cooling totally disappear. When the vessel is cooled, a quantity of water is found in it equal to the weight of the air employed. This water is

then the only remaining product of the process, and water, light, and heat are all the products. Are we not then authorised to conclude that water is composed of dephlogisticated air and phlogiston deprived of part of their latent or elementary heat; that dephlogisticated or pure air is composed of water deprived of its phlogiston and united to elementary heat and light, &c.?"

This letter, although shown to several Fellows of the Society, was not publicly read at the time intended. Priestley, before its receipt, had detected the fallacy of his experiments on the seeming conversion of water into air, and as much of the letter was concerned with this matter Watt requested that it should be withdrawn. Watt, however, as he tells Black* in a letter dated June 23, 1783, had not given up his theory as to the nature of water, and on November 26, 1783, he re-stated his views more fully in a letter to De Luc. In the meantime Cavendish, having completed one section of his investigation, sent in a memoir to the Royal Society, which was read on January 15, 1784, in which he gives an account of his experiments and announces his conclusion "that dephlogisticated air is in reality nothing but dephlogisticated water, or water deprived of its phlogiston; or, in other words, that water consists of dephlogisticated air united to phlogiston; and that inflammable air is either pure phlogiston, as Dr. Priestley and Mr. Kirwan suppose, or else water united to phlogiston." Watt thereupon requested that his letter to De Luc should be published, and it was accordingly read to the Royal Society on April 29, 1784. Which of the two—Cavendish or Watt—is, under these circumstances, to be considered as "the true and first discoverer" of the compound nature of water is the question which has been hitherto the main subject of the water controversy.

Let us now consider the matter as it affects Lavoisier. In 1783 Lavoisier had publicly declared against the doctrine of phlogiston, or rather, as M. Dumas puts it, "against the crowd of entities of that name which had no quality in common except that of being intangible by every known method." (*Leçons sur la Philosophie Chimique*, p. 161). How completely Lavoisier had dissociated himself from the theory may be gleaned from his memoir of that year. "Chemists," he says, "have made a vague principle of phlogiston which is not strictly defined, and which in consequence accommodates itself to every explanation into which it is pressed. Sometimes this principle is heavy and sometimes it is not; sometimes it is free fire and sometimes it is fire combined with the earthy element; sometimes it passes through the pores of vessels and sometimes they are impenetrable to it: it explains at once causticity and non-causticity, transparency and opacity, colours and the absence of colours. It is a veritable Proteus which changes its form every moment."

But Lavoisier had merely renounced one fetish for another. At the time that he penned these lines he was as much under the thralldom of *le principe oxygène* as the most devoted follower of Stahl was in the bondage of phlogiston. The idea that the calcination of metals was but a slow combustion had been fully recognised. M. Berthelot tells us that as far back as the March of 1774 Lavoisier had written in his laboratory journal:—"I am persuaded that the inflammation of inflammable air is nothing but a fixation of a portion of the atmospheric air, a decomposition of air. . . . In that case in every inflammation of air there ought to be an increase of weight," and he tried to ascertain this by burning hydrogen at the mouth of a vessel from which it was being disengaged. In the following year he asks, what remains when inflammable air is burnt completely? According to the theory by which he is now swayed it should be an acid, and he made many attempts to capture this acid. In 1777 he and Berquet burnt six pints of the inflammable air from metals in a bottle containing lime-water, in the expecta-

tion that fixed air would be the result. And, in 1781, he repeated the experiment with Gengembre, with the modification that the oxygen was caused to burn in an atmosphere of hydrogen, but not a trace of any acid product could be detected. Of course there must have been considerable quantities of water formed in these experiments, but Lavoisier was pre-occupied with the conviction that oxidation meant acidification, and its presence was unnoticed, or, if noticed, was unheeded. Macquer, in 1776, had drawn attention to the formation of water during the combustion of hydrogen in air, but Lavoisier had stated that he was ignorant of that observation. What was it, then, that put him on the right track? We venture to think that M. Berthelot has himself supplied the answer. He says (p. 114) "rumours of Cavendish's trials had spread throughout the scientific world during the spring of 1783. . . . Lavoisier, always on the alert as to the nature of the products of the combustion of hydrogen, was now in such position that the slightest hint would enable him to comprehend its true nature. He hastened to repeat his trials, as he had the right to do, never having ceased to occupy himself with a question which lay at the very heart of his doctrine."

"On the 24th of June, 1783," continues M. Berthelot, "he repeated the combustion of hydrogen in oxygen, and he obtained a notable quantity of water without any other product, and he concluded from the conditions under which he had worked that the weight of the water formed could not be other than equal to that of the two gases which had formed it. The experiment was made in the presence of several men of science, among whom was Blagden, a member of the Royal Society of London, who on this occasion recalled the observations of Cavendish (*qui rappela à cette occasion les observations de Cavendish*)."

On the following day Lavoisier published his results. The following is the official minute of the communication taken from the register of the sittings of the Académie des Sciences:—

Meeting of Wednesday, June 25, 1783.

MM. Lavoisier and De Laplace announced that they had lately repeated the combustion of Combustible Air with Dephlogisticated Air; they worked with about 60 pints of the airs, and the combustion was made in a closed vessel: the result was very pure water.

The cautious scribe who penned that minute did not commit himself too far. M. Berthelot, however, regards it as the first certain date of publication, established by authentic documents, in the history of the discovery of the composition of water, "a discovery," he adds, "which, on account of its importance, has excited the keenest discussion."

You will search in vain through the laboratory journals as given by M. Berthelot, for any indications either of experiments or reflections which would enable you to trace the course of thought by which Lavoisier was guided to the truth. There is absolutely nothing on the subject until in the eighth volume (25 mars, 1783, au février 1784), and on p. 63 we come to the experiment of June 24, and we read:—"In presence of Messieurs Blagden, of [name illegible], de Laplace, Vandermonde, de Fourcroy, Meusnier, and Legendre, we have combined in a bell-jar dephlogisticated air and inflammable air drawn from iron by means of sulphuric acid, &c. . . . The amount of water may be estimated at 3 drachms: the amount which should have been obtained was 1 ounce 1 drachm and 12 grains. Thus we must suppose that there was a loss of two-thirds of the amount of the air or that there has been a loss of weight.

And this is the experiment which, according to M. Berthelot, enabled Lavoisier to conclude that "the weight of the water formed could not be other than equal to that of the two gases which had formed it!" It is on this single experiment, hurriedly and imperfectly done, that Lavoisier's claim to the discovery of the compound

* Watt, *Correspondence*, p. 31.

nature of water is based! M. Berthelot objects to the assumption that it was hurriedly done. He says, on p. 114:—"Lavoisier caused a new apparatus to be made, with a couple of tubes and two reservoirs for the gases, an arrangement which would require a certain amount of time to put together; this circumstance proves that it could not have been an improvised trial." To what extent it was improvised will be seen immediately.

Now, although the laboratory journals do not in this case "inform us of Lavoisier's methods, and of the direction of his mind . . . the successive steps in the evolution of his private thought," we have other means of ascertaining how he arrived at his knowledge. The method was simplicity itself: he was told of the fact, and his informant was none other than Cavendish's assistant, Blagden.

Cavendish's memoir was published in 1784. Before it was struck off its author caused the following addition to be made:—"During the last summer also a friend of mine gave some account of them [the experiments] to M. Lavoisier, as well as of the conclusion drawn from them, that dephlogisticated air is only water deprived of phlogiston; but at that time so far was M. Lavoisier from thinking any such opinion warranted that, till he was prevailed upon to repeat the experiment himself, he found some difficulty in believing that nearly the whole of the two airs could be converted into water." This addition, as I have had the opportunity of verifying by an inspection of the original MSS. in the archives of the Royal Society, was made in the handwriting of Cavendish's assistant and amanuensis, Blagden.

When Lavoisier's memoir appeared it was found to contain the following reference to this circumstance:—"It was on the 24th of June that M. de Laplace and I made this experiment in presence of MM. le Roi, Vandermonde, and several other Academicians, and of Mr. Blagden, the present Secretary of the Royal Society of London. The latter informed us (*ce dernier nous apprit*) that Mr. Cavendish had already tried, in London, to burn inflammable air in closed vessels, and that he had obtained a very sensible quantity of water."

This reference was so partial, and its meaning so ambiguous, that Blagden addressed the following letter to Crell to be published in his "Chemische Annalen" (Crell's "Annalen," 1786, vol. i., p. 58).

It is so direct and conclusive that I offer no apology for giving it almost entire:—

"I can certainly give you the best account of the little dispute about the first discoverer of the artificial generation of water, as I was the principal instrument through which the first news of the discovery that had been already made was communicated to Mr. Lavoisier. The following is a short statement of the history:—

"In the spring of 1783 Mr. Cavendish communicated to me, and other members of the Royal Society, his particular friends, the result of some experiments with which he had for a long time been occupied. He showed us that out of them he must draw the conclusion that dephlogisticated air was nothing else than water deprived of its phlogiston; and, *vice versa*, that water was dephlogisticated air united with phlogiston. About the same time the news was brought to London that Mr. Watt, of Birmingham, had been induced by some observations to form a similar opinion. Soon after this I went to Paris, and in the company of Mr. Lavoisier and of some other members of the Royal Academy of Sciences I gave some account of these new experiments and of the opinions founded upon them. They replied that they had already heard something of these experiments, and particularly that Dr. Priestley had repeated them. They did not doubt that in such manner a considerable quantity of water might be obtained, but they felt convinced that it did not come near

to the weight of the two species of air employed, on which account it was not to be regarded as water formed or produced out of the two kinds of air, but was already contained in and united with the airs, and deposited in their combustion. This opinion was held by Mr. Lavoisier, as well as by the rest of the gentlemen who conferred on the subject; but, as the experiment itself appeared to them very remarkable in all points of view, they unanimously requested Mr. Lavoisier, who possessed all the necessary preparations, to repeat the experiment on a somewhat larger scale as early as possible. This desire he complied with on the 24th June, 1783 (as he relates in the latest volume of the Paris memoirs). From Mr. Lavoisier's own account of his experiment it sufficiently appears that at that period he had not yet formed the opinion that water was composed of dephlogisticated and inflammable airs, for he expected that a sort of acid would be produced by their union. In general, Mr. Lavoisier cannot be convicted of having advanced anything contrary to truth: but it can still less be denied that he concealed a part of the truth; for he should have acknowledged that I had, some days before, apprised him of Mr. Cavendish's experiments, instead of which the expression '*il nous apprit*' gives rise to the idea that I had not informed him earlier than that very day. In like manner Mr. Lavoisier has passed over a very remarkable circumstance, namely, that the experiment was made in consequence of what I had informed him of. He should likewise have stated in his publication not only that Mr. Cavendish had obtained '*une quantité d'eau très sensible*,' but that the water was equal to the weight of the two airs added together. Moreover, he should have added that I had made him acquainted with Messrs. Cavendish and Watt's conclusions, namely, that water, and not an acid, or any other substance, arose from the combustion of the inflammable and dephlogisticated airs. But those conclusions opened the way to Mr. Lavoisier's present theory, which perfectly agrees with that of Mr. Cavendish, only that Mr. Lavoisier accommodates it to his old theory, which banishes phlogiston. . . . The course of all this history will clearly convince you that Mr. Lavoisier (instead of being led to the discovery by following up the experiments which he and Mr. Bucquet had commenced in 1777) was induced to institute again such experiments, solely by the account he received from me, and of our English experiments; and that he really discovered nothing but what had before been pointed out to him to have been previously made out and demonstrated in England."

To this letter, reflecting so gravely on his honour and integrity, Lavoisier made no reply. Nor did Laplace, Le Roi, Vandermonde, or any one of the Academicians concerned vouchsafe any explanation. *De non apparentibus et de non existentibus eadem ratio*. No explanation appeared because none was possible. M. Berthelot ignores this letter, which is the more remarkable, since reference is made to it in more than one of the publications which he tells us he has consulted in the preparation of his account of the Water Controversy. If he knew of it he must regard it either as unworthy of an answer or as unanswerable.

It would be heaping Ossa on Pelion to adduce further evidence from letters of the time of what Lavoisier's contemporaries thought of his claims. *De mortuis nil nisi bonum*. I would much more willingly have dwelt upon the virtues of Lavoisier, and have let his faults lie gently on him; but I have felt it incumbent on me on this occasion to make some public answer to M. Berthelot's book, and in no place could that answer be more fittingly given than in this town, which saw the dawn of that work out of which these grand discoveries arose. It may be that much of what I have had to say is as a twice-told tale to many of you. I trust I need make no apology on that account. The honour of our ancestors is in our keeping, and we should be unworthy of our heritage and

* Mr. Muirhead's translation. Vide Watt, *Correspondence*, "Composition of Water," p. 71.

false to our trust if we were slow to resent or slack to repel any attempt to rob them of that glory which is their just right and our proud boast.

EXAMINATION OF OILS, FATS, AND ALLIED SUBSTANCES.

By THOMAS T. P. BRUCE WARREN.

In ascertaining the composition of a mixture of oils, I was guided, in my earlier experiments, by the condition of the products resulting from the treatment with sulphur chloride, and whilst it is quite possible to obtain a fair idea of what oils are present in a mixture, the products themselves give no definite information of the probable quantities; the Hubl reagent was worked on to supply this. The iodine absorption of the original oil or mixture is taken and also that of the soluble portion of the magma by sulphur chloride, the same quantities being used in each case. The iodine absorption is calculated, first, for the total weight equal to that of the original oil, and, secondly, for the corresponding weight obtained from a definite quantity of the original oil; this latter I shall refer to as the *corrected* iodine absorption of the soluble extract from the magma.

I prepare and use the Hubl reagent in the following way. 50 grms. pure re-sublimed iodine is dissolved in alcohol, sp. gr. 795 at 60° F., and made up to 500 c.c. 60 grms. mercuric chloride, in powder, dissolved in another portion of the same spirit, is filtered, and the spirit washings of the filter added to make up 500 c.c.; these solutions are kept separately in a cool, dark cupboard. When required equal parts of these solutions are mixed together just before being used, sufficient for the samples, &c., to be tested. The advantage of this is evident when only 30 or 40 c.c. Hubl is wanted, and, perhaps, in a hurry. The Hubl is standardised in the ordinary way with sodium thiosulphate, which is previously adjusted with pure and dry re-sublimed iodine.

The oil, &c., after digesting for the required time with the reagent and chloroform, is emptied into a stout glass and the flask rinsed out with 10 c.c. of a 10 per cent solution of KI and 40 c.c. water. It is again rinsed out with 100 c.c. water in two separate portions. During titration the whole is kept well stirred with an ebonite rod, so as to avoid scratching the glass. If mercuric iodide is precipitated on dilution, it is best to add KI in crystals rather than solution.

The sulphur chloride is prepared by distilling the commercial yellow chloride and collecting the portion coming over about 284° F.; the portion coming over under 284° may be digested with an excess of S, and distilling again when required. If the dark chloride only is available it should be digested with S for some time in a warm place before distilling. The prepared chloride may be kept for some time mixed with an equal volume of CS₂ in a stoppered bottle, the neck of which should be kept clean, so as to prevent the stopper getting fixed. The quantity required should be taken out with a fine pipette.

The bulk of chloride may be kept in a bottle well closed with a piece of paraffined merino or cotton, or an ordinary cork well soaked in paraffin may be used; however preserved it should be occasionally looked to and kept in a cool place.

The details of the process for using the chloride have already appeared in this journal.

If two oils be mixed together and we know the iodine absorption of each oil and of the mixture, a simple calculation will enable us to tell how much of each oil is present in the mixture.

A mixture of olive oil and sesame oil is found to have an iodine absorption = 96.4 per cent. Olive oil = 84.5 per cent, and sesame oil = 106 per cent. If we divide the iodine absorption of the mixture (96.4) into two parts, pro-

portional to the iodide absorption of olive oil (84.5) and sesame oil (106), we obtain the proportional quantities of iodine absorbed by each oil contained in the mixture:—

$$\frac{96.4}{84.5 + 106} \times 84.5 = 42.8 \text{ absorption due to olive oil}$$

$$,, \times 106 = 53.6 \text{ ,, ,, sesame oil}$$

In the same way, if we have obtained a fair clue of what a mixture contains, even if 3 or 4 oils are mixed together we can obtain an approximation for our first result; unfortunately the oils separately might be so altered in their original iodine absorption that our first approximation might yield a mixture quite unlike what we are trying to imitate, although the iodine absorption is exactly that of the sample.

A mixture of olive oil, lard oil, and linseed oil has an iodine absorption identical with olive oil = 84.5, lard oil = 52.5, and linseed oil = 170. The iodine absorption of such a mixture admits of a double rendering—we may either compound a mixture of linseed oil and lard oil which shall have an iodine absorption = olive oil, and which, of course, may be mixed in all proportions with olive oil without affecting the iodine absorption, or we may calculate for a mixture of the three oils

First Case.

$$\frac{84.5}{52.5 + 170} \times 52.5 = 19.95 = \text{iodine absorption due to lard oil}$$

$$,, \times 170 = 64.6 = \text{,, ,, linseed ,,}$$

Second Case.

$$\frac{84.5}{84.5 + 52.5 + 170} \times 84.5 = 23.24 \text{ iodine ,, olive ,,}$$

$$,, \times 52.5 = 14.44 \text{ ,, ,, lard ,,}$$

$$,, \times 170 = 46.75 \text{ ,, ,, linseed ,,}$$

In both cases the proportional absorptions for lard oil and linseed oil are the same as demanded by the original iodine absorption; for if we remove the olive oil, the remaining lard oil and linseed oil should have the same iodine absorption as olive oil.

The mixture is then made up as indicated by the second case, and examined side by side with the original mixture. Linseed oil and olive oil both yield insoluble products with sulphur chloride; the lard oil would be removed by CS₂, with more or less of the non-solidified products from the other oils, and which is subsequently examined by Hubl's reagent as given in this communication.

ON THE EFFECT OF TEMPERATURE UPON THE DETERMINATION OF AMMONIA BY NESSLERISATION.

By ALLEN HAZEN and HARRY W. CLARK.

IN making a number of distillations of standard ammonium chloride solution to determine the loss due to incomplete condensation, as stated by Dr. Smart,* results were obtained similar to those given by him, namely, that only from 85 to 95 per cent of the ammonia taken was found in the distillate. It was observed, however, that no more ammonia was obtained when the end of the condenser dipped below the surface of cold water, and also that by repeatedly re-distilling a distillate from standard ammonium chloride solution, no more was lost than by a single distillation. The loss could not therefore be due to incomplete condensation.

The cause of this apparent loss was found to be the low temperature of the distillates. The city water, at a

* "Report of the National Board of Health," 1882; also the *American Chemical Journal*, xi., 367.

temperature of 5°, running about the block tin condensers, cooled the distillate to nearly the same temperature, and the time that the tubes stood before Nesslerising was insufficient to warm them to the temperature of the room. It was found that the colour obtained by Nesslerising an ammonia solution depends upon its temperature. The warmer the solution the deeper will be the colour produced, so that a standard containing 4 c.c. of ammonia solution Nesslerised at 30° will give a colour equal to that obtained from 5 c.c. Nesslerised at 15°, or 6 c.c. Nesslerised at 0°. A change in temperature after Nesslerising will not change the colour very much.

To obtain accurate results it is necessary to bring standards and distillates to the same temperature before Nesslerising. This is easily accomplished by allowing them to stand in a room with even temperature for a sufficient time. It was found that the difference between the temperatures of two 50 c.c. Nessler tubes of water, standing side by side, was reduced to one-half every thirteen minutes. With racks of three dozen tubes each the adjustment was much slower, forty-five minutes being required to reduce a difference of 10° 5°. When the possible difference of temperature between different tubes at the start is 10° or more, three or four hours will be required to bring them to a sufficiently even temperature. We find it most convenient to let them stand over night. Standards and distillates are made ready for Nesslerisation during the day, and all stand on the same table over night. In the morning they are Nesslerised and compared. There is not the slightest loss by evaporation of ammonia in this way, even upon standing some days, and in a laboratory where ammonia fumes are excluded there is no danger of absorption of ammonia from the air.

Our earlier conclusion, that there is no loss of ammonia by incomplete condensation, has been confirmed by numerous determinations made in this way, with most satisfactory results. The condenser tubes used are of block tin, 20 inches long and $\frac{3}{8}$ inch internal diameter.—*American Chemical Journal*, xii., No. 6.

APPARATUS FOR THE DETERMINATION OF AMMONIAS IN SAND AND SEWAGE.

By ALLEN HAZEN.

In examining sand from filters it has been thought desirable to determine free and albumenoid ammonia, as this shows the amount of organic matter stored in the same terms as it is given for the filtered water or sewage.

To accomplish this the apparatus shown by the figure has been used during the last two years. A litre flask, A,

filled with ammonia-free water, serves simply to supply steam. A small glass tube carries the steam to the bottom of the small flask, B, which contains the sand. The steam passing through the sand very rapidly removes all free ammonia. Alkaline permanganate solution is then put in B and the distillation continued. The albumenoid ammonia is given off much more rapidly than in the ordinary water distillation, owing to the concentration of the permanganate which is put upon the sand full

strength, while in water-analysis it is diluted to eight of ten times its volume by the water. One portion of 50 c.c. invariably contains all the free ammonia. The first portion of albumenoid ammonia, when boiling rapidly, usually contains at least eight or nine tenths of the whole, and the second portion has almost all of the rest, so that only two tubes need be collected. Bumping is impossible. The condensation of steam in the small flask is not excessive, but if necessary it may be heated with a low flame.

I have found this apparatus to be well adapted to the examination of sewage and anything which contains enough ammonia. The great bulk of a pure water which it would be necessary to use prevents its application to ordinary water-analysis.

The amount of free ammonia thus obtained is the same as that found by the usual process of dilution with pure water and direct distillation. The albumenoid ammonia is commonly a little greater, owing to the concentration of the permanganate, but the results are sharper and different determinations agree with each other more closely. There is also a very considerable saving of time when a number of determinations are to be made.

I prefer to use rubber stoppers and connections. It requires considerable boiling to get new rubber entirely free from ammonia, but once free there is no more trouble, and a stopper will last for a very long time.—*American Chemical Journal*, xii., No. 6.

OBITUARY.

PROFESSOR THOMAS CARNELLEY.

ON the 27th ult. the chemical world sustained a severe and unexpected blow by the sudden death of Prof. Thomas Carnelley. He was only in his thirty-eighth year, and all who knew him naturally hoped that he might continue doing excellent work for at least a quarter of a century. The deceased was educated at University College, London. His first appointment was that of Demonstrator of Chemistry at the Owens College, Manchester. He then occupied successively the Chemical Chair at Firth College, Sheffield, and at the Universities of Dundee and Aberdeen.

His work included especially the further development of the periodic system of Newlands and Mendeleeff, to which he made most important contributions. Up to the time of his death he was engaged upon a great work on the chemical and physical constants, in which he was tracing out relations and uniformities not previously detected. Whether this, his *magnum opus*, is sufficiently advanced to be capable of publication we are unable to say. Prof. Carnelley likewise carried on some investigations on questions of sanitary chemistry. Thus he published an investigation of the sanitary condition of Board Schools, &c., in Scotland and England, with especial reference to the prevalence of microbia in their atmospheres. The last article from his pen which appeared in the *CHEMICAL NEWS* was an account of researches undertaken in concert with Mr. W. Frew on "The Antiseptic Powers of Isomeric Organic Compounds." Thomas Carnelley was a man whom the scientific world could ill spare.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

LEEDS, 1890.

INAUGURAL ADDRESS OF THE PRESIDENT,

SIR FREDERICK AUGUSTUS ABEL,
C.B., D.C.L. (Oxon.), D.Sc. (Cant.), F.R.S., P.P.C.S.
Hon. M.Inst.C.E.

Concluded from p. 118).

THE Crimean War taught Nations many lessons of gravest import, to some of which Sir Richard Owen took occasion to call attention most impressively in the address delivered here, before the miseries of that war had become past history. The development of sanitary science, to which he especially referred, and which sprang from the bitter experience of that sad epoch, has had its parallel in the development of the science of artillery; but it would indeed be difficult to establish any parallelism between the benefits which even the soldier and sailor have reaped from the great strides made by both these sciences. The acquisition of knowledge of the causes of the then hopelessness of gallant struggles which medical skill and self-sacrificing devotion made against the sufferings of the victims of battles and of fell diseases, as deadly as the cruellest implements of war; the application of that knowledge to the provision of the blessings of antiseptic treatment of wounds and to the intelligent utilisation of disinfectants and of other valuable preventive measures, to the supply of wholesome water, of wholesome food in campaigning, of sensible clothing, and of wholesome air in hospitals, barracks, and ships—these are some few of the benefits which the soldier and the sailor have derived from the development of sanitary science, which was so powerfully stimulated by the terrible lessons learned during the long-drawn-out siege of Sebastopol; and it is indeed pleasant to reflect that there has been, for years past, most wholesome competition between Nations in the enlargement of those benefits, and their dissemination among the men whose vocation it is to slay and be slain. The periodical International Congresses on Hygiene and Demography, of which we shall cordially welcome next year's assemblage in London, and whose members will deplore the absence from among them of the veteran Nestor in the science and practice of hygiene, Sir Edwin Chadwick, have afforded conclusive demonstration of the heartiness with which Nations are now co-operating with a view to utilise the invaluable results attained by the successful labourers in sanitary science.

What, on the other hand, shall we say of the benefits which sailors and soldiers, in the pursuit of their calling, derive from the ceaseless costly competition amongst Nations for supremacy in the possession of formidable artillery, violent explosives, quick-firing arms of deadly accuracy, and fearful engines which, unseen, can work wholesale destruction in a fleet? And what can we say of the benefits acquired by individual countries in return for their continuous, and sometimes ruinous, expenditure in endeavouring to maintain themselves upon an equality with their neighbours in man-killing power? The conditions under which engagements by sea or land will in the future be fought have certainly become greatly modified from those of thirty-five years ago, and the duration of warfare, even between Nations in conflict who are on a

fair equality of resources, must become reduced; but, as regards the results of a trial of strength between contending forces, similarly equipped, as they now will be, with the latest of modern appliances only varying in detail, these must, after all, depend, as of old, partly upon accident, favoured, perhaps, by a temporary superiority in equipment, partly upon the skill and military genius of individuals, and very much upon the characteristics of the men who fight the battles.

What really can be said in favour of the advances made in the appliances of war—and this is, perhaps, the view which in such a town as Leeds we should keep before our eyes to the exclusion of the dark side of the picture—is, that by continuous competition in the development of their magnitude, diversity, and perfection, the resources of the manufacturer, the chemist, the engineer, the electrician, are taxed to the uttermost, with the very important, although incidental, results, that industries are created or expanded and perfected, trades maintained and developed, and new achievements accomplished in applied science, which in time beneficially affect the advance of peaceful arts and manufactures. In these ways the expenditure of a large proportion of a country's resources upon material which is destroyed in creating destruction does substantially benefit communities, and tends to the accomplishment of such material progress by a country as goes far to compensate its people for the sacrifices which they are called upon to incur for the maintenance of their dignity among Nations.

From this point of view, at any rate, it may interest members of the British Association for the Advancement of Science, and for the promotion of its applications to the welfare and happiness of mankind, to hear something of recent advances in one of the several branches of science in its applications to naval and military requirements with which, during a long and arduous official career, now approaching its close, I have become in some measure identified.

Since the meeting of the Association in this town in 1858, the progress which has been made in the regulation of the explosive force of gunpowder, so as to adapt it to the safe development of very high energy in guns presenting great differences in regard to size and to the work which they have to perform, has been most important. The different forms of gunpowder which were applied to war purposes in this and other countries, until within the last few years, presented comparatively few differences in composition and methods of manufacture from each other and from the gunpowder of our ancestors. The replacement of smoothbore guns by rifled artillery, which followed the Crimean War, and the great increase in the size and power of guns, necessitated by the application of armour to ships and forts, soon called, however, for the pursuit of investigations having for their object the attainment of means for variously modifying the action of fired gunpowder, so as to render it suitable for artillery of different calibres whose power could not be effectively, or, in some instances, safely, developed by the use of the only kind of gunpowder then employed in English artillery of all calibres.

The means resorted to in the earlier of these investigations, and adhered to for many years, for controlling the violence of explosion of gunpowder, consisted exclusively in modifying the size and form of the individual masses composing a charge, and of their density and hardness, with the object of varying the rate of burning of those masses in a gun; it being considered that, as the proportions of ingredients generally employed very nearly correspond to those required for the development of the greatest chemical energy by the thoroughly-incorporated materials, the attainment of the desired results should be, if possible, effected rather by modifications of the physical and mechanical characters of gunpowder, than by variations of the proportions and chemical characters of its ingredients.

The varieties of powder from time to time introduced

into artillery-service, as the outcome of investigations in this direction, were of two distinct types: the first of these consisted of further developments of the old granulated or corned powder, being produced by breaking up more or less highly-pressed slabs of the material into grains, pebbles, or boulders of approximately uniform size and shape. Gunpowders of this class, ranging in size from about 1000 pieces to the ounce to about 6 pieces to the pound, have performed efficient service, and certain of them are still employed. The character of the other type is based upon the theoretical view that uniformity in the action of a particular gunpowder, when employed under like conditions, demands not merely identity in regard to composition, but also identity in form, size, density, and structure of the individual masses of which a charge consists. To approach the practical realisation of this view, equal quantities of one and the same mixture of ingredients, presented in the form of powder of uniform fineness and dryness, must be submitted to a particular pressure, for a fixed period, in moulds of uniform size, the surrounding conditions and subsequent manufacturing processes being as nearly as possible alike. Practical experience has shown that uniformity in the ballistic properties of black powder can be even more readily secured by the thorough blending or mixing together of different products of manufacture, presenting some variations in regard to size, density, hardness, or other features, than by aiming at an approach to identity in the characters of the individual grains or masses.

When our attention was first actively directed to the modification of the ballistic properties of powder, the subject had already been to some extent dealt with in the United States by Rodman and Doremus, and the latter had proposed the employment, in heavy guns, of charges consisting of large pellets of prismatic form. While this prismatic powder, which was first used in Russia, was being perfected, and extensively applied there as well as in Germany and England, the production of powder-masses more suitable, by the comparatively gradual nature of their explosion, for the very large charges required for the heavy artillery of the present day, was actively pursued in Italy, and by our own Government Committee on Explosives, the outcome of very exhaustive practical investigations being the very efficient Fossano powder, or *poudre progressif* of the Italians, and the boulder and large cylindrical powders produced at Waltham Abbey.

Researches carried out by Captain Noble and myself some years ago, with a series of gunpowders, presenting considerable differences in composition, indicated that decided advantages might be secured, for heavy guns especially, by the employment of such a powder as would furnish a comparatively very large volume of gas, its explosion being at the same time attended by the development of much less heat than in the case of ordinary black powder. In the course of these researches much light was thrown upon the causes of the wearing or erosive action of powder-explosions upon the inner surface of the gun, an action which, especially in the larger calibres of artillery, produces so serious a deterioration of the arm that the velocity of projection and accuracy of shooting suffer considerably, the wear being especially great where the products of explosion, while under the maximum pressure, can escape between the projectile and the bore. The great velocity with which the very highly heated gaseous and liquid (fused solid) products of explosion sweep over the heated surface of the metal, gives rise to a displacement of the particles composing the surface of the bore, which increases in extent as the latter becomes roughened, and thus opposes greater resistance; at the same time, the high temperature to which the surface is raised reduces the rigidity of the metal, and its consequent power of resisting the force of the gaseous torrent; and, lastly, some amount of chemical action upon the metal, by certain of the highly-heated non-gaseous products of explosion, contributes towards an increase in the erosive

effects. Experiments made upon a large scale by Captain Noble with powders of different composition, and with other explosives, have afforded decisive evidence that the explosive agent which furnishes the largest proportion of gaseous products, and the explosion of which is attended by the development of the smallest amount of heat, exerts least erosive action.

Some eminent German gunpowder manufacturers, who were at this time actively engaged upon the production of a suitable powder for heavy guns, directed their attention, not merely to an alteration of the proportions of the ingredients, but also to a modification in the character of charcoal employed; the eventual result was the production of a new prismatic powder, composed of saltpetre in somewhat higher proportion than in normal black powder, and of a very slightly-burned charcoal of reddish brown colour, quite similar to the *charbon roux* which Violette produced about forty years ago for use in sporting-powder, by the action of super-heated steam upon wood or other vegetable matter. This brown prismatic powder (or "cocoa powder") differs from black powder not merely in colour: it burns very slowly in the open air, and in guns its action is comparatively gradual and long-sustained. The products of its explosion are simple; as the powder contains saltpetre in large proportion relatively to the sulphur and charcoal, these become fully oxidised, and a relatively very large amount of water-vapour is produced, partly because of the comparatively high proportion of water in the finished powder, and partly from the large amount of hydrogen in the slightly-charred wood or straw used. The smoke from a charge of brown powder differs but little in volume from that of black powder, but it disperses much more rapidly, owing to the speedy absorption of the finely-divided potassium salts, forming the smoke, by the large proportion of water-vapour through which they are distributed.

This kind of powder has been substituted, with considerable advantage, for black powder in guns of comparatively large calibre, but it soon became desirable to attain even more gradual action in the case of the very large charges required for guns of the heaviest calibres, such as the 110-ton gun, from which shot of about 1800 lbs. weight are propelled by a powder-charge of 960 lbs. Brown powder has, therefore, been modified in composition to suit these conditions; while, on the other hand, a powder intermediate in rapidity of action between black powder and the brown prism powder has been found more suitable than the former for use in guns of moderately large calibre.

The importance which machine-guns and comparatively large quick-firing guns have assumed in the armament of ships has made it very desirable to provide a powder for them which will produce comparatively little or no smoke, as their efficient employment becomes greatly limited when, after a very few rounds rapidly fired with black powder, the objects, against which it is desired to direct the fire, are more or less completely hidden by the interposed smoke. Hence much attention has of late been directed to the production of smokeless, or nearly smokeless, powders for naval use. At the same time, the views of many military authorities regarding the importance of dispensing with smoke in engagements on land, have also created a demand for smokeless powders suitable for field-artillery and for small arms.

The properties of ammonium nitrate, of which the products of decomposition by heat are, in addition to water-vapour, entirely gaseous, have rendered it a tempting material to those who have striven to produce a smokeless powder; but its deliquescent character has been a formidable obstacle to its application as a component of a useful explosive agent. By incorporating charcoal and saltpetre in particular proportions with ammonium nitrate, F. Gaus recently claimed to have produced an explosive material free from the hygroscopic character common to other ammonium nitrate mixtures, and furnishing only permanently gaseous and volatile, or

smokeless, products of explosion. These anticipations were not realised, but they led the talented German powder-maker, Mr. Heidemann, to produce an ammonium nitrate powder possessing remarkable ballistic properties, and producing comparatively little smoke, which speedily disperses. It yields a very much larger volume of gas and water-vapour than either black or brown powder, and is considerably slower in action than the latter; the charge required to produce equal ballistic results is less, while the chamber-pressure developed is lower, and the pressures along the chase of the gun are higher, than with brown powder. No greater tendency is exhibited by it to absorb moisture from an ordinarily dry, or even somewhat moist, atmosphere, but it rapidly absorbs water when the hygroscopic condition of the air approaches saturation, and this greatly restricts its use.

About five years ago reports began to reach us from France of the attainment of remarkable results with a smokeless powder employed with the repeating or magazine rifle then in course of adoption for military service, and of marvellous velocities obtained by the use of this powder, in specially constructed artillery of great length. As in the case of the explosive agent called *Mélinite*, the fabulously destructive effects of which were much vaunted at about the same time, the secret of the nature of this smokeless powder was well preserved by the French authorities; it is now known, however, that more than one smokeless explosive has succeeded the original, and that the material at present in use with the Lebel repeating rifle belongs to a class of nitro-cellulose or nitro-cotton preparations, of which several have been made the subject of patents in England, and of which varieties are also being used in Germany and other countries.

A comparison between the chemical changes attending the burning or explosion of gunpowder, and of the class of nitro-compounds represented by gun-cotton, at once explains the cause of the production of smoke by the former, and of the smokelessness of the latter. Whilst the products of explosion of the nitro-compounds consist exclusively of gases and of water-vapour, gunpowder, being composed of a large proportion of saltpetre, or other metallic nitrate, mixed with charred vegetable matter and variable quantities of sulphur, furnishes products of which over 50 per cent are not gaseous, even at high temperatures, and which are in part deposited as a fused solid—which constitutes the fouling in a fire-arm—and in part distributed in an extremely fine state of division through the gases and vapours developed by the explosion, thus giving to these the appearance of smoke as they escape into the air.

So far as smokelessness is concerned, no material can surpass *gun-cotton* (or other varieties of nitro-cellulose); but, even if the rate of combustion of the fibrous explosive in a firearm could be controlled with certainty and uniformity, its application as a safe propulsive agent is attended by so many difficulties that the non-success of the numerous early attempts to apply it to that purpose is not surprising. Those attempts, commencing soon after the discovery of *gun-cotton*, in 1846, and continued many years later in Austria, consisted entirely in varying the density and mechanical condition of employment of the *gun-cotton* fibre. No difficulty was experienced in thus exercising complete control over the rapidity of burning in the open air; but when the material was strongly confined, as in the bore of a gun, such methods of regulating its explosive force were quite unreliable, as some slight unforeseen variation in its compactness or in the amount and disposition of the air-spaces in the mass, would develop very violent action. Much more promising results were subsequently obtained by me by reducing the fibre to a pulp as in the ordinary process of making paper, and converting this into highly-compressed homogeneous masses of the desired form and size. Some favourable results were obtained at Woolwich in 1867-8 in field-guns, with cartridges built up of compressed *gun-cotton* variously formed and arranged, with the object of

regulating the rapidity of explosion of the charge. But although comparatively small charges often gave high velocities of projection without any indications of injury to the gun, the uniform fulfilment of the conditions essential to safety proved to be beyond absolute control, even in guns of small calibre; and military authorities not being in those days alive to the advantages which might accrue from the employment of an entirely smokeless explosive in artillery, experiments in this direction were not persevered in. At the same time, considerable success attended the production of *gun-cotton* cartridges for sporting purposes, the rapidity of its explosion being controlled by various methods; very promising results were also attained with the Martini-Henry rifle and a lightly-compressed pulped *gun-cotton* charge, of pellet-form, the uniform action of which was secured by simple means.

A nearly smokeless sporting powder had, in the meantime, been produced by Colonel Schultze, of the Prussian Artillery, from finely-divided wood, converted after purification into a mildly explosive form of nitro-cellulose, and impregnated with a small portion of an oxidising agent. Subsequently this powder was produced in a granular form, and rendered considerably more uniform in character, and less hygroscopic; it then closely resembled the well-known E.C. sporting powder, which consists of a nitro-cotton reduced to pulp, incorporated with the nitrates of potassium and barium, and converted into grains through the agency of a solvent and a binding material. Both these powders produce very little smoke compared with black powder, but do not compete with the latter in regard to accuracy of shooting when used in military arms.

In past years both camphor and liquid solvents have been applied to the hardening of the surfaces of granulated or compressed masses of *gun-cotton* and of this class of its preparations, with a view to render them non-porous. In some smokeless powders of French, German, Belgian, and English manufacture, acetic ether and acetone have been also used, not merely to harden the granules or tablets of the explosive, but to convert the nitrocellulose, in the first instance, into a more or less gelatinous condition, so that it can readily be incorporated with other components and rolled, or spread into sheets, or pressed into moulds, or squirted into wires, rods, or tubes, while still in a plastic state. When the solvent has afterwards been removed, the hardened, horn-like, or somewhat plastic product is cut up into tablets, or into strips or pieces of suitable dimensions, for conversion into charges or cartridges.

Another class of smokeless powder, similar in physical characteristics to these nitrocellulose powders, but containing nitroglycerin as an important component, has been originated by Mr. Alfred Nobel, the well-known inventor of dynamite, and bears resemblance in its physical characteristics to another of his inventions, called blasting-gelatin, one of the most interesting of known violent explosive agents. When one of the lower products of nitration of cellulose is impregnated with the liquid explosive, nitroglycerin, it gradually loses its fibrous nature, becoming gelatinised while assimilating the liquid; and the resulting product almost possesses the characters of a compound. This preparation, and certain modifications of it, have acquired high importance as blasting agents more powerful than dynamite, and possessed of the valuable property that their prolonged immersion in water does not separate from them any appreciable proportion of nitroglycerin. The nitroglycerin powder first produced by Mr. Nobel was almost perfectly smokeless and developed very high energy, accompanied by moderate pressures at the seat of the charge, but it possessed certain practical defects, which led to the development of several modifications of that explosive and various improvements in manufacture. The relative merits of this class of smokeless powder, and of various kinds of nitro-cellulose powder, are now under careful investigation in

this and other countries, and several more or less formidable difficulties have been met with in their application, in small-arms especially; these arise in part from the comparatively great heat they develop, which increases the erosive effects of the products of explosion, and in part from the more or less complete absence of solid products. The surfaces of the barrel and of the projectile being left clean, after the firing, are in a condition favourable to their close adhesion while the bullet is propelled along the bore, with the consequent establishment of very greatly increased friction. The latter difficulty has been surmounted by more than one expedient, but always at the cost of absolute smokelessness.

Our knowledge of the results obtained in France and Germany with the use of smokeless powders in the new rifles and in artillery is somewhat limited; our own experiments have demonstrated that satisfactory results are attainable with more than one variety of them, not only in the new repeating-arm of our infantry, but also with our machine-guns, with field-artillery, and with the quick-firing guns of larger calibre which constitute an important feature in the armament of our Navy. The importance of ensuring that the powder shall not be liable to undergo chemical change detrimental to its efficiency or safety, when stored in different localities where it may be subject to considerable variations of temperature (a condition especially essential in connection with our own Naval and Military service in all parts of the world), necessitates qualities not very easily secured in an explosive agent consisting mainly of the comparatively sensitive nitro-compounds to which the chemist is limited in the production of a smokeless powder. It is possible, therefore, that the extent of use of such a material in our ships, or in our tropical possessions, may have to be limited by the practicability of fulfilling certain special conditions essential to its storage without danger or possible deterioration. If, however, great advantages are likely to attend the employment of a smokeless explosive, at any rate for certain Services, it will be well worth while to adopt such special arrangements as may be required for securing these without incurring special dangers; this may prove to be especially necessary in our ships of war, where temperatures so high as to be prejudicial even to ordinary black powder, sometimes prevail in the magazines, consequent mainly upon the positions assigned to them in the ships, but which may be guarded against by measures not difficult of application.

The Press accounts of the wonderful performances of the first smokeless powder adopted by the French—which, it should be added, were in some respects confirmed by official reports of officers who had witnessed experiments at a considerable distance—engendered a belief that a very great revolution in the conduct of campaigns must result from the introduction of such powders. It was even reported very positively that noiselessness was one of the important attributes of a smokeless powder, and highly-coloured comparisons have, in consequence, been drawn in Service-periodicals, and even by some military authorities, between the battles of the past and those of the future: the terrific din caused by the firing of the many guns and the roar of infantry-fire, in heavy engagements, being supposed to be reduced to noise so slight that distant troops would fail to know in what direction their comrades were engaged, and that sentries and outposts would no longer be able to warn their comrades of the approaching foe by the discharge of their rifles. Military journals of renown, misled by such legendary accounts, chiefly emanating from France, referred to the absence of noise and smoke in battles as greatly enhancing the demands for skill and courage, and as surrounding a fight with mystery. The absence of recoil when a rifle was fired with smokeless powder was another of the marvels reported to attend the use of these new agents of warfare. It need scarcely be said that a closer acquaintance with them has dispelled the credit given to such of the accounts of their supposed qualities.

as were mythical, and a belief in which could only be ascribable to a phenomenal combination of credulity with ignorance of the most elementary scientific knowledge.

The extensive use which has been made in Germany of smokeless or nearly smokeless powder in one or two special military displays has, however, afforded interesting indications of the actual change which is likely to be wrought in the conditions under which engagements on land will be fought in the future, provided these new explosives thoroughly establish and maintain their position as safe and reliable propelling agents. Although the powder adopted in Germany is not actually smokeless, the almost transparent film of smoke produced by independent rifle-firing is not visible at a distance of about 300 yards; at shorter distances it presents the appearance of a puff of a cigar. The most rapid salvo-firing by a large number of men does not have the effect of obscuring them from distant observers. When machine guns and field artillery are fired with the almost absolutely smokeless powder which we are employing, their position is not readily revealed to distant observers by the momentary vivid flash of flame and slight cloud of dust produced.

There now appears little doubt that in future warfare belligerents on both sides will alike be users of these new powders; the screening or obscuring effect of smoke will therefore be practically absent during engagements between contending forces, and while, on the one hand, the very important protection of smoke, and its sometimes equally important assistance in manoeuvres, will thus be abolished, both combatants will, on the other hand, secure the advantages of accuracy of shooting and of the use of individual fire, through the medium of cover, with comparative immunity from detection. Such results as these cannot fail to affect, more or less radically, the principles and conditions under which battles have hitherto been fought. With respect to the Naval Service, it is especially for the quick firing guns, so important for defensive purposes, that a smokeless powder has been anxiously looked for; by the adoption of such a powder as has during the past year been elaborated for our artillery, should experience establish its reliability under all Service conditions and its power to fulfil all reasonable requirements in regard to stability, these guns will not only be used by our ships under conditions most favourable to their efficiency, but their power will also be very importantly increased.

The ready and safe attainment of very high velocities of projection through the agency of these new varieties of explosive agents, employed in guns of suitable construction, would appear at first sight to promise a very important advance in the power of artillery; the practical difficulties attending the utilisation of these results are, however, sufficiently formidable to place, at any rate at present, comparatively narrow limits upon our powers of availing ourselves of the advantages in ballistics which they may present. The strength of the gun-carriages and the character of the arrangements used for absorbing the force of recoil of the gun, need considerable modifications, not easy of application in some instances; greater strength and perfection of manufacture are imperative in the case of the hollow projectiles or shells to be used with charges of a propelling agent, by the firing of which in the gun they may be submitted to comparatively very severe concussions; the increased friction to which portions of the explosive contents of the shell are exposed by the more violent setting back of the mass may increase the possibility of their accidental ignition before the shell has been projected from the gun; the increase of concussion to which the fuse in the shell is exposed may give rise to a similar risk consequent upon an increased liability to a failure of the mechanical devices which are applied to prevent the igniting arrangement, designed to come into operation only upon the impact or graze of the projected shells, from being set into action prematurely by the shock of the discharge; lastly, the circumstance, that the rate of burning of the time-fuze which determines

the efficiency of a projected shrapnel shell is materially altered by an increase in the velocity of flight of the shell, also presents a source of difficulty.

The fallibility of even the most simple forms of fuze, manufactured in very large numbers, although it may be remote, must always engender a feeling of insecurity, when shells are employed containing an explosive agent of the class which, in recent years, it has been sought, by every resource of ingenuity, combined with intimate knowledge of the properties of these explosives, to apply as substitutes for gunpowder in shells, on account of their comparatively great destructive power.

One of the first uses, for purposes of warfare, to which it was attempted to apply gun-cotton, was as a charge for shells. But even when this was highly-compressed, and accurately fitted the shell chamber, with the intervention only of a soft packing between the surfaces of explosive and of metal, to guard against friction between the two upon the shock of the discharge, no security was attainable against the ignition of the comparatively sensitive explosive by friction established within its mass at the moment when the shell is first set in motion. By the premature explosion of a shell charged with gunpowder, no important injury is inflicted upon the gun, but a similar accidental ignition of a gun-cotton charge must almost inevitably burst the arm. The earlier attempts to apply gun-cotton as a bursting-charge for shells were several times attended by very disastrous accidents of this kind; but the fact, afterwards discovered, that wet compressed gun-cotton, even when containing sufficient water to render it quite unflammable, can be detonated through the agency of a sufficiently powerful charge of fulminate of mercury, or of a small quantity of dry gun-cotton, imbedded within it, has led to the perfectly safe application of gun-cotton in shells, provided the fuze, through the agency of which the initiative detonating agent in the shell comes into operation, is secure against any liability to premature ignition when the gun is fired. Many successful experiments have been made with shells thus charged with wet gun-cotton, which is now recognised as a formidable destructive agent applicable in shells with much less risk of casualty than attends the use of many other of the violent explosive bodies which it has become fashionable, in professional parlance, to designate as "high explosives."

Many devices and arrangements, more or less ingenious and complicated, have been schemed, especially in the United States, for applying preparations of the very sensitive liquid, nitro-glycerin, such as dynamite and blasting-gelatin, as charges for shells. Some of these consist in subdividing the charge by more or less elaborate methods; in others the shell is also lined with some soft elastic packing material, and paddings of similar material are applied in the head and the base of the shell-chamber, with the object of reducing the friction and concussion to which the explosive is exposed when the projectile is first set in motion. Such arrangements obviously reduce the space available for the charge in the shell, and the best of them fail to render these explosives as safe to employ as wet gun-cotton. In order to avoid exposing shells loaded with such explosives to the concussion produced when propelling them by a powder-charge, compressed air has been applied as the propelling agent, and guns of special construction and very large dimensions, from which shells containing as much as 500 lbs. of gun-cotton or dynamite are projected through the agency of compressed air, have recently been elaborated in the United States, where great expectations are entertained of the value, for war purposes, of these so-called pneumatic guns.

A highly ingenious device for utilising a class of very powerful explosives in shells, without any risk of accident to the gun, was not long since brought forward by Mr. Grusen, the well-known armour-plate and projectile manufacturer of Magdeburg. It consisted of a thoroughly efficient arrangement for applying the fact, first demon-

strated by Dr. Sprengel, that mixtures of nitric acid of high specific gravity with solid or liquid hydrocarbons, or with the nitro-compounds of these, are susceptible of detonation, with development of very high energy. The two agents, of themselves non-explosive—nitric acid and the hydro-carbon, or its nitro product—are separately confined in the shell; when it is first set in motion by the firing of the gun, the fracture of the receptacle containing the liquid nitric acid is determined by a very simple device; the two substances are then free to come into contact, and their very rapid mixture is promoted by the rotation of the shell, so that almost by the time that it is projected from the gun, its contents, at first quite harmless, have become converted into a powerfully explosive mixture, ready to come into operation through the action of the fuze. Although safety appears assured by this system, the comparatively complicated nature of the contrivance, and the loss of space in the shell thereby entailed, place it at a disadvantage, especially since some other very violent explosive agents have come to be applied with comparative safety in shells.

Between four and five years ago intelligence first reached us of marvellously destructive effects produced by shells charged with an explosive agent which the French Government was elaborating. The reported results surpassed any previously recorded in regard to violently destructive effects and great velocity of projection of the fragments of exploded shells, and it was asserted that the employment of this new material, Mélinite, was unattended by the usual dangers incident to this particular application of violent explosive agents, an assertion scarcely consistent with accounts which soon reached us of several terrible calamities due to the accidental explosion of shells loaded with Mélinite.

Although the secret of the precise nature of Mélinite has been extremely well preserved, it transpired ere long that extensive purchases were made in England, by or for the French authorities, of one of the many coal-tar derivatives which for some years past has been extensively manufactured for tinctorial purposes, but which, although not itself classed among explosive bodies until quite lately, had long before been known to furnish, with some metals, more or less highly explosive combinations, some of which have been applied to the production of preparations suggested as substitutes for gunpowder.

The product of destructive distillation of coal from which, by oxidation, this material is now manufactured, is the important and universally-known antiseptic and disinfectant, carbolic acid, or phenol. Originally designated carbazotic acid, the substance now known as picric acid was first obtained in small quantities as a chemical curiosity by the oxidation of silk, aloes, &c., and of the well-known blue dye indigo, which thus yielded another dye of a brilliant yellow colour. To the many who may regard this interesting phenol-derivative as a material concerning the stability and other properties of which we have little knowledge, it will be interesting to learn that it has been known to chemists for more than a century. It was first manufactured in England for tinctorial purposes by the oxidation of a yellow resin (*Xanthorrhoea hastilis*), known as Botany Bay gum. Its production from carbolic acid was developed in Manchester in 1862, and its application as a dye gradually extended, until, in 1886, nearly 100 tons were produced in England and Wales.

Although picric acid compounds were long since experimented with as explosive agents, it was not until a very serious accident occurred, in 1887, at some works near Manchester where the dye had been for some time manufactured, that public attention was directed in England to the powerfully explosive nature of this substance itself. The French authorities appear, however, to have been at that time already engaged upon its application as an explosive for shells. It is now produced in very large quantities at several works in Great Britain, and it has been exten-

ively exported during the last four years, evidently for other than the usual commercial purposes. Large supplies of phenol, or carboic acid, have, at the same time, been purchased in England for France, and lately for Germany, doubtless for the manufacture of picric acid, very extensive works having been established for its production in both those countries. It has been made the subject of experiment by our military authorities, and its position has been well established as a thoroughly stable explosive agent, easily manufactured, comparatively safe to deal with, and very destructive when the conditions essential for its detonation are fulfilled.

The precise nature of Mélinite appears to be still only known to the French authorities: it is asserted to be a mixture of picric acid with some material imparting to it greater power; but accounts of accidents which have occurred even quite recently in the handling of shells charged with that material appear to show that, in point of safety or stability, it is decidedly inferior to simple picric acid. Reliable as the latter is, in this respect, its employment is, however, not unattended with the difficulties and risks which have to be encountered in the use, in shells, of other especially violent explosives. Future experience in actual warfare can alone determine decisively the relative value of violent explosive agents, like picric acid or wet gun-cotton, and of the comparatively slow explosive, gunpowder, for use in shells; it is certain, however, that the latter still presents distinct advantages in some directions, and that there is no present prospect of its being more than partially superseded as an explosive for shells.

With regard to submarine mines and locomotive torpedoes, such as those marvels of ingenuity and constructive skill, the Whitehead and Brennan torpedoes, the important progress recently made in the practical development of explosive agents has not resulted in the provision of a material which equals wet compressed gun-cotton in combining with great destructive power the all-important essential of safety to those who have to deal with these formidable weapons and to man the small vessels which have to perform the very hazardous service of attacking ships of war at short distances by means of locomotive torpedoes.

Although the subject of the development of explosive force for purposes of war has of late received from workers in applied science, from seekers of patentable inventions, and even from the public generally, a somewhat predominating share of attention, considering that we congratulate ourselves upon the enjoyment of a period of profound peace, yet the production of new explosive agents for mining and quarrying purposes, which present or lay claim to points of superiority over the well-established blasting agents, has been by no means at a standstill. For many years the main object sought to be achieved in this direction was to surpass, in power or adaptability to particular classes of work, the well-known preparations of nitroglycerin and gun-cotton, which, during the past twenty years, have been formidable competitors and, in many directions, absolutely successful rivals of black powder. It is both interesting and satisfactory to note, however, that this object has of late, and especially since the publication of the results of labours of English and foreign Commissions on the causes of mine accidents, been prominently associated with endeavours to solve the important problems of combining, in an explosive agent, efficiency in point of power with comparative non-sensitiveness to explosion by friction or percussion, and of securing its effective operation with little or no accompaniment of projected flame. Safety-dynamites, flameless explosives, water-cartridges, and other classes of materials and devices connected with the getting of coal, the quarrying of rock, or the blasting of minerals, have claimed the attention of those who guide the miner's work; in some of these directions the practical results obtained have been beyond question important,

and, indeed, conclusive as regards the great diminution of risks to which men need be exposed in those coal mines where the ordinary use of explosives, although not altogether inadmissible, may at times be attended with danger. It is to be feared that those results are still far from receiving the amount of application which might reasonably be hoped for; but, at any rate, there are, among the extensive mining districts where the employment of explosives in connection with the getting of coal cannot be dispensed with, several of importance where the use of gunpowder has almost entirely given place to the adoption of blasting-agents or methods of blasting, the employment of which is either not, or only very exceptionally, attended by the projection of flame or incandescent matter into the air where the shot is fired.

The mining public is especially indebted to German workers for much of the success which has been obtained in this direction, and also to the eminent French authorities, Mallard and Le Chatelier, for their thorough theoretical and practical investigations bearing upon the prevention of accidental ignition of fire-damp during blasting operations. Having arrived at the conclusion that fire-damp and air-mixtures are not ignited by the firing of explosive preparations which develop by their detonation temperatures lower than 2220° C., they found that ammonium nitrate, although in itself susceptible of detonation, does not develop a higher temperature than 1130° C., while the temperature of detonation of nitroglycerin and gun-cotton are, respectively, 3170° and 2636°. The admixture of that salt with nitroglycerin or gun-cotton in sufficient proportion to reduce the temperature of detonation to within safe limits allows, therefore, of the employment of those explosive agents in the presence of fire-damp mixtures without risk of accident, and this fact has led to the effective use of such mixtures as safe blasting agents in coal.

Those who have been content to labour long and arduously with the objects steadily in view of advancing our knowledge of the causes of mine accidents and of developing resources and measures for removing or combating those causes, can cherish the conviction that recent improved legislation in connection with coal mines, based upon the results of those labours, has been already productive of decided benefits to the miner, even although it has fallen short of what might reasonably have been hoped for as an outcome of the very definite results and conclusions arrived at by the late Royal Commission on Accidents in Mines (in the recent much-lamented death of whose universally respected chairman, my late esteemed friend and colleague, Sir Warrington Smyth, the scientific world has sustained the loss of an ardent worker, and the miner of an invaluable friend).

The fearful dangers arising from the accumulation of inflammable dust in coal mines, and the equality of mine dust with fire-damp in its direful power of propagating explosions, which may sometimes even be, in the first instance, established chiefly or entirely through its agency, have now been long recognised as beyond dispute; and it is satisfactory to know that permission to fire shots in mine workings which are dry and dusty has, by recent legislation, been made conditional upon the previous laying of the dust by effective watering. In some mining districts, moreover, the purely voluntary practice has been extensively adopted by mine-owners of periodically watering the main roads in dry and dusty mines, or of frequently discharging water-spray into the air in such roads, which must tend greatly to reduce the possible magnitude of the disastrous results of a fire-damp or dust-explosion in any part of the mine workings.

The encouragement given to the application of the combined resources of ingenuity, mechanical skill, and knowledge of scientific principles, through the elaborate, but thoroughly practical comparative trials to which almost every variety of safety lamp has, during the last few years, been submitted by competent and conscientious experimenters, has resulted in the provision of lamps to

the hand of the miner which combine the essential qualities of safety, under the most exceptionally severe conditions, with good illuminating power, simplicity of construction, lightness, and moderate cost. Very important progress has also been made, since the first appointment of the late Accidents in Mines Commission, towards the provision of thoroughly serviceable and safe portable electric lamps for use in mines. Of those which have already been in the hands of the miners, several have fairly fulfilled his requirements as regards size, weight, and illuminating power of sufficient duration; but much still remains to be accomplished with respect to durability, simplicity, thorough portability, and cost, before the self-contained electric lamp can be expected to compete successfully with the greatly improved miners' lamps which are now in use, or available.

The recent legislation in connection with mines is certainly deficient in any sufficiently decisive measure for excluding from mine workings certain forms of lamps which, while fairly safe in the old days of sluggish ventilation, are unsafe in the rapid air-currents now frequently met with in mines; it is, however, very satisfactory to know that the strong representations on this subject, made by the late Commission, combined with force of example and with the conclusive demonstration of the superiority of other lamps, by exhaustive experiments, have led within the last two years to the very general abandonment of the unprotected Davy, Clanny, and Stephenson lamps in favour, either of simple, safe, modifications of these, or of other safe and efficient lamps, and that one possible element of danger to the miner has thus been eliminated, at any rate in many districts. In one important respect recent improved legislation has failed to effect a most desirable change—namely, in the substitution of safety lamps for naked lights in workings where small local accumulations of fire-damp are discovered from time to time. There appears little doubt that one of the three fearful explosions which have occurred within the last twelve months—the explosion at Llanerch Colliery, near Pontypool—was caused by the continued employment of naked lights in a mine where inspection constantly revealed the presence of fire-damp. This explosion, and two other terrible disasters, at Mossfield Colliery, in Staffordshire, and at Morfa Colliery, near Swansea, which have occurred since the last meeting of the Association, may have seemed to weaken the belief that the operation of the recent Mines Regulation Act, which was based upon some of the results of seven years' arduous labour of the late Mines' Commission, must have resulted in very substantial improvement in the management of mines and in the conduct of work by the men. Happily, however, there is a consensus of opinion among those most competent to judge—i.e., the Government Mine Inspectors—that very decided benefits have already accrued from the operation of the new Act. Although far from embodying all that the experienced mine owners, miners, and scientific workers upon that Commission, as well as practical authorities in Parliament, concurred in regarding as reasonably adaptable, from the results of observation and experiment, to the furtherance of the safer working of mines, this Act does include measures, precautionary and preventive, of undeniable utility, well calculated to lessen the dangers which surround the miner, and to add to his personal comfort underground. We may hope, moreover, that the operation of the Act is paving the way to more comprehensive legislation in the near future; for it can scarcely be doubted by the light of recent sad experience, that there are indications in which both masters and men still hesitate to adopt, of their own free will, measures or regulations, methods of working or appliances and precautions, which are calculated to be important additional safeguards against mine accidents, and which are either left untouched, or only hesitatingly and imperfectly dealt with in the recent enactments.

My labours upon the late Mines' Commission represent

only one of several subjects in connection with which it has been my good fortune to have opportunities of rendering some slight public service in directions contrasting with one of the main functions of my career, by endeavouring to apply the results of scientific research to a diminution of the risks to which particular classes of the community, or the public at large, are exposed—of being sufferers by explosions, the results of accidents or other causes.

During the pursuit of bread-winning vocations, and even in ordinary domestic life, the conditions, as well as the materials, requisite for determining more or less disastrous explosions are often ready to hand, and their activity may be evoked at any moment through individual heedlessness or through pure accident. Steam, or gases confined under pressure, volatile inflammable liquids, combustible gases, or finely-divided inflammable solids, are now all well recognised as capable of assuming the character of formidable explosive agents; but with respect to the three last named, it is only of late that material progress has been made towards a popular comprehension and appreciation of the conditions conducive to danger, and of those by the fulfilment of which danger may be avoided. Thus, the causes of explosions in coal-laden ships, together with the occurrence of spontaneous ignition in coal cargoes, another fruitful source of disaster, were made the subject of careful inquiry some years ago by a Royal Commission, upon which I had the pleasure of working with the late Dr. Percy, whose invaluable labours for the advancement of metallurgic science will always be gratefully remembered. The light thrown by that inquiry upon the causes of those disasters, and upon the conditions to be fulfilled for guarding against the accumulations of fire-damp, gradually escaping from occlusion in coal, and of heat, developed by chemical changes occurring in coal cargoes, has unquestionably led to an important reduction of the risks to which coal-laden ships are exposed. Subsequent official inquiries and experimental investigations, in which I took part with the late Sir Warrington Smyth and other eminent naval officers, consequent upon the loss of H.M.S. *Doterel* through the accidental ignition of an explosive mixture of petroleum spirit-vapour and air (and other calamities in warships originating with the gradual emission of fire-damp from coal), have resulted in the adoption of efficient arrangements for ventilating all spaces occupied by, and contiguous to, the large supplies of fuel which these vessels have to carry.

The thorough investigation, by Rankine and others, of the causes of explosions in flour mills, which in years past were so frequent and disastrous, has secured the adoption of efficient measures for diminishing the production, and the dissemination through channels and other spaces in the mills, of explosive mixtures of flour-dust and air, and for guarding against their accidental ignition. The numerous terrible accidents caused by the formation and accidental ignition of explosive mixtures of inflammable vapour and air in ships carrying cargoes of petroleum stored in barrels or in tanks, have, by the investigations to which they have given rise, led to the indication of effective precautionary measures for guarding against their recurrence. Again, the many distressing accidents, frequently fatal, which have attended the domestic use of those valuable illuminants, petroleum and mineral oils of kindred character, have been made the subject of exhaustive investigations, which have demonstrated that these disasters may readily be prevented by the employment of lamps of proper construction, and by the observance of very simple precautions by the users of them; and a recent official inquiry which I have conducted with Mr. Boverton Redwood has furnished most gratifying proof that very substantial progress has been made within the last few years by lamp manufacturers in the voluntary adoption of such principles of construction as we had experimentally demonstrated to be essential for securing the safe use of mineral oils in lamps for lighting and heating purposes, the employment of which has,

within a brief period, received enormous extension in this and other countries.

The creation and rapid development of the petroleum industry has, indeed, furnished one of the most remarkable illustrations which can be cited of industrial progress during the period which has elapsed since the British Association last met in Leeds. One year after that meeting—viz., on August 28, 1859, the first well, drilled in the United States with the object of obtaining petroleum, was successfully completed, and the rate of increase in production in the Pennsylvania oil-fields during the succeeding years is shown by the following figures:—

In 1859, 5000 barrels (of forty-two American gallons) were produced. In the following year the production increased to 500,000 barrels; while in the next year (1861) it exceeded 2,000,000 barrels, at which figure it remained, with slight fluctuations, until 1865. The supply then continued to increase gradually, until, in 1870, it reached nearly 6,000,000 barrels; while in 1874 it amounted to nearly 11,000,000 barrels. In 1880 it amounted to over 26,000,000 barrels, and in 1882 it reached 31,000,000. Since then the supply furnished by the United States has fallen somewhat, and last year it amounted to 21,500,000 barrels. The production of crude petroleum in the Pennsylvania fields, large as it has been, has not, however, kept pace with the consumption, for we find that the accumulated stocks, which on December 31, 1888, amounted to over 18,000,000 barrels, had become reduced to about 11,000,000 barrels at the close of last year. At this rate the surplus stock above ground will have vanished by the end of the current year. In addition to the petroleum raised in Pennsylvania, there is now a very large production in the State of Ohio; but this has not as yet been employed as a source of lamp-oil; it is, however, transported by pipe line in great quantities to Chicago, for use as liquid fuel in industrial operations.

A few years after the development of the United States petroleum industry, the production of crude petroleum in Russia also began to extend very rapidly. For more than 2500 years Baku, on the borders of the Caspian Sea, has been celebrated for its naphtha springs and for the perpetual flames of the Fire Worshippers, fed by the marvellous subterranean supplies of natural gas. To a limited extent neighbouring nations appear to have availed themselves of the vast supplies of mineral oil at Baku during the past one thousand years. By the thirteenth century the export of the crude oil had already become somewhat extensive, but the production of petroleum from it by distillation is of comparatively recent date. In 1863 the supplies of petroleum from the Baku district amounted to 5018 tons; they increased to somewhat more than double during the succeeding five years. In 1869 and following three years the production reached about 27,000 tons annually, and in 1873 it was about 64,000 tons; three years later, 153,000 tons were produced, and in the following five years there was a steady annual increase, until, in 1882, the production amounted to 677,269 tons; in 1884 it considerably exceeded 1,000,000 tons, and last year it had reached the figure of about 3,300,000 tons. The consumption of crude petroleum as fuel for locomotive purposes has, moreover, now assumed very large proportions in Russia, and many millions of gallons are annually consumed in working the vast system of railways on both sides of the Caspian Sea.

The imported refined petroleum used in this country in lamps for lighting, heating, and cooking, was exclusively American until within the last few years, but a very large proportion of present supplies comes from Russia. The imports of kerosene into London and the chief ports of the United Kingdom during 1889 amounted to 1,116,205 barrels of United States oil, and 771,227 barrels of Russian oil. During the same period the out-turn of mineral oil for use in lamps by the Scottish Shale Oil Companies probably amounted to about 500,000 barrels.

Another important feature connected with the development of the petroleum industry is the great extent to

which the less volatile products of its distillation have replaced vegetable and animal oils and fats for lubricating purposes in this and other countries. The value of petroleum as a liquid fuel and as a source of gas for illuminating purposes has, moreover, been long since recognised, as it is probable that one outcome of the attention which is now being given to the hitherto unworked deposits of petroleum in the East and West Indies, South America, and elsewhere, will be a very large increase in its application to these purposes. In the East Indies there are vast tracts of oil-fields in Burmah, Baluchistan, Assam, and the Punjab. The native Rangoon oil industry is one of great antiquity, although the oil was only used in the crude condition until about thirty-five years ago, at which time Dr. Hugo Müller, with the late Warren De la Rue, whose many sided labours and generous benefactions have so importantly contributed to the advancement of science, made valuable researches on the products furnished by crude oil imported from Rangoon. The resources of the oil-fields of Upper Burmah, especially of the district of Yenangyoung (or *crack of stinking water*), have since then been developed by British enterprise, and have attained to considerable importance since our annexation of Upper Burmah.

The great extension of the petroleum trade is gradually leading to very important improvements in the system of transport of the material over water and on land. Until recently this has been carried out entirely in barrels and tin cases; the consequent great loss from leakage and evaporation, accompanied by risk of accident, is now becoming much reduced by the rapidly increasing employment of tank steamers, which transport the oil in bulk. Tank railway wagons have for some time past been in use in Russia, and there is prospect of these and of tank barges being adopted here for the distribution of the oil; while in London, the practice is already spreading gradually of distributing supplies to tradesmen from tank road wagons. Some considerable doubt as to whether the risk of accident has not rather been altered in character than actually reduced by the new system of transport, has not unnaturally been engendered in the public mind by the occurrence within a comparatively short period of several serious disasters during the discharge of cargoes from tank vessels. The memorable explosion which took place in October, 1888, on board the *Ville de Calais*, in Calais Harbour, with widespread, destructive effects, was followed by a similarly serious explosion in the *Ferguson*, at Rouen, last December, and, more recently, by a fire of somewhat destructive character at Sunderland, resulting from the discharge into the river of petroleum residues from a ship's tanks. In all these cases the petroleum was of a nature to allow inflammable vapour to escape readily from the liquid, so that an explosive mixture could be rapidly formed by its copious diffusion through the air. No similar casualty has been brought to notice as having happened to tank ships carrying petroleum oil of which the volatility is in accordance with our legal requirements, and this points to the prudence of restricting the application of the tank system to the transport and distribution of such petroleum as complies with well-established conditions of safety.

Another most remarkable feature connected with the development of the petroleum industry is presented by the utilisation within the last few years of the vast supplies of natural inflammable gas furnished by the oil-fields.

In America this remarkable gas supply was for a long time only used locally, but before the close of 1885 its conveyance to a distance by pipes, for illuminating and heating purposes, had assumed large proportions, one of the companies in Pittsburgh having alone laid 335 miles of pipes of various sizes, through which gas was supplied equivalent in heating value to 3,650,000 tons of coal per annum. Since then the consumption in and around Pittsburgh has probably been at least tripled. At the close of 1886 six different companies were conveying

natural gas by pipes to Pittsburgh from 107 wells; 500 miles of pipe ranging in diameter from 30 inches to 3 inches, were used by these companies, 232 miles of which were laid within Pittsburgh itself. The Philadelphia Company, the most important of these associations, then owned the gas supply from 54,000 acres of land situated on all the anti-clinals around Pittsburgh, but drew its supplies only from Tarentum and the Murraryville field. It supplied, in 1886, 470 factories and about 5000 dwellings within the city, besides many factories and dwellings in Alleghany, and in numerous neighbouring villages. The average gas pressure at the wells, when the escape is shut off, is about 500 lbs. per square inch, and in the case of new wells this pressure is very greatly exceeded. In order to minimise the danger from leakage, the gas-pressure in the city is reduced to a maximum of 13 lbs., and is regulated by valves at a number of stations under the control of a central station. The usual pressure in the larger lines is from 6 to 8 lbs., while in the low pressure lines it does not exceed 4 to 5 ounces.

The effect of the change from coal gas to natural gas upon the atmosphere over Pittsburgh has been most marked: formerly the sky was constantly obscured by a canopy of dense smoke; now the atmosphere is clear, and even white paint may with impunity be employed for the house fronts.

The very rapid development of the employment of natural gas is not confined to the neighbourhood of Pittsburgh; it is used for heating purposes in the cities of Buffalo, Erie, Jamestown, Warren, Olean, Bradford, Oil City, Titusville, Meadville, Youngstown, and perhaps twenty more towns and villages in Pennsylvania and North-Western New York. In North-Western Ohio, the cities of Toledo and Sandusky, the towns of Findlay, Lima, Tiffin, Fostoria, and others in that section are also supplied with natural gas; a pipe line has moreover been recently laid to Detroit, Mich., and it is estimated that in these localities 36,131,669,000 cubic feet of the gas were consumed during last year, displacing 1,802,500 tons of coal. To the south-west of Pittsburgh there are many smaller places which consume natural gas; it also occurs in considerable quantity, and is being utilised, in Indiana (whence an account has recently reached us of a terrific subterranean explosion of the gas); and it is at the present time contemplated to carry a natural gas supply to Chicago.

The utilisation of the natural gas of the Russian oil fields, although of a very ancient date, has hitherto not been extensive, neither does the magnitude of the supply appear to bear comparison with that of the Pennsylvanian district.

A form of gaseous fuel which has long been known to technical chemists and metallurgists, but which has of late attracted considerable attention, especially in connection with the recent interesting work relating to its applications pursued by Mr. Samson Fox, of Leeds, has become, within the last four years, a competitor in the United States, both of the natural gas of Pennsylvania and of coal gas. Since Felix Fontana first produced so-called water-gas in 1780, by passing vapour of water over highly heated fuel, many methods, differing chiefly in small details, have been proposed for carrying out the operation, with a view to the ready and cheap production of the resulting mixture of hydrogen and carbonic oxide, and numerous technical applications of water-gas have been suggested from time to time, with no very important results, excepting as regards its use for lighting purposes. Being of itself non-luminous, its utilisation in this direction is accomplished, either by mixing it with a highly luminous gas, or by causing a hydrocarbon vapour to be diffused through it, or the non-luminous flame, produced by burning it in the air, is made to raise to incandescence some suitably prepared solid substance, such as magnesia, lime, a zirconium salt, or platinum, whereby bright light is emitted. The objection to its employment as an illuminant for use in buildings,

to which great weight is attached by us, and rightly, as sad experience has shown—viz., that, as it consists, to the extent of about one-half its volume, of the highly poisonous gas carbonic oxide, the atmosphere in a confined space may be rendered irrespirable by a small accidental contamination with water-gas, by leakage or otherwise, not detectable by any odour—appears to constitute no great impediment to its employment in the United States, as it is now manufactured for illuminating and heating purposes by a large proportion of their gasworks, being in some places employed in admixture with a highly luminous coal-gas, in others rendered luminous by the alternative methods mentioned. It is stated that about three-fourths of the illuminating gas now supplied to the cities of New York, Brooklyn, Philadelphia, Jersey, St. Paul, and Minneapolis, is carburetted water gas; in Chicago the entire supply now consists of this gas, and Boston will also soon be supplied exclusively with it. The use of water-gas for metallurgic work does not appear to be contemplated in the United States, but it is especially to such applications of the gas that much attention has been devoted here in Leeds; and although some eminent experts are sceptical regarding the attainment of advantages, especially from an economical point of view, by the employment of this form of gaseous fuel, especially after practical experience in the same direction acquired in Germany, the technical world must feel grateful to Mr. Fox for his work in this direction, affording, as it does, an interesting illustration of the qualities of perseverance and energy which, when combined with sound knowledge, often achieve success in directions that have long appeared most unpromising—qualities which have been characteristic of many pioneers in industrial progress in this country.

Leeds has been especially fortunate in the possession of such pioneers who, when competition brought about great changes in the particular trade through which, for many generations, this city chiefly enjoyed prosperity and high renown, developed its power and resources in new directions, from which success soon flowed in continually increasing measure. The rapid rise of Leeds to its present high position in industrial prosperity and national importance most probably dates from the period when its chief staple industry began to experience serious rivalry, in its own peculiar achievements, on the part of other districts of the kingdom and of other countries. From early days a flourishing Centre of one of the provinces of Great Britain most richly endowed with some of Nature's best treasures, Leeds could scarcely have failed, through the energy, acute intelligence, and powerful self-reliance especially characteristic of the men of Yorkshire, to rapidly acquire fresh renown in connection with industries which either were new to the town and district, or had been pursued in comparatively modest fashion, and which have combined to place the Leeds of to day upon a higher pinnacle of commercial prosperity, power, and influence than her patriotic citizens of old could ever have dreamt of.

An examination into the present educational resources of Leeds places beyond any doubt the fact that her present prosperity in commerce and industries is in no small degree ascribable to the paramount importance long since attached here to the liberal provision of facilities for the diffusion of knowledge among the artisan and industrial classes, and especially for the acquisition of a sound acquaintance with the principles of the sciences and their applications to technical purposes, with particular reference to the prominent local industries, by all grades of those who pursue or intend to pursue them. There is, probably, no town in the kingdom more amply provided with efficient elementary and advanced schools for both sexes, while the special requirements of the artisan are efficiently met by the prosperous School of Science and Technology. The resources of the Yorkshire College provide, in addition a combination of thorough scientific education with really practical training in the more

important local industries; indeed, during the sixteen years of its continually progressive work, this institution has acquired so widespread a reputation that students come from abroad to reap the advantages afforded by the unrivalled textile and dyeing departments of the Leeds College. The keen competition now existing between these departments and the corresponding branches of the much younger but most vigorous sister College at Bradford, can only conduce to the further development of both, and to their thorough maintenance up to the requirements of the day.

The very important pecuniary aid afforded to these establishments, and to a number of other technical schools in Yorkshire, by one of the most important of the ancient companies of the City of London, the Clothworkers, affords an interesting illustration of the good work in the cause of education performed by those Guilds and, especially of late years, by means of their flourishing Institute for the advancement of technical education which, through its two great instructional establishments in London, and through the operation of its system of examinations throughout the country, extending now even to the Colonies, has afforded very important aid towards eradicating the one great blot upon our national educational organisation. To have been first in the field in practically developing a far-reaching scheme for the advancement of technical education in this country must continue to be a source of pride to the City of London and its ancient Guilds in time to come, when the operation of efficient legislation, supported and extended by patriotic munificence and by the hearty co-operation of associations of earnest and competent workers in the cause, shall have placed the machinery and resources for the technical instruction of the people upon a footing commensurate with our position among Nations.

The remarkable Address delivered by Owen here in 1858, wherein the condition, at that time, of those branches of natural science which he had made particularly his own was most comprehensively reviewed, included some specially interesting observations on the importance to the cultivation and progress of the natural sciences, and to the advancement of education of the masses of this country, of providing adequate space and resources for the proper development of our National Museum of Natural History; and it cannot but be a source of great satisfaction and pride to him to have lived to witness the thoroughly successful realisation of the objects of his own indefatigable strivings and powerful advocacy in that direction. Comprehensive as were the views adopted by Owen regarding the scope and possible extension of that museum, it may, however, be doubted whether they ever embraced so extensive a field as was presented for our contemplation by his successor last year, when he told us that a natural history museum should, in its widest and truest sense, represent so far as they can be illustrated by museum specimens, all the sciences which deal with natural phenomena, and that the difficulties of fitly illustrating them have probably alone excluded such subjects as astronomy, physics, chemistry, and physiology, from occupying departments in our National Museum of Natural History.

The application, in its broadest signification, of the title Natural History Museum may doubtless be considered to include, not only illustrations and examples of the marvellous works of the Creator and of the results of man's labours in tracing their intimate history and their relations to each other, but also illustrations of the means employed, and of the results attained, by man in his strivings to fathom and unravel the laws by which the domains of Nature are governed. But, the reason why representative collections, illustrative of the physical sciences, do not form part of our National Natural History Museum, has, I venture to think, scarcely been correctly ascribable to any difficulty of organising fit illustrations of methods of investigation, of the attendant

appliances, and of the results attained by experimental research; it appears rather to exist in the fact that physical science has hitherto had no share in such a combination of circumstances as has been favourable to the good fortunes and advancement of the natural sciences, and is analogous to those which, from time to time, give rise to the provision of increased accommodation for our National Art Treasures. Our present National Science Collection, which has, indeed, had a struggle for existence, does not owe the development it has hitherto experienced to any such moral pressure as has been several times exercised in the case of our art collections, by the munificence of individuals, with the result of securing substantial aid from national resources; its gradual increase in importance has been due to the untiring perseverance of men of science, and of a few prominent influential and public spirited authorities, in keeping before the public the lessons taught by careful inquiries, such as those entrusted to the Royal Commission on Scientific Instruction, into the opportunities afforded for the cultivation of science and the development of its applications, in other countries, as compared with those provided here.

The success of the efforts made in 1875 by a committee thoroughly representative of every branch of experimental science to bring together in London an international loan collection of scientific apparatus, and the widespread interest excited by that collection, led the President of the Royal Society, in union with many distinguished representatives of science, to lay before our Department of Education a proposal to establish a national museum of pure and applied science, including the Museum of Inventions, which had already existed since 1860 as a nucleus of a science museum, the establishment whereof had formed part of the original scheme of the Science and Art Department. The Loan Collection of 1876 did, in fact, and in consequence of the urgent representations then made, first put into practical shape the long cherished desire of men of science to see an Institution arise in England similar to the Conservatoire des Arts et Métiers of France, and it became the starting point of the National Collection representative of the several branches of experimental science, which has been undergoing slow but steady development since that time, patiently awaiting the provision of a suitable home for its contents. This collection, which illustrates not only the means whereby the triumphs of scientific research have been and are achieved, but also the methods by which these departments of science are taught, yields, small as it is, to none of our national museum treasures in interest and importance.

In yet another way did that Loan Collection become illustrious: one of the most interesting features connected with it was the organisation of a series of important conferences and explanatory lectures, serving to illustrate, and also greatly to enhance, its value, and affording most invaluable demonstration of the way in which such collections must exercise direct influence upon the advancement of science and upon the diffusion of scientific knowledge. These lectures and conferences demonstrated the wisdom of the suggestion made by the illustrious representative of associated Science in Leeds eighteen years previously, that public access to museums should be combined with the delivery of lectures emphasising and amplifying the information afforded by their contents. The example there set of thoroughly utilising for instructional purposes, and for the advancement of science, a collection illustrative of the physical sciences, has since been followed by the Science and Art Department; illustrative lectures connected with the existing nucleus of a national science collection therewith have been delivered from time to time, and the objects in the collection are constantly utilised in the courses of instruction of the adjoining Normal School of Science.

Although the national importance of thoroughly representative and continuously maintained science

collections has long been manifest, not only to all workers in science, but also to all who have cared to enquire, even superficially, into the influence of the cultivation of science upon the industrial and commercial prosperity of the country, the labours of a Royal Commission and of successive Committees, in demonstrating the necessity for the provision of adequate accommodation for such collections, and for their support upon the basis of that afforded to the natural history collections, have been very long in bearing fruit. However, lovers of science, and those who have the prosperity of the country near at heart, have at length cause for rejoicing at the acquisition by the Nation of a site in all respects suitable and adequate for the accommodation of the science collections, which, as soon as appropriate buildings are provided for their reception, will not fail, in comprehensiveness and completeness, to become worthy of a Country which has been the birthplace of many of the most important discoveries in science, and of a People who have led the van among all Nations in making the achievements of science subservient to the advancement of industries and commerce.

The site selected as the permanent home of our National Science Collections is immediately in rear of the Natural History Museum, and faces the stately edifice, now rapidly progressing towards completion, for the erection of which, as an Imperial memorial of the Queen's Jubilee, funds were provided by voluntary contributions from every portion of the Empire and every class in the Empire's Nations. The Imperial Institute, the conception of which we owe to His Royal Highness the Prince of Wales, occupies a central position among buildings devoted to the illustration and cultivation of pure and applied Science and of the Arts—i.e., the Normal School of Science, the Technical College of the City and Guilds of London, the National Schools of Art, the Science Museum, the South Kensington Museum, and the Royal College of Music; to which we may ere long see added a National Gallery of representative British Art. A more fitting location could scarcely be conceived for this pre-eminently National Institution, which has for its main objects the comprehensive and continuously progressive illustration: of the practical applications of the vast resources presented by the Animal, Vegetable, and Mineral Kingdoms to Industries and the Arts; of the extent and the progressive opening of those resources in all parts of the Empire; of the practical achievements emanating from the results of scientific research; and of the utilisation of the Arts for the purposes of daily life. With the attainment of these objects it will be the function of the Imperial Institute to combine the continuous elaboration of systematic measures tending to stimulate progress in trades and handicrafts, and to foster a spirit of emulation among the artizan and industrial classes. Another branch of the Institute's work, upon which it is already engaged, is the systematic collection of data relating to the natural history, commercial geography, and resources of every part of the empire, for wide dissemination together with all current information, bearing upon the commerce and industries of the Empire and of other Countries, which can be comprised under the head of Commercial Intelligence. The achievement of these objects should obviously tend to maintain intimate intercourse, relationship, and co-operation between the great Home and Colonial centres of Commerce, Industries, and Education, and to enhance importantly our power of competing successfully in the great struggle, in which Nations are continuously engaged, for supremacy in commercial and industrial enterprise and prosperity.

To the elaboration of the practical details of a system of operation calculated to secure the objects I have indicated, eminent public spirited men are now devoting their best energies, with the sanguine expectation of realising the hope cherished by the Royal Founder of the Imperial Institute, that this memorial of the completion, by our beloved Sovereign, of fifty years of a wise and

prosperous reign, is destined to be one of the most important bulwarks of this County, its Colonies and Dependencies, by becoming a great centre of operations, ceaselessly active in fostering the unity, and developing the resources, and thus maintaining and increasing the power and prosperity, of our Empire.

CORRESPONDENCE.

ELECTRO-DEPOSITION OF SILVER.

To the Editor of the Chemical News.

SIR,—I had occasion recently to prepare a conducting surface on plaster casts for coating with copper by electrical deposit; the ordinary method of obtaining a deposit of finely-divided silver seemed rather lengthy, especially as it necessitated soaking the cast in wax. A good deposit of silver may be obtained by a somewhat simpler mode of procedure if the cast be moistened with water and brushed over with a solution of silver nitrate; it is then allowed to come into contact with antimoniretted or arseniuretted hydrogen, which can readily be prepared by adding compounds of antimony or arsenic to a flask in which hydrogen is being evolved from lime and dilute sulphuric acid. An instant deposit of Ag_3Sb occurs, which is an excellent conductor.

It is advisable to have the flask in a draft cupboard, as the hydrogen compounds of antimony and arsenic are very poisonous.—I am, &c.,

S. ERNEST LINDEN.

Oakfield, Buckhurst Hill, N.E.,
August 27, 1890.

MISCELLANEOUS.

British Association for the Advancement of Science.—The following are the names of the Officers and Committee of Section B (Chemical Science) of the Leeds Meeting of the British Association:—

President—Professor T. E. Thorpe, B.Sc., Ph.D., F.R.S., Treas.C.S.

Vice-Presidents—Professor P. Phillips Bedson, D.Sc., F.C.S.; Professor H. B. Dixon, M.A., F.R.S., F.C.S.; J. H. Gladstone, Ph.D., F.R.S.; Professor G. H. Liveing, M.A., F.R.S.; Dr. W. H. Perkin, F.R.S.; Sir H. E. Roscoe, D.C.L., F.R.S.; Dr. Schunck, F.R.S.; Professor A. Smithells, B.Sc., Ph.D., LL.D., F.R.S., F.C.S.

Secretaries—C. H. Bothamley, F.C.S., F.I.C.; H. Forster Morley, M.A., D.Sc., F.C.S. (*Recorder*); Dr. D. H. Nagel, M.A.; Dr. W. W. J. Nicol, M.A., F.R.S.E.

Committee—A. H. Allen; Professor H. E. Armstrong, F.R.S.; R. W. Atkinson; Dr. Vidor Auger; Dr. G. H. Bailey; Professor F. Clowes; George Duncan; Professor W. R. Dunstan; T. Fairley; A. E. Fletcher; Professor P. F. Frankland; Professor W. Noel Hartley, F.R.S.; A. G. V. Harcourt, F.R.S.; Professor Van't Hoff; Professor J. J. Hummel; B. P. Lascelles; Professor H. M'Leod, F.R.S.; Sydney Lupton; Dr. Stevenson Macadam; Professor R. Meldola, F.R.S.; M. M. P. Muir; Professor W. Ostwald; Dr. A. Pauli; Professor W. H. Perkin, F.R.S.; S. U. Pickering, F.R.S.; Professor W. Ramsay, F.R.S.; R. Reynolds; Dr. A. Richardson; Dr. S. Rideal; Dr. S. Rubemann; G. F. Schacht; W. A. Shenstone; Professor H. Lloyd Snape; W. Thomson; V. H. Veley; J. Ward; R. Warington, F.R.S.; Dr. J. Watts; J. J. Wertheimer; Professor A. W. Williamson, F.R.S.

The Papers brought before the Section were as follows:—

President's Address.

Report of the Committee on the History of Chemistry.

Report of the Committee on the Silent Discharge of Electricity in Gases.

Report of the Committee on the Present Methods of Teaching Chemistry.

Sir Henry Roscoe, F.R.S.—On Recent Legislation as Facilitating the Teaching of Science.

Dr. J. H. Gladstone, F.R.S., and G. Gladstone.—The Refraction and Dispersion of Fluorobenzene and allied compounds.

Dr. G. H. Bailey and J. C. Cain.—A method of Quantitative Analysis by Weighing Precipitates Suspended in Liquids.

Dr. G. H. Bailey and A. A. Read.—The Behaviour of the more stable Oxides at High Temperatures.

Dr. G. H. Bailey.—The spectra of the Haloid Salts of Didymium.

W. Hepworth Collins.—The Condition of the Air in Public Places of Amusement.

Report on Isomeric Naphthalene Derivatives.

Dr. W. H. Perkin, F.R.S.—The Development of the Coal Tar Colour Industry since 1880 (illustrated by specimens).

Professor J. H. Van't Hoff.—Behaviour of Copper Potassium Chloride and its Aqueous Solutions at different temperatures.

Report of the Committee on the Action of Light on the Hydracids of the Halogens in presence of Oxygen.

Professor Living, F.R.S., and Professor Dewar, F.R.S.—Experiments on the Combustion of Gases under Pressure.

Professor H. B. Dixon, F.R.S., and J. A. Harker.—The Rate of Explosion of Hydrogen and Chlorine in the dry and moist states.

Dr. G. S. Turpin.—On the Ignition of Explosive Gaseous Mixtures.

Jas. T. Brown.—The Orthophote.

Report of the Committee on an International Standard for the Analysis of Iron and Steel.

Report of the Committee on the Influence of Silicon on the Properties of Steel.

Report of the Committee on the Properties of Solutions.

Report of the Committee on the Bibliography of Solution.

Dr. O. Pettersson.—Recent Swedish Investigations on the Gases held in solution by the Sea-water of the Skagerack.

Joint Discussion with Section A on the Nature of Solution and its connection with Osmotic Pressure, opened by S. U. Pickering, F.R.S., in a paper on "The Present Position of the Hydrate Theory of Solution." Professors Van't Hoff and Ostwald took part in the discussion.

Dr. J. H. Gladstone.—The Molecular Refraction of Substances in Solution.

P. J. Hartog and J. A. Harker.—An Apparatus for the determination of the Freezing-points of Solutions.

C. H. Bothamley.—The Sulphur Waters of Yorkshire.

T. H. Easterfield, B.A., and J. Mitchell Wilson, M.D.—The River Aire—a study in River Pollution.

Report of the Committee on the Bibliography of Spectroscopy.

Report of the Committee for preparing a new series of Wave Length Tables of the Spectra of the Elements.

Report of the Committee on the Absorption Spectra of Pure Compounds.

Prof. T. E. Thorpe, F.R.S.—On Phosphorous Oxide.

Prof. R. Meldola, F.R.S.—Diazo-amido-compounds; a Study in Chemical Isomerism.

A. G. Green, C. F. Cross, and E. J. Bevan.—On the Action of Light on the Diazo-compounds of Primuline and of Dehydrothiolutidine; a Method of Photographic Dyeing and Printing.

Prof. J. J. Hummel.—Fast and Fugitive Coal-tar Colours.

T. Fairley.—Some Reactions of Hydrogen Peroxide.

Dr. Ahrens.—Veratrin, and the Existence of Two Isomeric β -picolines.

C. H. Bothamley.—Action of Phosphorus Trichloride on Organic Acids and on Water.

Prof. W. H. Perkin, Jun., F.R.S.—The Constitution of the Alkaloid Berberin.

J. E. Marsh and R. Stockdale.—The Production of Camphor from Turpentine.

T. Fairley.—A Continuous Aspirator.

W. Thomson.—Note on the Vulcanisation and Decay of Indiarubber.

W. Thomson.—On the Unburned Gases Contained in the Flue Gases from Gas Stoves and Other Burners.

Dr. J. Lewkowitsch.—Some Points on the Analysis of Fats.

Dr. T. Ewan.—Condensation of Dibenzyl Ketone with Oxalic Ether.

TO CORRESPONDENTS.

H. H.—Hofer's "Histoire de la Chimie." The work is in French, and we are not aware of an English version. Concerning the price, we must refer you to any foreign bookseller in London.

PATENTS.

Provisional Protection, from £2 2s.

Lowest cost of complete English and Foreign on application. Also, Designs and Trade Marks. Inventions financed.

WALLACE, WEATHERDON, & CO.,

REGISTERED PATENT AGENTS,

57 & 58, Chancery Lane, and 11, Southampton Buildings, W.C.

Established 1849.

OWEN'S COLLEGE, VICTORIA UNIVERSITY, MANCHESTER.

CHEMISTRY COURSE.

Full particulars of this Course, qualifying for the Victoria University Degrees in Chemistry and the College Certificate in Applied Chemistry, will be forwarded on application.

The Session begins October 7.

H. W. HOLDER, M.A., Registrar.

Containing Valuable and Important Works from the Dr. John Percy's Library.

W. WESLEY & SON, 28, Essex Street, Strand, London.

THE LONDON HOSPITAL MEDICAL COLLEGE.—THE WINTER SESSION will commence on Wednesday, October 1st.

The Hospital, which is the largest general hospital in the kingdom, contains nearly 800 beds, all in constant use. There are wards for accidents, surgical and medical cases, diseases of women and children, and ophthalmic cases. Special departments for diseases of the eye, ear, throat, skin and teeth, and for cancer, tumours, diseases of the bladder, piles and fistula. Number of in-patients last year, 9105; out-patients, 109,839; accidents, 11,400.

Surgical operations daily.
APPOINTMENTS.—Resident accoucheur, house physicians, house surgeons, &c. Forty of these appointments are made annually. Numerous dressers, clinical clerks, post-mortem clerks, and maternity assistants are appointed every three months. All appointments are free. Holders of resident appointments are also provided free board. Two Entrance Science Scholarships, value £75 and £50, and two Buxton Scholarships, value £30 and £20, will be offered for competition at the end of September to new Students. Sixteen other Scholarships and prizes are given annually.

The London Hospital is now in direct communication with all parts of the metropolis. The Metropolitan, District, and other railways have stations within a minute's walk of the Hospital and College.

For further information apply, personally or by letter, to—

MUNRO SCOTT, Wardens
Mile End, E.

THE CHEMICAL NEWS.

VOL. LXII. No. 1608.

ADDRESS TO STUDENTS.

As the season comes round we are again led to call attention to certain points relating to higher education which, often as they have been raised, are still neglected. The claims of chemistry—and indeed of the physical and natural sciences altogether—to a much larger share of attention have been urged upon educators and students chiefly upon the ground of utility. This plea has been met with the sneering remark that we are not all going to become calico-printers, or iron-masters, tanners, or soap-boilers.

But we submit that physical and natural science—in a word, the study of *things* in contradistinction to *words* and *abstractions*—is entitled to eminence as an instrument of intellectual culture. Without it we can never, unless exceptionally gifted by nature, acquire the art of observation. In our present educational curricula, alike in board-school and grammar-school, this art is not merely left untaught, it is crowded out and starved at the very roots because the energies of the student are drawn off in other directions. A gentleman whose duty it became at one time to administer the somewhat homœopathic doses of science admitted at a public school puts on record the fact that the boys of the lower forms assimilated more readily than the seniors the elementary truths of chemistry and physics. The intellects of the latter had been so modified by a persistent course of verbalism that they could not see any meaning in *things*.

In like manner many working-men, possessing but a very scanty knowledge of the "three r's," were very good observers in botany, entomology, ornithology, &c. But the number of such men is certainly not on the increase. Indeed, an acute contemporary some years ago expressed the fear that the "vice of inobservance," so conspicuous among our upper classes, was being spread to the great mass of the nation in consequence of the exclusively literary character of our present system of education.

Yet, again, we may even venture to say that savages are often better observers than civilised Europeans or Americans, unless the latter have been systematically trained in research. More than one scientific traveller, on noticing some rare and curious plant, has been told by a "Redskin" in Texas or by a "Black fellow" in Queensland where such plant could be found in quantity.

Now the only way to escape from our present humiliating inferiority as observers is to give to natural and physical science a leading place in our courses of instruction. And as the mass of the public are now cooped up in towns the sciences to which their attention must mainly be directed are chemistry and physics.

But one caution must be kept in mind. The question how we are to learn is not less important than its companion what we are to learn. The youth who studies chemistry from books, however closely and laboriously, will reap little or no advantage from his labours. If he has done nothing further than read

he will still be in the bonds of verbalism, unable to learn from and to interpret phenomena.

It need scarcely be said that the main prop of verbalism is the examinational system. It is truly painful to have to remind our readers how completely the great protest against this system appears to have been forgotten, and how completely success in these displays is regarded as a triumph.

UNIVERSITIES AND COLLEGES.

UNIVERSITY OF LONDON.

CANDIDATES for any Degree granted by this University are required to have passed the Matriculation Examination, and all candidates for Matriculation will henceforth be required to comply with the following instructions:—(1) Not less than five weeks before the commencement of the Examination every candidate must apply to the Registrar, by letter, for a Form of Entry, which, together with all particulars respecting the arrangements for the Examination, will be sent to him immediately on receipt of the application. (2) This form, duly filled up, must be returned to the Registrar not less than four weeks before the commencement of the Examination, and with it, in the same cover, must be sent (a) the candidate's certificate of age, and (b) his fee for the Examination. No candidate's name will be placed on the list of candidates unless his form of entry, certificate of age, and fee shall have been received at the University on or before the fourth Monday before the commencement of the Examination. In the course of the week following the closing of the list, but not previously, each candidate's certificate and fee will be acknowledged, his certificate will be returned, and a Number, by which he is to be designated throughout the Examination, will be assigned to him.

The Fee for this examination is £2.

There are two Examinations for Matriculation in each year; one commencing on the second Monday in January, and the other on the second Monday in June. The Examination is conducted by means of Printed Papers; but the Examiners are not precluded from putting, for the purpose of ascertaining the competence of the candidates to pass, *viva voce* questions to any candidate in the subjects in which they are appointed to examine.

Candidates are not approved by the Examiners unless they have shown a competent knowledge in each of the following subjects:—Latin. Any one of the following Languages:—Greek, French, German, Sanskrit, or Arabic. The English Language, and English History, with the Geography relating thereto. Mathematics. Mechanics. One of the following branches of Experimental Science:—Chemistry, Heat and Light, Magnetism and Electricity, Botany.

The Examination in Chemistry is—Chemistry of the Non-metallic Elements; including their compounds—their chief physical and chemical characters—their preparation—and their characteristic tests.

A Pass Certificate, signed by the Registrar, will be delivered to each candidate after the Report of the Examiners has been approved by the Senate.

If in the opinion of the Examiners any candidates in the Honours Division of not more than twenty years of age at the commencement of the Examination possess sufficient merit, the first six among such candidates will receive an Exhibition of thirty pounds per annum for the next two years; the second among such candidates will receive an Exhibition of twenty pounds per annum for the next two years; and the third will receive an Exhibition of fifteen pounds per annum for the next two years; such exhibitions are payable in quarterly instalments provided that on receiving each instalment the Exhibitioner declares his intention of presenting himself either

at the two Examinations for B.A., or at the two Examinations for B.Sc., or at the Intermediate Examination in Laws, or at the Preliminary Scientific M.B. Examination, and Intermediate Examination in Medicine, within three academical years from the time of his passing the Matriculation Examination.

Under the same circumstances, the fourth among such Candidates will receive a prize to the value of ten pounds in books, philosophical instruments, or money; and the fifth and sixth will each receive a prize to the value of five pounds in books, philosophical instruments, or money.

Any candidate who may obtain a place in the Honours Division at the Matriculation Examination in January is admissible to the Intermediate Examination either in Arts or in Science in the following July.

INTERMEDIATE EXAMINATION IN SCIENCE.

The Intermediate Examination in Science will be held in July, 1891.

No candidate (with the exception of such as have obtained Honours at the Matriculation Examination in the preceding January) is admitted to this Examination within one academical year of the time of his passing the Matriculation Examination.

The Fee for this Examination is £5.

Examination for Honours.

Candidates for Honours in Chemistry will be examined in Inorganic Chemistry, treated more fully than in the Pass Examination. In addition, they will be examined practically in Simple Qualitative Analysis. This Examination will consist of six hours' examination by two printed papers and of six hours' practical work.

In the Examination for Honours, the Candidate, not being more than 22 years of age at the commencement of the Pass Examination, who most distinguishes himself will receive an Exhibition of £40 per annum for the next two years.

B.Sc. EXAMINATION.

The B.Sc. Examination will be held in October.

Candidates for this Examination are required to have passed the Intermediate Examination in Science at least one academical year previously.

The Fee for this Examination is £5.

Examination for Honours.

The examination for Honours in Chemistry will take place on Monday and Tuesday in the week following the Examination for Honours in Mathematics; on Monday by printed papers (chiefly on Organic Chemistry), and on Tuesday by practical examination in Qualitative and Quantitative Analysis.

The candidate, being not more than 23 years of age, who most distinguishes himself in Chemistry, will receive £50 per annum for the next two years, with the style of University Scholar.

DOCTOR OF SCIENCE.

The examination for the Degree of Doctor of Science takes place annually within the first twenty-one days of June.

No candidate is admitted to the examination for the Degree of D.Sc. until after the expiration of two Academical Years from the time of his obtaining the Degree of B.Sc. in this University.

Every candidate for this Degree must state in writing the special subject within the purview of the Faculty of Science, as set out in the Programme of the B.Sc. Examination, upon a knowledge of which he rests his qualification for the Doctorate; and with this statement he shall transmit an original printed Dissertation or Thesis (at least six copies) treating scientifically some special department of the subject so named, embodying the result of independent research, or showing evidence of his own work, whether based on the discovery of new facts observed by himself, or of new relations of facts observed by others, or, generally, tending to the advancement of Science. The Dissertation or Thesis shall have been written in view of candidature, or shall have been

published within the two academical years immediately preceding. Every candidate may further specify any printed contribution or contributions to the advancement of Science which he has at any time previously published, and every contribution so specified and submitted shall be considered and taken as part of his qualification for the Degree. If the Dissertation or Thesis be approved by the Examiners, the candidate shall be required to present himself at the University upon such day or days within the first twenty-one days of June as may be notified to him, and shall, at the discretion of the Examiners, be further tested, either orally or practically, or by printed questions or by all of these methods, and with especial reference to his Dissertation or Thesis.

Candidates for the Degree of D.Sc. will be expected to be so fully conversant with the branch of Science they profess as to be able, if required, to satisfy any test of their acquirements in that branch that it may be thought expedient to apply.

The Fee for this Examination is £10.

PRELIMINARY SCIENTIFIC (M.B.) EXAMINATION.*

This Examination takes place twice in each year,—once, for Pass and Honours, commencing on the third Monday in July; and once for Pass Candidates only, commencing on the third Monday in January.

No candidate shall be admitted to this Examination unless he shall have passed the Matriculation Examination, nor unless he have given notice of his intention to the Registrar at least one calendar month before the commencement of the examination.

The Fee for this examination is Five Pounds.

EXAMINATION IN SUBJECTS RELATING TO PUBLIC HEALTH.

A Special Examination will be held in December in subjects relating to public health.

No candidate is admitted to this Examination unless he has passed the Second Examination for the Degree of Bachelor of Medicine in this University at least one year previously; nor unless he shall have given notice of his intention to the Registrar at least two calendar months before the commencement of the Examination.

The Fee for this Examination is £5.

UNIVERSITY OF OXFORD.

Waynflete Professor of Chemistry.—W. Odling, M.A., F.R.S.

Every Student must reside in one or other of the Colleges or Halls, or in licensed lodgings, for a period of three years, passing at least two examinations in Arts, and one in either Mathematics, Natural Science, Law, Modern History, or Theology, when, if he obtain a first, second, or third class, he can take his B.A. Degree; if he do not gain such honour he has to pass a third examination in *Literis Humanioribus*.

The fee for students working in the Laboratory for three days in the week during the Term is £3; for students working every day, £5.

Scholarships of about the value of £75 are obtainable at Christ Church, Magdalen, and other colleges, by competitive examination in Natural Science.

More detailed information may be obtained from the University Calendar; from the professors; and from the Sub-Librarian in the Radcliffe Library or the Museum.

UNIVERSITY OF CAMBRIDGE.

Professor of Chemistry.—G. D. Liveing, M.A., F.R.S.
Jacksonian Professor of Natural and Experimental Philosophy.—J. Dewar, M.A., F.R.S.

The Student must enter at one of the Colleges, or as a Non-collegiate Student, and keep terms for three years by residence in the University. He must pass the previous

* Candidates who pass in all the subjects of the Preliminary Scientific (M.B.) Examination, and also pass at the same time in the Pure and Mixed Mathematics of the Intermediate Examination in Science, or who have previously passed the Intermediate Examination in Arts, are admissible to the B.Sc. Examination.

examination in Classics and Mathematics, which may be done in the first or second term of residence, or, through the Oxford and Cambridge Schools Examination Board, or through the Senior Local Examinations, before commencing residence. He may then proceed to take a Degree in Arts, either continuing mathematical and classical study, and passing the ordinary examinations for B.A., or going out in one of the Honour Triposes.

The scholarships, ranging in value from £20 to £80 a year, are chiefly given for mathematical and classical proficiency. Scholarships are given for Natural Science in Trinity, St. John's, St. Peter's, Clare, Christ's, Sidney, Pembroke, Caius, Downing, and Cavendish Colleges; the examinations being in December, at Easter, and in June and October.

The Chemical Laboratory of the University is open daily for the use of the Students. The Demonstrators attend daily to give instructions. A list of the lectures is published annually, in June, in a special number of the *Cambridge University Reporter*, which may be had from the Cambridge Warehouse, in Paternoster Row, or through any bookseller.

Non-collegiate Students are allowed to attend certain of the College Lectures and all the Professors' Lectures, and have the same University status and privileges as the other Students. Full particulars may be obtained by forwarding a stamped directed envelope to the Assistant Registrar, Cambridge, or from the *Cambridge University Calendar*.

UNIVERSITY OF DUBLIN. TRINITY COLLEGE.

Professor of Chemistry.—J. Emerson Reynolds, M.D., F.R.S., V.P.C.S.

Assistant Lecturer.—Emil A. Werner, F.C.S., F.I.C.

Demonstrator.—William Early, F.I.C.

The general Laboratories include working accommodation for 120 Students, and the Quantitative and Research Laboratories for about 40 Students. The Laboratories will open on the 1st of October. Lectures will commence about November 1st.

The Laboratories and the Lectures of the Professor of Chemistry can now be attended by Students who do not desire to reside in the University or proceed to its Degrees.

The full Course of General and Analytical Chemistry occupies three years, but a Student is free in his third year to devote most of his time to a special department of Pure or Technical Chemistry. Students can enter for any portion of the Course. The following Lectures are delivered:—

1. *Inorganic Chemistry and Chemical Philosophy.*—Elementary, first year; advanced, second year.
2. *Organic Chemistry.*—General, second year; advanced, third year.
3. *Metallurgy.*—A Course for Engineering and Technical Students.

The Laboratories are open every day from 10 to 5 o'clock (except Saturdays, when they close at 1 o'clock).

The *Summer Course of Practical Chemistry for Medical Students* begins during the first week in April and terminates with the first week in July.

The University of Dublin grants the Degree of Doctor of Science to graduates of Master's standing whose independent researches in any branch of Science are of sufficient merit.

KING'S COLLEGE.

(DEPARTMENT OF ENGINEERING AND APPLIED SCIENCE).

Professor of Chemistry.—J. M. Thomson, F.C.S.

Demonstrator of Practical Chemistry.—G. S. Johnson, F.C.S.

Assistant Demonstrator.—Herbert Jackson, F.C.S.

On Tuesday and Thursday at 10.20 a.m. Students of the First Year are admitted to the Course of Theoretical and Applied Chemistry. The Course commences with a View of the Forces which concur to the production of Chemical Phenomena, after which the laws of Chemical Attraction

are discussed, and the Non-metallic elements and their principal Compounds are described.

The Metals and their principal compounds are next examined, care being taken to point out the applications of the Science to the Arts; and the processes of the different Manufactures and of Domestic Economy are explained and illustrated.

Examinations of the Class, both *visd voce* and by written papers, are held at intervals during the course at the usual Lecture hour.

Second Year.—Students attend in the Laboratory twice a week, on Tuesday and Friday, at 10.20, and they go through a course of Manipulation in the most important operations of Chemistry, including the first steps of Analysis.

Any Student of this Department may be admitted to this Class at any period of his study on payment of an extra fee.

Experimental and Analytical Chemistry in the Laboratory.—The object of this Class is to afford to Students who are desirous of acquiring a knowledge of analysis, or of prosecuting original research, an opportunity of doing so under the superintendence of the Professor and Demonstrator; Students may enter, upon payment of extra Fees, at any time except during the vacation, and for a period of one, three, six, or nine months, as may best suit their convenience. The laboratory hours are from ten till four daily, except Saturday, on which day the hours are from ten till one.

In addition to the Laboratory Fee, each Student defrays the expenses of his own Experiments. The amount of this expense, which is comparatively trifling, is entirely under his own control.

Special hours and fees are arranged for the convenience of such Third Year Students as wish to study Analytical Chemistry.

Fees.—Chemistry per term, £3 3s. od.; per ann., £8 8s. od.; Practical Chemistry per term, £4 4s. od.; per ann., £10 10s. od.; Experimental and Analytical Chemistry—One Month (daily attendance), £4 4s. od.; Three Months (daily attendance), £10 10s. od.; Six Months (daily attendance), £18 18s. od.; Nine Months (daily attendance), £26 5s. od. A student taking a month's ticket may attend daily during 1 month, or 3 days a week during 2 months, or 2 days a week during 3 months.

Rules as to Admission of Students.

I. The Academical Year consists of Three terms: Michaelmas Term, from beginning of October to the week before Christmas; Lent Term, from the middle of January to the week before Easter; Easter Term, from Easter to the beginning of July.

II. The days fixed for the Admission of New Students in the Academical Year 1890-91, are Tuesday, September 30, Wednesday, January 14, and Wednesday, April 15.

METALLURGY.

Professor.—A. K. Huntington, F.I.C., F.C.S., &c.

The following subjects are treated of in the Lectures: The Selection and Economic Preparation of Fuel and of Refractory Materials; the methods by which metals are obtained from their ores, and the means by which they are rendered suitable for the various requirements of the Arts.

Particular attention is made to the study of the Nature and Properties of Metals and Alloys available for Constructive Purposes.

In the Metallurgical Laboratory, which is always open during College hours, the relation between the Chemical Composition of Metals and their Mechanical Properties may be studied by the aid of Testing Machinery. The instruction given to each student is regulated by his special requirements.

PHOTOGRAPHY.

Lecturer.—J. M. Thomson, F.R.S.E., F.C.S.

Arrangements are made for a complete Course of Instruction in Photography to the students of the third

year. A glass house has been erected, and in connection with it a Laboratory for the preparation of Photographic Chemicals. Students entering to this department will be afforded every facility for practising the Art in all its branches.

In addition to the regular College Course in Photography occasional classes are formed, consisting each of about six gentlemen, who meet twice a week. The fee for private instruction is £5 5s. for ten lessons, or £10 10s. for three courses. There is in every case a charge of £1 each course for chemicals.

EVENING CLASSES.

Classes for Evening Instruction in various subjects are held during the months from October to March, inclusive, and during the months of April, May, and June.

UNIVERSITY COLLEGE.

FACULTY OF SCIENCE.

Professor.—William Ramsay, Ph.D., F.R.S.

Assistant Professors.—R. T. Plimpton, Ph.D., and J. N. Collie, Ph.D.

The Session is divided into three Terms, as follows, all the dates being inclusive:—

First Term, from Thursday, October 2nd, until Friday, December 19th;

Second Term, from Tuesday, January 6th, 1891, till Wednesday, March 25th;

Third Term, for Lectures, from Tuesday, April 14th, till Wednesday, July 1st. Class Examinations occupy about ten days, beginning on Thursday, June 18th.

Students, who having entered in October do not intend to present themselves in all three subjects at the July Preliminary Science Examination, should during the first term confine their attention to Chemistry, and take this subject alone at the January Examination.

Students entering in January should take Physics and Biology at the July Examination, and Chemistry at the succeeding January Examination.

Junior or Matriculation Course.

Tuesday, Thursday, and Saturday, at 10, commencing October 7, 1890, and April 14th, 1891. Fee:—£4 4s.

These Courses will each consist of about thirty lessons, partly theoretical and partly practical, on the non-metallic elements. Frequent exercises will be given.

Senior Course of Chemistry.

First and Second Terms: Inorganic.—The Class meets four times a week: Mondays, Wednesdays, Fridays, and Saturdays, at 9, for Lectures, Examinations, and Exercises, commencing October 6th.

Fee:—For the Course, £7 7s.; Perpetual, £9 9s.; for the First or Second Terms, £4 4s.

This Course and the Practical Class cover the subject as prescribed for the Preliminary Scientific (M.B.) and Intermediate Examination in Science of the University of London.

For the Preliminary Scientific Examination Students who take the three subjects for that examination in July attend during the First and Second Terms.

Advanced Course of Chemistry.

Second and Third Terms.—The class meets twice a week, on Tuesdays and Thursdays, at 9. The hour will be altered by special arrangement with the class if necessary.

Fee:—For the Course, £3 3s.; for a Term, £2 2s.

This Course will be found suitable for those about to proceed to graduation as Bachelor of Science in London University, and to those who intend to choose Chemistry as a profession. Such students should also work in the Laboratory during as many hours as they can spare.

Organic Chemistry.

Tuesday and Thursday, at 9, in the First Term; Tuesday, Thursday, and Saturday, at 10, in the Second

Term; and Monday, Wednesday, and Friday, at 9, in the Third Term. The hour of meeting will be altered should the class desire it.

This Course of Organic Chemistry is intended for those who in studying the subject have not a Medical Examination chiefly in view. Candidates for Honours at the Int.M.B. are, however, recommended to attend this Course during the Second and Third Terms, instead of the Special Summer Course.

The Course includes the subjects required at the B.Sc. Examination, Pass and Honours; but no previous acquaintance with Organic Chemistry will be expected of those joining the Class.

Fee:—For the Course, £6 6s.; for a Term, £2 12s. 6d.

An Advanced Course for those engaged in prosecuting research in Organic Chemistry will be held three times a week during the Second Term. Fee, £2 12s. 6d.

Practical Class.

First and Second Terms, Tuesday and Thursday, at 11, commencing October 7th.

Fee, including cost of materials, £5 5s.; for a Second Course, £3 3s.

The Course includes the Practical Chemistry required at the Preliminary Scientific and Intermediate Science Examinations.

Senior Practical Class.

Wednesdays from 2 to 4 and Saturdays from 10 to 12 during the Third Term.

Fee:—(Including cost of materials) £5 5s.; for a Second Course, £3 3s.

Analytical and Practical Chemistry.

The Laboratory is open daily from 9 a.m. to 4 p.m., Saturdays excepted, from October until the middle of July, with a short recess at Christmas and at Easter.

Fees: for the Session, £26 5s.; six months, £18 18s.; three months, £10 10s.; one month, £4 4s.

Three specified days a week:—for the Session, £15 15s.; six months, £11 11s.; three months, £6 6s.; one month, £2 12s. 6d., exclusive of expense of materials. Students may enter at any period of the Session.

The Laboratory Course includes the Practical Chemistry required at the following Examinations of the University of London:—Prel. Sci. (M.B.), Intermediate M.B., Intermediate Science, B.Sc.

Students who wish to attend the Lectures on Chemical Technology may acquire here the requisite preliminary knowledge of Practical Chemistry and Analysis.

When accompanied by, or preceded by, attendance on the Lectures on Inorganic and Organic Chemistry, the Laboratory Course qualifies Students in the application of Chemistry to Manufactures, Metallurgy, Medicine, or Agriculture, &c.

There is also a Chemical Library containing the chief Journals and Standard Works on Chemistry.

A Gold Medal and Certificates of Honour are competed for by first year's Students. The Tuffnell Scholarship (£100 for two years) will also be competed for in the Session 1890-91; also the Clothworker's Scholarship of £50.

Chemical Technology.

Lecturer, Watson Smith, F.I.C., F.C.S.

Courses of Lectures will be given on the following subjects:—Manufacture of Sulphuric Acid, Alkali, &c. Fuel and Gas Manufacture. Chemical Technology of Building Materials. Coal tar Products and Colours. Applications of Chemistry to Engineering.

Evening Lectures will be given by gentlemen qualified by practical and theoretical acquaintance with special subjects, and occasional visits to Works will be arranged.

Residence for Students.

Students can obtain residence at University Hall, Gordon Square. Particulars can be obtained at the office of the College.

**NORMAL SCHOOL OF SCIENCE AND
ROYAL SCHOOL OF MINES.**

Professor.—T. E. Thorpe, Ph.D., B.Sc., F.R.S.
Assistant Professor.—F. R. Japp, M.A., LL.D., F.R.S.
Demonstrators.—H. Chapman Jones and A. E. Tutton.
Assistants.—G. S. Newth, J. W. Rodger, and W. Tate.

The Normal School of Science at South Kensington is intended, primarily, for the instruction of teachers, and of students of the industrial classes selected by competition in the examinations of the Science and Art Department. The Royal School of Mines is affiliated to the Normal School. Students entering for the Associateship of the School of Mines obtain their general scientific training in the Normal School. The instruction in the Normal School is arranged in such a manner as to give the Students a thorough training in the general principles of Science, followed by advanced instruction in one or more special branches of Science. The Associateship is granted in certain divisions or lines of study. Students who go through any one of the prescribed courses of instruction and pass the necessary Examinations receive a Certificate of Associateship of the Normal School, or of the Royal School of Mines. But students who are not candidates for the Associateship are permitted to take up the course of instruction in one or more special branches of science, and on passing the examination receive a Certificate to that effect. The Associateship of the Normal School of Science is given in one or more of the following divisions:—Mechanics, Physics, Chemistry, Biology, Geology, and Agriculture, and the Associateship of the Royal School of Mines in Metallurgy and Mining.

The course of instruction, which lasts for three years, is the same for all the divisions during the first year, after which it is specialised in accordance with the Scheme detailed in the Prospectus of the School.

The Session is divided into two Terms. The first Term begins on the 1st of October and ends about the middle of February. The second Term begins in the middle of February and ends about the middle of June.

Examinations are held at the end of each course of instruction and at such other periods as may be found necessary. On the results of these examinations the successful candidates are arranged in two classes, first and second. There are also "Honours" examinations for the subjects of the third year, the successful candidate being placed in order of merit. A student obtains the Associateship who passes in all the subjects of the first two years and of the special division he selects for his Associateship. A student who goes through the prescribed course of instruction in any subject and passes the final examination in it receives a certificate to that effect.

Students who do not wish to attend the lectures are admitted for short periods to the laboratories, at the discretion of the Professors. The fees for the laboratories are £4 per month.

Students not entering for the Associateship are admitted to any particular course of study, so far as there is room, on payment of the fees shown in the following table:—

	Lectures.	Laboratory.
Chemistry	3	13
Physics	5	12
Biology with Botany	5	12
Geology with Mineralogy	4	8
Mechanics	4	6
Metallurgy	2	13
Mining	4	
Agriculture	4	10
Astronomical Physics	2	

Mathematics and Mechanical Drawing, £3 per term. Geometrical Drawing £3 per session. Freehand Drawing, £1 per term.

The fees for the first two years amount to about £75, and for the remainder of the course for the Associateship they vary from £30 to about £40.

Both the private and the State-aided students are required to furnish themselves with certain instruments and apparatus before the commencement of the courses. These are enumerated in the syllabuses of the several subjects.

Officers of the Army, Navy, and Civil Service, recommended by their respective Departments, are admitted to the Lectures and Laboratories at half the foregoing charges.

Associates of the Normal School of Science or of the Royal School of Mines have the privilege of free admission to the Library and to all the courses of lectures.

Science teachers actually engaged in teaching who are registered by the Science and Art Department as qualified to earn payments for teaching Science may attend any course of lectures on the payment of £1.

Several valuable Exhibitions, Scholarships, and Prizes are attached to the studentship.

Summer Courses for Teachers.—Short courses of instruction are given annually, about July, in different branches of science for the benefit of teachers of science schools in the country. The courses last three weeks. About 200 teachers are admitted to them, and they receive 3rd class railway fare to and from South Kensington, and a bonus towards their incidental expenses of £3 each. (See Science Directory.)

Working Men's Lectures.—Three courses of evening lectures for working men will be given during the session in Astronomy, Chemistry, and Mechanics. The admission to each course of six lectures will be 6d. The number of tickets is limited by the size of the lecture theatre.

**UNIVERSITY COLLEGE OF WALES,
ABERYSTWYTH.**

Professor.—H. Ll. Snape, D.Sc. (Lond.), Ph.D. (Göttingen), F.I.C.

Demonstrator.—A. W. Warrington, M.Sc. (Vic.), F.I.C.

The College is open to male and female students above the age of sixteen years. The Session commences on Monday, September 29, on which day all Students will be expected to meet the Professors in the Library of the College.

Lecture Courses.—(1) Matriculation Course; two lectures weekly during the Lent and three during the Easter Term. (2) Intermediate Science Pass Course; three lectures weekly during the Lent and Easter Terms. For those Students who have selected Physics or Botany instead of Chemistry at the Matriculation Examination, an Introductory Course of three lectures weekly will be delivered during the Michaelmas Term. (3) Intermediate Science Honours Course; two lectures weekly during the Lent and Easter Terms. (4 and 5) B.Sc. Pass and Honours Courses; each three lectures weekly throughout the Session.

Laboratory Courses.—The Laboratory is open daily from 10 a.m. to 1 p.m., and from 2 to 5 p.m., except on Saturdays. Classes for the Systematic Study of Qualitative and Quantitative Analysis will be formed, and Special Courses will be arranged for those who intend to follow Medicine or Pharmacy, or any one particular branch of Applied Chemistry, always provided that such Students possess the requisite knowledge of Theoretical Chemistry. The hours will be arranged to suit the requirements of the individual Student.

Students intending to proceed to the M.B. or B.Sc. Degree of the University of Edinburgh may count one or two years' residence respectively spent at this College.

Fees.—The Fee for the whole Session, if paid in advance, is £10; if paid by Single Terms, for the first term of attendance in each Session, £4; for the second term, £3 10s.; for the third term, £3. These composition fees enable the Student to attend any or all the Classes of the College, with the exception that a small extra fee is charged for Laboratory Instruction. Thus, for Practical Chemistry, the additional fee is, for six hours' work per week, 10s. per term, and for twelve hours, 20s. per term.

The fees for those who desire to spend several days weekly in the laboratory may be learned on application to the Registrar. Fee for a single Lecture Course £1 per term.

Scholarships and Exhibitions varying in value from £10 to £40 per annum will be offered for competition at examinations which commence on September 17, and exhibitions are awarded at the end of the Session on the results of the class examinations.

The Chemical Laboratories in connection with this College have been recently built, and are fitted with every convenience for the prosecution of chemical studies.

UNIVERSITY COLLEGE OF NORTH WALES, BANGOR.

Chemistry.—Professor, James J. Dobbie, M.A., D.Sc. Demonstrator, George McGowan, Ph.D., F.R.S.E.

Physics.—Professor, Andrew Gray, M.A., F.R.S.E. Demonstrator, David M. Lewis, M.A.

The Session opens September 30th, 1890. All regular classes are open to men and women students above the age of 16 years. The following Courses of Lectures will be given.

Matriculation Course.—Subjects: Those prescribed for the London University Matriculation Examination. A class for revision of Matriculation Work will be held during the Summer Term. Fee for the Term, £1 1s.

Intermediate Course.—Elementary Physical Chemistry. Fee for the Term, £2 2s.

B.Sc. Course.—Organic Chemistry. Fee for the Session, £3 3s.

Medical Course.—Inorganic and Organic Chemistry. Fee for the whole Course, £4 4s.

Agricultural Chemistry.—Fee, £1 1s.

Laboratory Courses.—The laboratory is open on five days of the week from 10 a.m. to 4 p.m. for instruction in Chemical Analysis and in the Application of Chemistry to Medicine and the Industrial Arts. Fees: six hours per week, £1 1s. per Term; twelve hours, £2 2s.; eighteen hours, £3 3s.; twenty-four hours, £4 4s.

A Committee has been appointed to frame a complete scheme of Agricultural Instruction for North Wales, and the College has received a grant of £400 from the Board of Agriculture. Three Dairy Schools in connection with the College have been established in Welshpool, Denbigh, and Bangor, and an Agricultural Department will be opened next session, in which students may receive a complete training in Agricultural Science.

UNIVERSITY COLLEGE OF SOUTH WALES AND MONMOUTHSHIRE.

Professor.—C. M. Thompson, M.A., D.Sc., F.C.S.

Demonstrator.—G. S. Turpin, M.A., D.Sc.

The Session commences October 6th, and terminates in June, and is divided into three terms.

The Junior Course (delivered during the Michaelmas term only) consists of about 55 lectures, and will cover the subjects prescribed for the London University Matriculation examination. Fee, £2 2s. A revision class is held in the Summer term.

The Intermediate Course consists of 90 lectures in continuation of the Junior Course, and, together with laboratory practice, will cover the subjects required for the Intermediate Examination in Science and the Prel. Sci. (M.B.) Examination of the University of London. Fee £3 3s.

The Senior Course includes some 90 lectures devoted to Organic Chemistry; Fee, £3 3s.

An Elementary Organic Course of 10 lectures, and a course of 30 lectures on Qualitative and Quantitative Analysis will also be given.

In the laboratory each student works independently, so that the course of study may be adapted to the requirements of the individual. Hours, 9 to 1 and 2 to 4.30; Saturday, 9 to 1. Fees—Six hours per week, £3 3s. per session; twelve hours, £2 2s. per term; eighteen hours, £3 3s. per term; twenty-four hours £4 4s. per term.

Professors Thompson and Parker are recognised by the Universities of Edinburgh, Glasgow, and Aberdeen as teachers in Chemistry and Natural History respectively, so that registered Medical Students can spend one year of their course at the University College, Cardiff. The College is also recognised as an institution at which two years of the course for the degree of Bachelor of Science of the University of Edinburgh may be spent.

Students by making a payment of £10 at the commencement of each session may compound for all lecture fees for the whole session. Laboratory fees are not included in the composition fee.

At the entrance examination in September, and the annual examination in June, several scholarships and exhibitions are awarded. Great importance is attached to special excellence in one subject.

The College Prospectus, and also further information as to scholarships, may be obtained from the Registrar.

A Hall of Residence for Female Students is attached to the College.

UNIVERSITY COLLEGE, BRISTOL.

Professor of Chemistry.—Sydney Young, D.Sc.

Lecturer.—Arthur Richardson, Ph.D.

The session 1890-91 will begin on October 1st. Lectures and classes are held every day and evening throughout the Session. In the Chemical Department lectures and classes are given in all branches of theoretical chemistry, and instruction in practical chemistry is given daily in the chemical laboratory. The department of experimental physics includes various courses of lectures arranged progressively, and practical instruction is given in the physical and electrical laboratory. The Department of Engineering and the Constructive Professions is designed to afford a thorough scientific education to students intending to become engineers, or to enter any of the allied professions, and to supplement the ordinary professional training by systematic technical teaching. This department includes courses specially arranged for students intending to become civil, mechanical, electrical, or mining engineers, surveyors, or architects. Those who attend the mechanical engineering course enter engineering works during the six summer months, and, in accordance with this scheme, various manufacturing engineers in the neighbourhood have consented to receive students of the College into their offices and workshops as articulated pupils at reduced terms. Medical education is provided by the Bristol Medical School, which is affiliated to the College. Several Scholarships are tenable at the College. Full information may be obtained of the Secretary.

DAY LECTURES.

Inorganic Chemistry.

The Course treats of the principles of Chemistry, and of the Chemistry of the Non-Metals and Metals.

Lectures will be given daily at 10 and 11 o'clock.

Organic Chemistry.

This Course will relate to the more important groups of the Compounds of Carbon.

Lectures will be given during the Second Term on Tuesdays and Thursdays at 10 o'clock; during the Third Term on Mondays, Wednesdays, and Fridays at 10 o'clock. Fee, £3 3s.

Practical Chemistry.—Laboratory Instruction.

The Laboratory will be open daily from 10 a.m. to 5 p.m., except on Saturdays, when it is closed. Instruction will be given in the Laboratory in all branches of Practical Chemistry, including Qualitative and Quantitative Inorganic and Organic Analysis, the preparation of Chemical Products, and Inorganic and Organic Research. Special facilities will be afforded to those who desire to study Practical Chemistry as applied to the different processes employed in the Arts and Manufactures, and to Scouring, Bleaching, and Dyeing. The Laboratory is under the immediate supervision of the Professor and the Lecturer. Fees in Guineas—

	5 Days a Week.	4 Days a Week.	3 Days a Week.	2 Days a Week.	1 Day a Week.
Per Session ..	15	13	10	7½	5
„ Two Terms ..	11	9	7½	5½	4
„ One Term ..	6	5	4	3	2
„ Month ..	3	2½	2	1½	—

Students may arrange to divide their days of laboratory work into half-days.

Analytical Course.

A Course of Lectures on the Principles of Qualitative Analysis will be given during the First and Second Terms; it is intended to supplement the instruction in Practical Chemistry. All first year's Laboratory Students are expected to attend this Course. The Lectures will be given on Mondays at 10 a.m. Fee, £1 1s. for the two Terms.

Photographic Chemistry.

Instruction will be given in the Photographio Laboratory in Dry-plate Processes, Printing, Enlarging, and in Microscopical Photography, at times to be arranged with those who enter. Fee, £3 3s. for each Term.

Chemical Scholarship.—Among others, a Chemical Scholarship of £25 is offered for competition.

EVENING LECTURES.

Two courses of Lectures will be delivered during the First and Second Terms; they will be devoted to the consideration of the general Principles of Chemistry and Chemical Physics and the Chemistry of Non-Metallic Elements. Special attention will be paid throughout to those products which have a practical application in the Arts and Manufactures.

A course of Lectures will also be delivered on Photographic Chemistry. Fee for each course, 7s. 6d.

With the approval of the Council of the Institute of Chemistry students desiring to qualify as Associates may pass through the requisite amount of study at this College, which has also been approved as a centre for the Practical Examination of the Institute.

MASON SCIENCE COLLEGE, BIRMINGHAM.

Professor.—W. A. Tilden, D.Sc. Lond., F.R.S.

Assistant Lecturers.—W. W. J. Nicol, M.A., D.Sc. Edin., and Thomas Turner, Assoc.R.S.M., F.C.S.

Demonstrator.—T. Rhymer Marshall, D.Sc. Edin.

The Session will be opened on Tuesday, September 30th 1890.

Elementary Course.

Forty Lectures adapted to the requirements of beginners will be given in the Winter and Spring Terms. A Second Course of Twenty Lectures, having reference only to the subjects included in the syllabus of the Matriculation Examination of the University of London, will be given in the Summer Term. Lecture days—Wednesdays and Fridays at 11.30, Thursdays at 3.30.

Persons entirely unacquainted with Chemistry are recommended to attend the first of these Courses before entering for the General Course, which commences in October. Candidates for the Matriculation Examination of the University of London are advised to attend both these Courses.

General Course.

The General Course of Lectures on Chemistry will be found useful by Students who are afterwards to become Engineers, Architects, Builders, Brewers, or Manufacturers (such as Metallurgists, Alkali, Soap, Manure, Glass, or Cement Makers, Bleachers and Dyers, &c.)

Students preparing for the Intermediate Examination in Science and Preliminary Scientific (M.B.) Examination of the University of London should attend the Lectures on Inorganic Chemistry (Winter and Spring Terms).

Candidates for B.Sc. and Intermediate Examinations in Medicine will in general require only that part of the course (Summer Term) which relates to Organic Chemistry.

The full course, extending over three terms, will also

satisfy the requirements of Students preparing for the Associateship of the Institute of Chemistry, so far as attendance at lectures on General and Theoretical Chemistry is concerned.

1. From October to March (Winter and Spring Terms). About eighty lectures on Inorganic Chemistry and Chemical Philosophy will be given on Mondays, Tuesdays, Wednesdays, and Thursdays, at 9.30 a.m. Fee, £5 5s. for the course.

2. April to June (Summer Term). About thirty lectures will be given on Elementary Organic Chemistry, or the chemistry of the most important series of carbon compounds. This course will include all the subjects required for the Intermediate Examination in Medicine of the University of London. Lecture Days—Monday, Tuesday and Wednesday at 9.30 a.m. Fee, £1 11s. 6d.

Advanced Course.

An Advanced Course for the study of Theoretical Chemistry and those parts of the subject which are required for the degree of B.Sc. in the University of London will meet once or twice a week. Fee for the session, £3 3s.

Laboratory Practice.

The College Laboratory is open daily from 9.30 to 5, except on Saturdays, when it will be closed at 1 p.m.

Candidates for Intermediate Examination in Science, Preliminary Scientific (M.B.), B.Sc., and Intermediate Examination in Medicine of the University of London, may obtain in the Laboratory of the College the instruction necessary. The three months Course of Practical Chemistry for the B.Sc., Edinburgh, in the department of Public Health, may be taken in the Mason College Laboratory. Fees:—

	All day.	Three hours per day.
One Term	7 guineas	4½ guineas.
Two Terms	13 „	8½ „
Three Terms	18 „	12 „

A Course of short demonstrations and exercises is given by the Professor or one of his Assistants once a week. All first-year Students are required to attend, unless exempted for special reasons by the Professor. No Fee.

Metallurgy.

Three Courses of Ten Lectures will be given on the Principles and Practice of Metallurgy. Fee, 10s. 6d. for each course. A more advanced course upon selected subjects is also given by Mr. Turner, the Lecturer in Metallurgy.

There is a separate laboratory for metallurgical students in which provision is made for instruction in assaying, &c.

Evening Classes.

Several Courses of Evening Lectures are arranged during the Winter and Spring Terms of each session. The subjects are treated in a less technical manner and the fees are nominal.

Excursions.

During previous Sessions permission has been obtained to visit some of the great factories in or near Birmingham, in which chemical and metallurgical industries are carried on. Students have thus had most valuable opportunities of gaining a practical acquaintance with some branches of Applied Science. The privilege thus courteously granted by several manufacturers will, it is hoped, be enjoyed in every future Session. The excursions will be conducted by the Professor.

BRADFORD TECHNICAL COLLEGE.

CHEMISTRY AND DYEING DEPARTMENT.

Professor.—Christopher Rawson, F.I.C., F.C.S.

Demonstrator.—Percy Kay.

Lecturer on Botany and Materia Medica.—William West, F.L.S.

The school year is divided into three terms. The

Session began on September 15th and terminates on July 10th. The course of instruction extends over two years, and embraces Lecture Courses on Inorganic and Organic Chemistry, the technology of the textile fibres, mordants, natural and artificial colouring matters, technical analysis, and laboratory practice in analytical chemistry, chemical preparations, and dyeing. Inclusive fee, £4 4s. per term.

During the first and second terms Evening Classes are held for the benefit of persons engaged during the day and for pharmaceutical students.

ROYAL AGRICULTURAL COLLEGE, CIRENCESTER.

CHEMICAL DEPARTMENT.

Professor.—Prof. E. Kinch, F.C.S., F.I.C.

Assistants.—A. G. Bloxam, F.C.S., A.I.C., and W. James.

Systematic courses of Lectures are given on the various branches of Chemistry in its relation to Agriculture, illustrated by experiments, and by the collections in the College Museum. They comprise the laws of Chemical Combination and the general Chemistry of mineral bodies, and of the more frequently occurring bodies of organic origin, with the relationships of their leading groups; and, finally, the applications to practical operations of the Chemistry of the atmosphere, of soils and manures, of vegetation and stock feeding, and of the processes and products of the dairy.

In the Laboratory practical instruction is given in the construction and use of apparatus and in Chemical manipulation and analysis, both qualitative and quantitative. After studying the simple operations and the properties of the commonly occurring substances, the Students are taught to analyse a series of compounds, and apply the knowledge thus obtained to the analysis of manures, soils, waters, feeding stuffs, dairy products, and other substances met with in the ordinary course of Agricultural practice. Chemico-agricultural researches are undertaken by the senior Students under the direction of the Professor and his Assistants.

VICTORIA UNIVERSITY. THE YORKSHIRE COLLEGE, LEEDS.

Professor of Chemistry.—Arthur Smithells, B.Sc. Lond., F.C.S.

Assistant Lecturers.—C. H. Bothamley, F.C.S., and Herbert Ingle, F.C.S.

The Session begins October 7, 1890.

Lecture Courses.

1. General Course of Chemistry.—Monday, Wednesday, and Friday, at 11.30 a.m., from October to the end of the second term, and during part of the third term. Fee for the Course, £4 4s.

2. Inorganic Chemistry.—First years' Honours Course, Non-metals. Monday, Wednesday, and Friday, at 9.30 a.m. Fee, £3 13s. 6d.

3. Inorganic Chemistry.—Second years' Honours Course, Metals. Tuesday, Thursday, and Saturday at 9.30 a.m. Fee, £3 13s. 6d.

4. Organic Chemistry.—Tuesday and Thursday at 11.30 p.m. Fee £2 12s. 6d.

5. Theoretical Chemistry.—Advanced Course. Fee, £1 11s. 6d.

6. Chemistry as Applied to Coal Mining.—Tuesday during the First Term, at 4 p.m.

7. Photographic Manipulation.—A Course of Ten Lessons will be given on Fridays, from 2 to 5, during the Third Term, with special reference to dry plate processes and silver and platinum printing. Fee, £1.

Laboratory Courses.

The College Laboratory will be open daily from 9 a.m. to 1 p.m., and from 2 to 5 p.m., except on Saturdays, when it will close at 1 p.m.

Fees for the Session.—Students working six days per week, £18 18s.; five, £16 16s.; four, £14 14s.; three, £12 12s.

Class in Practical Chemistry, Saturday mornings, from 9.30 to 12.30. Fee £1 11s. 6d.

Practical Chemistry for Medical Students.—On Tuesday and Thursday, from 10 to 12 a.m., from May to July.

Evening Classes.

A Course of twenty Lectures by Mr. C. H. Bothamley, on the Elements of Inorganic Chemistry (the Non-Metals) will begin during the first and second Terms, on Wednesdays, at 7.30 p.m., beginning October 9. Fee, 10s. 6d.

Dyeing Department.

Professor.—J. J. Hummel, F.C.S.

This Course extends over a period of three years, and is intended for those who wish to obtain a full scientific and practical education in the art of dyeing. It is suitable for those who purpose in the future to take any part in the direction of the operations of dyeing or printing of textile fabrics, e.g., the sons of manufacturers, calico printers, managers, master dyers, &c.

Several valuable Scholarships are at the disposal of the College, viz., the Cavendish, Salt, Akroyd, Brown, Emsley, Craven, and Clothworkers' Scholarships, and the Leighton Trustees' Exhibition, and one of the new 1851 Exhibition Scholarships.

UNIVERSITY COLLEGE, LIVERPOOL.

Professor.—J. Campbell Brown, D.Sc.

Demonstrators.—C. A. Kohn, B.Sc., Ph.D., and T. L. Bailey, Ph.D.

Assistant.—H. H. Frousell.

The Session commences October 2nd.

The Classes are arranged to suit the requirements of candidates for the Ordinary B.Sc. Degree, for Chemistry Honours, or for the D.Sc. Degree in Victoria University; for Degrees in Medicine of Victoria, London, and Edinburgh; for a special Technological Certificate of University College; and for those studying Chemistry as a preparation for professional, technical, or commercial life. The Classes qualify for the Fellowship of the Institute of Chemistry of Great Britain and Ireland, and other Examination Boards.

Lecture Courses.

General Elementary Course on the principal non-metallic elements and the most important metals, the principles of Chemical Philosophy, and an introductory sketch of Organic Chemistry.

Course A.—Non-metals.

Course B.—Metals.

Course C.—Organic Chemistry.

Course D.—Physical Chemistry.

Course E.—History of Chemistry and of the Development of Modern Chemical Philosophy.

Course F.—Technological Chemistry: Lectures on Technology are given in connection with Laboratory work at hours to be arranged. The subjects are varied in different years. (1) Alkali and Allied Manufactures. (2) Copper, Iron, and Steel. (3) Distillation of Coal, and Tar Industries. (4) Fuel. (5) Chemistry Applied to Sanitation. (6) Technical Gas Analysis. (7) Spectroscopy.

Practical Classes.

(1) Junior. (2) Intermediate: Qualitative Analysis of Inorganic Substances and of some of the more common Organic Substances. (3) Special: For the Conjoint Board of Colleges of Physicians and Surgeons. (4) Senior: Practical Organic (Advanced Medical Class). (5) Practical Exercises on Technology, Pharmaceutical Chemistry, Sanitary subjects, Adulterations of Drugs and of Food, Examination of Water and Air, of Animal Secretions, Urinary Deposits, Calculi, and Poisons. (6) Quantitative Class: Course arranged to suit the requirements of the London University B.Sc. Examinations, Pass and Honours, and for Inter-mediate M.B. Honours.

Chemical Laboratory.

The Chemical Laboratories provide accommodation for every kind of chemical work.

TABLE OF FEES.

Per Week.	One Month.	One Term. Three Months.	Two Terms. Six Months.	Three Terms. One Session.
One day ..	—	£4	£6	£8
Two days ..	—	6	8	10
Three days..	£4	8	10	12
Four days ..	5	9	12	15
Five days ..	—	10	14	18

Students desirous of gaining a thorough theoretical and practical acquaintance with Technical Chemistry, or who intend to adopt Chemical work as a profession, must devote three or four years to special study.

Technological Curriculum.

First Year.—Chemistry, either the Elementary Course or Course A, according to the previous knowledge of the Student. Practical Classes 1 and 2. Mathematics and Mechanics. Engineering Drawing and Design (in this or the following year). French or German. Physics.

Second Year.—Chemistry—Courses A and B; Chemical Laboratory three days per week, and the Practical Organic Class during the Summer Term; Technological Chemistry, Course F. Physics, with laboratory work. Mathematics (intermediate). German. Intermediate B.Sc. Examination may be passed.

Third Year.—Chemistry, Lecture Course on Organic Chemistry, C, Lecture Course E, Technological Chemistry, Course F. Chemical Laboratory. Engineering, Mathematics, or Physics (advanced). The Final Examination for the Victoria B.Sc. may be taken, or the Examination for the associateship of the Institute of Chemistry.

Fourth Year.—Courses D and F; part of Course C. Any other Courses omitted in a previous year. Laboratory, five days per week. Students may finally choose a special subject either of research or of applied Chemistry. Three years study after passing the Preliminary Examination of Victoria University are required for the B.Sc. Degree in the Honours School of Chemistry.

Evening Classes.

Lectures will be given on the Chemistry of Photography, and Copper and its Manufacture.

The Sheridan Muspratt Chemical Scholarship of £50 per annum, tenable for two years, and a Sheridan Muspratt Exhibition of £25 per one year, will be awarded in December, 1891, on an Examination in subjects which are included in the first two years of the above curriculum. Other Scholarships, Entrance Scholarships, and Free Studentships are also available to Students.

The Prospectus containing full particulars may be obtained from F. and E. Gibbons, 19, Ranelagh Street, Liverpool, price 6d.; or from the Registrar, University College, Liverpool.

LIVERPOOL COLLEGE OF CHEMISTRY.

Principal.—George Tate, Ph.D., F.I.C., F.C.S.

The Laboratories are open daily from 10 to 5, excepting Saturdays, when they close at 1 p.m. The course of instruction is adapted to the requirements of students of Chemistry as a science, and in its applications to chemical and metallurgical industries. The fee for a three years' course of study is eighty guineas, or per session of three months eight guineas.

Prospectuses, containing full particulars of the day and evening classes, may be had on application at the College.

**DURHAM COLLEGE OF SCIENCE,
NEWCASTLE-ON-TYNE.**

Professor of Chemistry.—P. Phillips Bedson, D.Sc., F.C.S.

Assistant Lecturer and Demonstrator.—Saville Shaw, F.C.S.

The Session will commence on September 29th, 1890.

Junior Division: First Year Course.—This Course of Lectures will extend over the three terms of the Session, and is intended to serve as an introduction to the Science. The Lectures will be of an elementary character, and whilst framed to meet the requirements of First Year Students will also be serviceable to such as intend pursuing Chemistry in its various applications in the arts and manufactures, as, for instance, Brewing, Metallurgy, the Manufacture of Soda, Soap, Glass, &c. The subjects treated will include an exposition of the Principles of Chemistry, and a description of the preparation and properties of the chief Elementary Substances, both metallic and non-metallic, and their more important native and artificial compounds. The class will meet on Mondays, Wednesdays, and Fridays, at 11 a.m., and will commence on Wednesday, October 8th.

Senior Division: Second Year Course.—A Course of about ninety Lectures will be given throughout the Session the subject of which will be Organic Chemistry, or the Chemistry of the Carbon Compounds. This class will meet on Tuesdays and Thursdays, at 11 a.m., and will commence on Tuesday, October 9th.

Fee, for either Course, £3 10s. for the Session.

Advanced Classes will be formed for the study of Inorganic, Organic, and Theoretical Chemistry. Fee for each course, £2 2s.

A Lecture Course in Analytical Chemistry will be given on Mondays, at 3 p.m., commencing October 13th. Fee, £1 1s.

Practical Chemistry.—The Laboratory is open from 10 a.m. to 1 p.m., and from 2 to 5 p.m., except on Saturdays, when it closes at 1 p.m. **Laboratory Fees.**—Students working six days per week, £5 5s. per term; alternate days, £3 3s.; one day per week, £1 1s.

Courses of Study.—Students will be divided into two classes:—(1) Regular, or Matriculated Students; and (2) Non-Matriculated Students. Regular Students will be required to follow such a course of study in the subjects professed in the College as will enable them to pass the Examinations for the title of Associate in Physical Science. Non-Matriculated Students will attend such classes as they may select. Every candidate for admission as a matriculated student must pass an examination on entrance, in reading, writing from dictation, English or Latin Grammar, arithmetic (including decimals), and geography. Registered students in medicine are exempted from this examination, or students who produce a certificate of having passed either of the two following examinations:—

1. Durham Examination for certificate of proficiency in General Education, held in March and September.
2. Durham Examination for Students in Arts in their first year, or any examination of a similar nature that may be accepted by the Council.

Associateship in Physical Science.—Every candidate for the Associateship in Physical Science will be required to satisfy the examiners in three, at least, of the five subjects,—Mathematics, Physics, Chemistry, Geology, and Biology,—in an examination, to be held at the beginning of his second year.

Exhibitions.—Three Exhibitions of the value of £25, £15, and £10 respectively will be awarded in October next to Candidates desirous of attending the first year course of study in the College.

The examination will be held at the College, and will commence on Monday, September 29th.

Evening Lectures.—Courses of Evening Lectures will be given, with a Practical Class for Laboratory instruction.

Two Exhibitions of £15 each will be awarded at the next examination of "Persons not members of the University," which will be held at Durham in March next.

Several other valuable Scholarships are available for students.

OWENS COLLEGE,
VICTORIA UNIVERSITY, MANCHESTER.

Professor and Director of the Chemical Laboratory.—Harold B. Dixon, M.A., F.R.S.

Professor of Organic Chemistry.—C. Schorlemmer, LL.D., F.R.S.

Demonstrators and Assistant Lecturers.—Julius B. Cohen, Ph.D., and George H. Bailey, D.Sc., Ph.D.

Assistant Demonstrators.—A. Harden, Ph.D., and G. Fowler, B.Sc.

Lecturer in Dyeing and Printing.—Ernest Bentz.

The Session begins on October 7, 1890, and ends on June 26, 1891.

The instruction is given by means of Experimental Lectures and Tutorial Classes. The Chemical Classes form part of the Courses for Chemistry in the University.

General Chemistry.

General Chemistry Course.—Tuesdays, Thursdays, and Saturdays, at 9.30, during the two Winter Terms.

Introduction to Organic Chemistry.—Wednesdays and Fridays, at 10.30, during Lent Term.

These courses are intended for Medical Students and others beginning the study of chemistry.

First Year Honour Course.—Mondays, Wednesdays, and Fridays, 3.30 p.m., during the two Winter Terms. The Non-Metals.

Second Year Honour Course.—Mondays, Wednesdays, Fridays, 9.30, during the two Winter Terms. The Metals.

Third Year Honour Course.—Tuesdays, 11.30. Physical Chemistry.

Organic Chemistry (Honours).—Tuesdays, Thursdays, Saturdays, 9.30, during the Session.

History of Chemistry and Chemical Philosophy.—Thursdays, 10.30, during the Session.

An ordinary degree of B.Sc. in Chemistry, Victoria University, may be taken at the College in either two or three years, according as the student passes the Preliminary Examination on joining the College or whether he takes a year to prepare for that examination. The Degree of B.Sc. with Honours in Chemistry can be taken in three years, and the College Certificate in Technological Chemistry may be taken in the same time.

A number of important Exhibitions, &c., are available to students.

Technological Chemistry.

First Course.—Sulphuric Acid and Alkali Manufactures. General Principles of Chemical Engineering.

Second Course.—The Chemistry of Fuel. The Manufacture of Illuminating Gas and Gaseous Fuel.

Third Course.—The Chemistry of Coal Tar.

Fourth Course.—Natural and Artificial Dye-stuffs.

Fifth Course.—Calico-printing.

Certificates in Applied Chemistry.

The course extends over a period of three years, and comprises systematic instruction by means of lectures and practical work in the laboratories.

Before admission to the first year's course students are required to give such evidence of elementary knowledge of Mathematics and Chemistry as shall be considered satisfactory by the Senate.

The first year's course is the same for all students working for the certificate.

In the second and third years a choice may be made between Inorganic and Organic Chemistry. By this division of the subject a student wishing to apply himself specially to the inorganic side of the science, may attend during his second year the Honours course in Metals, and courses on Geology or Mineralogy, and during his third year, courses on Metallurgy and on Geology or Mineralogy; while a student wishing to apply himself specially to the organic side of the science, may attend during his second and third years the Honours Course on Organic Chemistry, and courses on the Coal Tar Colours and on Dyeing and Printing.

Part of the Laboratory practice in the second and third

years will consist in the examination and analysis of raw materials, products from chemical works, &c., in connection with the special courses of lectures on Applied Chemistry. In the Chemistry and Physics laboratories the practical work in the second year will be arranged in accordance with the branch of Chemistry selected by the candidate.

In the third year the student, if sufficiently advanced, will be set to work on some analytical process or problem in Applied Chemistry, under the direction of the teaching staff.

UNIVERSITY COLLEGE, NOTTINGHAM.

DEPARTMENT OF CHEMISTRY.

Professor of Chemistry.—Frank Clowes, D.Sc. Lond., F.I.C., F.C.S.

Demonstrators.—J. B. Coleman, A.R.C.Sc. Dublin, F.I.C., F.C.S., and R. L. Whiteley, F.I.C., F.C.S.

Lecturers.—J. B. Coleman, F.I.C., F.C.S.; R. L. Whiteley, F.I.C., F.C.S.; C. Haydon White, M.R.C.S.; J. W. Carr, M.A.; and F. R. Sargeant.

The Classes of the College are open to students of both sexes above sixteen years of age.

The dates of commencement and end of Terms in the Session 1890-91 will be as follows:—First Term, October 6th to December 20th; Second Term, January 19th to April 4th; Third Term, April 20th to July 4th.

Lecture Courses.—The Chemistry Day Lectures extend over three years. In the first year a student enters for the course on Non-Metals for the first two terms and for Elementary Organic Chemistry in the third term. In his second year he takes the course on Metals for the first two terms, and Advanced Organic Chemistry in the third term. In his third year he attends a course on Applied Chemistry during the first two terms. Fee for Day Lectures and Classes, 50s. for the session of three terms: Non-Metals or Metals 42s.; Organic Chemistry (one term) 21s.; Applied Chemistry, 30s.

Demonstrations and Lectures on Analytical Chemistry will be given in the day and evening, and should be attended by all students.

A Chemical Calculation Class is also held. Fee per Term, 2s. 6d.

Students may qualify themselves by attendance at these lectures and classes for the Examinations of the Universities of London, Cambridge, or Oxford, and for the Medical Examinations of the Royal College of Surgeons and of the Universities of Cambridge and Edinburgh: they may also obtain instruction in Chemistry for technical or other purposes, and can enter for a full Chemical Engineering Curriculum. Special attention is given to the requirements of candidates for the Associateship of the Institute of Chemistry.

Practical Chemistry.—The chemical laboratory is open every day except Saturday from 10 to 5, on Saturday from 10 to 12, and on Tuesday and Thursday evenings from 7 to 9. Each Student works independently of other Students at a course recommended by the Professor. Instruction is given in general Chemical Manipulation and in Qualitative and Quantitative Analysis; and students are enabled to work out the applications of Chemistry to Pharmacy, Dyeing, Agriculture, Brewing, Iron and Steel, Tanning, and other Manufacturing Processes. Fees.—For one term, £6; for the session, £15; for day students for six hours weekly 40s., and 5s. extra for each additional hour per week. For evening students, 10s. for one evening per week, and 20s. for two evenings per week, per term.

Courses of Technical Chemistry Lectures are also given on Dyeing and Bleaching, Brewing, Bread-making, Gas Manufacture, and on other processes of applied Chemistry.

A *Pharmaceutical Curriculum* extending over three Winter Sessions, includes Pharmaceutical Chemistry (lectures and laboratory work), Pharmaceutical Botany (lectures and class work on specimens), Materia Medica (lectures and use of specimens), and Practical Dispensing,

taught by demonstrations and practical work in the laboratory.

Government Lectures and Classes.—Evening Lectures and Laboratory instruction will be given by the Demonstrators of Chemistry to Students who intend to present themselves for Examination by the Government Science and Art Department in May next. Inorganic, organic, and practical chemistry, agricultural chemistry, and metallurgy will be taught in the elementary, advanced, and honours stages, each of which commences at the beginning of the College Session in October. Fee for each Lecture Course, 2s. 6d.; for each Laboratory Course, 10s.

Full information concerning all College Classes is given in the College Prospectus, price one penny.

FIRTH COLLEGE, SHEFFIELD.

Professor of Chemistry.—W. Carleton Williams, B.Sc., F.C.S.

Demonstrator and Assistant Lecturer.—L. T. O'Shea, B.Sc., F.C.S.

The Session will commence on Friday, October 3.

First Year's Course.—Chemistry of the Non-Metallic Elements. Monday, Wednesday, Thursday, from 10 to 11 a.m. Fee, £3 3s.

Second Year's Course.—Chemistry of Metals. Tuesday, Wednesday, and Thursday, from 10 to 11 a.m. £3 3s.; or for the First and Second Courses, £5 5s.

Third Year's Course.—Organic Chemistry, on Wednesday, from 9 to 10, and Saturday, from 10 to 11. Fee, £2 2s.

A Course of Lectures is arranged for Medical Students, with a special class in Qualitative Analysis.

Laboratory.—Working hours to be arranged between Professor and Students.

Sessional Fees for Day Students:—Six hours per week, £5 5s.; Nine, £7; Twelve, £8 8s.; Eighteen, £11 5s.; Twenty-four, £14; Thirty-two, £17.

Day Students may not enter for less than six hours a week. Students joining the Laboratory at Christmas will be charged two-thirds and at Easter one-third of the Fees for the whole Session.

Fees for short periods (working thirty-two hours per week):—For one month, £3 3s.; two months, £5 5s.

An arrangement has been entered into with the Science and Art Department, South Kensington, which will enable Science Teachers to work in the Chemical Laboratory for six or twelve hours a week on payment of one-quarter of the usual fee, the Department being willing to pay the remainder under certain conditions, of which full information may be obtained on application to the Registrar.

Evening Classes.—Lectures, Wednesday, 8 to 9. Laboratory instruction, Monday and Wednesday, 6 to 9. Sessional Fee, one evening per week, £1 10s.; two, £3; or Lecture Class and Laboratory, on Wednesday evening, £1 10s.

UNIVERSITY COLLEGE, DUNDEE.

(UNIVERSITY OF ST. ANDREWS).

Professor.—Percy F. Frankland, Ph.D., B.Sc., F.I.C., &c.

Assistant Lecturers and Demonstrators.—F. J. Hambly, F.C.S., and J. R. Appleyard, F.C.S.

The eighth session of the College will be opened on October 14th, 1890.

The Lectures and Laboratory practice in this University are recognised by the Royal College of Physicians and Royal College of Surgeons, London, and by the Royal College of Surgeons, Edinburgh, and for degrees in Science and Medicine by the Universities of Edinburgh, Glasgow, and Aberdeen.

The courses are suitable for the Degrees of the London University and for the Civil Service appointments, and will also satisfy the requirements of students in Pharmacy, and of students who intend to become candidates for the Associateship of the Institute of Chemistry, so far as at-

tendance at lectures on General and Theoretical Chemistry is concerned.

Lecture Courses.

The object of these courses will be (1) to give systematic instruction in the general principles of the science, and information regarding the elements and their more important compounds; (2) to show how this knowledge may be usefully applied in the Arts and Manufactures.

A course of instruction in Practical Chemistry in the Laboratory is recommended to all who wish to obtain a sound knowledge of the science, and the methods of applying it to useful purposes—the duration of such course depending upon the special wants of the student.—The Professor will be glad to give any information to intending students.

First year's lecture course: Inorganic Chemistry (Non-Metals) (90 lectures), Monday, Wednesday, and Friday, from 10 to 11 a.m.; fee, £3 3s.

Second year's lecture course: 1. Inorganic Chemistry (Metals) (40 lectures), Tuesday and Thursday, from 9 to 10 a.m.; fee, £1 11s. 6d. 2. Organic Chemistry (50 lectures), Tuesday, Wednesday, and Thursday; fee, £1 11s. 6d.; fee for the entire year's course, £3 3s.

A Lecture Course on Analytical Chemistry will be given on Saturdays, from 9 to 10. Fee, £1 1s.

Courses of lectures will be given on Dyeing, Bleaching, and the Chemistry of the Textile Fibres, with practical instruction in the Laboratory and Dyehouse. In connection with this Department there is an extensive Technical Museum, containing a large collection of specimens illustrating many branches of Applied Chemistry, and particularly the local industries.

Practical Chemistry (Laboratory).

The aim of the Laboratory Courses is to make the student practically acquainted with the science, so that he may conduct chemical analysis and original research, and generally to fit him for applying the science to the Arts, Manufactures, Agriculture, and Public Health. The courses are also arranged for students preparing for their medical and pharmaceutical examinations. A three months' course of Practical Chemistry for the B.Sc., Edinburgh, in the department of Public Health, may be taken in the College Laboratory.

The Laboratory will be open for students daily from 9 a.m. to 4 p.m., except on Saturdays, when it will be closed at 3 p.m. Each student on entering will be allowed to arrange his working hours to suit his own convenience, but will be required to keep the hours when once fixed.

Sessional Fees for Day Students:—The fees for both sessions are—for six hours per week, £3 3s.; each additional hour per week, 10s. 6d. Day students may not enter for less than six hours a week. Students joining the Laboratory during the second term will be charged two-thirds, and during the third term one-third of the above fees. Students may also enter for short periods, working every day in the week at the following fees:—For one month, £2 12s. 6d.; for two months, £5 5s.; for three months, £7 7s.

Evening Classes.—Courses of Lectures and Practical Laboratory instruction.

Forster Research Scholarship.

This scholarship, of the value of £30, is awarded annually to the best student on the condition that he devotes himself during the ensuing year to original research in the College Laboratory.

UNIVERSITY OF EDINBURGH.

Professor.—A. Crum Brown, F.R.S.E.

Two degrees in Science are conferred by the University of Edinburgh, viz., Bachelor of Science (B.Sc.) and Doctor of Science (D.Sc.). Both these degrees are conferred in Physical and Natural Science, in Public Health, and in Engineering.

Candidates for degrees in Physical and Natural Science

must pass a preliminary examination in English, Latin, Arithmetic, the Elements of Mathematics, and the Elements of Mechanics, and in at least two of the following subjects:—Greek, French, German, Higher Mathematics, Natural Philosophy, Logic, and Moral Philosophy.

The First B.Sc. Examination embraces Mathematics, Natural Philosophy, Chemistry, Zoology, including Comparative Anatomy, and Botany. The Second B.Sc. Examination the Higher Mathematics, Experimental Physics, Chemistry, Zoology, Botany, Physiology, and Geology, including Palæontology and Mineralogy.

The D.Sc. Examination embraces Mathematics, Natural Philosophy, Applied Mathematics, Experimental Physics, Practical Astronomy, Chemistry, Zoology and Comparative Anatomy, Animal Physiology, Botany, and Geology, including Palæontology and Mineralogy.

GLASGOW AND WEST OF SCOTLAND TECHNICAL COLLEGE.

The main objects of this College are to afford a suitable education to those who wish to qualify themselves for following any industrial profession or trade, and to train teachers for technical schools. It was founded by an Order in Council, dated 26th November, 1886, according to a scheme framed by the Commissioners appointed under the provisions of the Educational Endowments (Scotland) Act, whereby Anderson's College, the Young Chair of Technical Chemistry in connection with Anderson's College, the College of Science and Arts, Allan's Glen's Institution, and the Atkinson Institution were placed under the management of one governing body.

The Diploma of the College is awarded to Day Students who have attended prescribed courses of instruction and passed the necessary examinations. The ordinary courses extend over three years, but arrangements are made for advanced students continuing their studies in special departments.

Copies of the Calendar for 1890-91 may be had from Mr. John Young, B.Sc., the Secretary, 38, Bath Street, Glasgow, price by post, 1s. 4d.

UNIVERSITY OF ST. ANDREWS.

UNITED COLLEGE OF ST. LEONARD AND ST. SALVATOR.

Professor of Chemistry.—T. Purdie, B.Sc., Ph.D., Assoc. R.S.M.

The Session begins on October 29th. A Competitive Examination, open to intending Students of Arts or Science, for a number of Entrance Bursaries, ranging in value from £30 to £10 each per annum, will be held during the last week of October. Two Degrees in Science are conferred by the University of St. Andrews, viz., Bachelor of Science (B.Sc.) and Doctor of Science (D.Sc.), the regulations regarding which will be found in the "University Calendar."

Lecture Course.

A Lecture is delivered by the Professor of Chemistry, at 11 o'clock, on five days in the week throughout the Winter Session. The Course commences with the study of a few typical substances, forming an introduction to the discussion of Chemical Theory; the Non-metallic and Metallic Elements, with their chief compounds, are then considered; and the latter part of the Course is devoted to Elementary Organic Chemistry. Three Lectures weekly are of an elementary character, and are intended to be useful to Students of Arts who desire to study Chemistry as a branch of general education, or with the view of teaching it in schools; the remaining two Lectures weekly constitute a Supplementary Course, framed so as to meet the additional requirements of Candidates for the Degree of Bachelor of Science and of Medical Students.

Certificates are awarded on the results of separate examinations on the subjects of the general and supple-

mentary Lectures, and the "Forrester Prize" of about £13 is awarded to the best Student of the year.

Fee for the Session, £3 3s.

Laboratory Course.

A class in Practical Chemistry meets for two hours weekly, to which Students attending the Lectures are admitted without additional fee. The Course consists of a series of qualitative and quantitative experiments, designed to give the Student a practical acquaintance with the principles of Chemistry regarded as a subject of general education.

The Laboratory is also open during the Session from 10 a.m. to 4 p.m., for instruction in Chemical Analysis. The fee is £10 10s. for the Session. Shorter Courses of Practical Chemistry will be arranged to meet the requirements of Students who cannot give so much time to the subject, the fees for which vary according to the number of hours taken weekly.

Several free places in the Laboratory will be given to Students desirous of engaging in original work. Applicants must satisfy the Professor that their studies are sufficiently advanced to admit of them prosecuting experimental research.

QUEEN'S COLLEGE, BELFAST.

Professor.—E. A. Letts, Ph.D., F.R.S.E., F.C.S.

I.—*Chemistry.*—The lectures are delivered at 3 p.m., on the first five days of each week until the beginning of April, and on two days of each week after May 1st. The course is divided into three parts:—(1) Chemical Philosophy; (2) Inorganic Chemistry; (3) Organic Chemistry.

II.—*Advanced and Organic Chemistry.*—Lectures on these subjects are given from the beginning of the Session, on Tuesdays and Thursdays, at 10 a.m., until the beginning of April, and at 3 p.m. after May 1st.

III.—*Practical Chemistry.*—In this course the Students are instructed in the general methods of conducting Chemical Analyses.

IV.—*Laboratory Pupils.*—The Chemical Laboratory is open from November until the beginning of April, and from May 1st until the middle of July, on the first five days of the week, from 10 a.m. until 4 p.m. Students are admitted as working pupils on payment of a fee of £5 for the first period, or of £3 10s. for the second period (or for a single term).

QUEEN'S COLLEGE, CORK.

Professor.—Maxwell Simpson, LL.D., M.D. (Hon.), F.R.S., &c.

The Course of Theoretical Chemistry is divided into Inorganic and Organic Chemistry.

In the first part are discussed the Laws of Combination and Affinity, Molecular Chemistry, and the History of the Non-Metallic and Metallic substances.

In the Organic portion of the Course will be considered the subjects of Organic Analysis, Organic Series, Compound Radicals and Types, Metamorphosis of Organic Bodies, History of Special Animal and Vegetable Bodies.

In treating of the Laws of Chemistry, and the History of Inorganic and Organic Bodies those points will be chiefly dwelt upon which have a practical bearing in the Arts, Medicine, Engineering, and Agriculture. Hence, during the Course, attention will be directed to the application of Chemistry to Medicine and Physiology, to Metallurgic Operations, Chemical Manufactures, Building Materials, Soils, and Manures.

Fee.—For each Sessional Course, £2. Each subsequent Course, £1.

The Chemical Laboratory is open daily except on Saturdays, from 10 to 4 o'clock, under the Superintendence of the Professor, to Students desirous of prosecuting an extended course of qualitative and quantitative analysis, and for the purpose of original investigation in connection with the Arts, or in the higher departments of Scientific Chemistry.

The Course of Practical Chemistry consists of about thirty-nine Lectures, and will commence at the beginning of the Second Term. Fee for each Sessional Course £3.

**ROYAL COLLEGE OF SCIENCE FOR IRELAND,
STEPHEN'S GREEN, DUBLIN.**

(SCIENCE AND ART DEPARTMENT).

Professor of Practical and Theoretical Chemistry.—W. N. Hartley, F.R.S.

Assistant Chemist.—T. A. Shegog, F.C.S., A.R.C.S.

The Session commences on Monday, October 6, 1890.

The Royal College of Science for Ireland supplies, as far as practicable, a complete course of instruction in Science applicable to the Industrial Arts, and is intended also to aid in the instruction of teachers for the local Schools of Science.

Diplomas are awarded in the Faculties of Mining, Engineering, and Manufactures. The Diploma in the Faculty of Manufactures is recognised by the Council of the Institute of Chemistry of Great Britain and Ireland as qualifying candidates for admission to the practical examinations of the Institute.

The instruction in Chemical Science includes (1) General Chemistry, (2) Applied Chemistry, (3) Analytical Chemistry, (4) Instructions in Chemical Research.

Fees payable by Associate Students in the Faculty of Manufactures:—For the entire Course—first year, £13; second year, £23; third year, £14.

Fees payable by Non-Associates:—£2 for each separate Course of Lectures. For Analytical Chemistry and Research—£2 for a special course of one month; £5 for three months; £9 for six months; £12 for the entire session. For Assaying—£5 for three months; £9 for six months; £12 for the entire session.

The following are supplementary courses of instruction for beginners:—

Laboratory Instruction in the Theory of Chemistry, February, March, April, and May, Tuesdays and Thursdays, 10 a.m. till 1 p.m. Fee for the Course, £4.

A Course of Lectures on Elementary Chemistry by the Assistant Chemist, February, March, April, and May, Wednesday, 3 to 4 o'clock. Fee for the Course, 10s.

There are four Royal Scholarships of the value of £50 each yearly, with Free Education, including Laboratory Instruction, tenable for two years; two become vacant each year; they are given to Associate Students, not being Royal Exhibitors, who have been a year in the College on the results of their examinations. There are also nine Royal Exhibitions attached to the College, of the yearly value of £50 each, with Free Education, including Laboratory Instruction, tenable for three years; three become vacant each year, and are competed for at the May Science Examinations of the Department of Science and Art.

**CHEMICAL LECTURES, CLASSES, AND
LABORATORY INSTRUCTION.**

**CITY AND GUILDS OF LONDON INSTITUTE FOR THE
ADVANCEMENT OF TECHNICAL EDUCATION.**—*Central Institution, Exhibition Road.*—Professor of Chemistry, H. E. Armstrong, Ph.D., F.R.S. The object of this Institution is to give to London a College for the higher technical education, in which advanced instruction shall be provided in those kinds of knowledge which bear upon the different branches of industry, whether Manufactures or Arts. The main purpose of the instruction given in this Institution is to point out the application of different branches of science to various manufacturing industries. In order that this instruction may be efficiently carried out, the Institution, in addition to the lecture theatres and class rooms, is fitted with laboratories, drawing

offices, and workshops; and opportunities are afforded for the prosecution of original research, with the object of the more thorough training of the students, and for the elucidation of the theory of industrial processes. The courses of instruction are arranged to suit the requirements of—1. Persons who are training to become Technical Teachers; 2. Persons who are preparing to enter Engineers' or Architects' offices, or Manufacturing works; 3. Persons who desire to acquaint themselves with the scientific principles underlying the particular branch of industry in which they are engaged.

Technical College, Finsbury.—Professor of Chemistry, Raphael Meldola, F.R.S. The operations of the Technical College, Finsbury, are divided into two distinct portions: Day Classes for those who are able to devote one, two, or three years to systematic technical education; Evening Classes for those who are engaged in industrial or commercial occupations in the daytime and who desire to receive supplementary instruction in the application of Science and of Art to the trades and manufactures in which they are concerned or employed. The College embraces the following departments:—1. Mechanical Engineering; 2. Electrical Engineering and Instrument-making; 3. Manufacturing Chemistry, and Industries involving the application of Chemistry; 4. The Art Industries, including Cabinet-making and Decoration in Colour and in Relief; 5. the Building Trades. The College is under the general direction of the Principal. Each Professor is assisted by Demonstrators. Besides these there are Lecturers and Teachers in special subjects. An examination for the admission of Students will be held at the College at 10 o'clock on Tuesday, September 30th, 1890, and the work of the Session will commence on October 7th.

**BIRKBECK LITERARY AND SCIENTIFIC INSTITUTION,
BREAM'S BUILDINGS, CHANCERY LANE.**—*Chemistry:* Courses will be conducted, commencing October 1st, adapted for the Elementary, Advanced, and Honours Examinations of the Science and Art Department, and for the Matriculation, B.Sc., and M.B. Degrees of the London University. *Inorganic Chemistry:* Mr. G. Chaloner, F.C.S. Lectures—Elementary, Tuesdays, 8.30 p.m.; Advanced, Thursdays, 7 p.m.; Practical, Tuesdays, 6–8 p.m.; Thursdays, 8–10 p.m.; Saturdays, 7–9 p.m. *Organic Chemistry:* Mr. F. Gossling, B.Sc. Lectures—Elementary, Wednesdays, 7.30 p.m.; Advanced, Wednesdays, 8.45 p.m.; Practical, Wednesdays, 6–7.30 p.m.; Fridays, 6–10 p.m.

**SCHOOL OF THE PHARMACEUTICAL SOCIETY OF GREAT
BRITAIN,** 17, Bloomsbury Square, London, W.C.—Professor of Chemistry, Wyndham R. Dunstan, M.A., F.C.S. Professor of Practical Chemistry, John Attfield, Ph.D., F.R.S. In this school, which is specially intended for Pharmaceutical Students, Courses of Instruction are given in the sciences of Chemistry (Physical, Inorganic, and Organic) and Botany, as well as in their applications to Pharmacy and Medicine. Professor Dunstan delivers during the Session (October to July) two Courses of Lectures on Chemistry; an Elementary Course from October to March and an Advanced Course from April to July. The Laboratories for practical instruction in Chemistry under the direction of Professor Attfield are open daily throughout the Session. Particulars respecting Scholarships, Medals, and Prizes, as well as other information relating to the School, may be obtained on application.

CHARTERHOUSE SCIENCE AND ART SCHOOLS.—The Winter Session commenced on Tuesday, September 16th, 1890, under the presidency of the Rev. H. Swann, M.A. Classes are established in this institution by which instruction of a practical character is given in most of the Sciences at a very nominal fee; whilst in Art, at an equally low rate, Students, under the direction of five competent instructors, can be advanced in their studies. Those who have leisure can, at a very moderate charge, attend the Day Classes in

Art. Day Classes will also be held to prepare Candidates for Matriculation (Lond.), the Clerical, Medical (including Dental), Legal, and other Examinations. Students who aim at becoming proficient in Chemistry (Organic and Inorganic) have the opportunity of working in a well-fitted Laboratory, capable of accommodating sixty Students. Aspirants for University Honours can at a small expense be assisted in their studies.

MIDDLESEX COLLEGE OF CHEMISTRY AND PHARMACY, 40, Charlotte Street, Portman Square.—Principal, F. H. Painter. Day and Evening Classes and Laboratory Instruction in Chemistry, Pharmacy, Materia Medica, &c.

THE CITY SCHOOL OF CHEMISTRY AND PHARMACY, 27, Chancery Lane, London, W.C.—Principal, Mr. Maurice Williams. Theoretical and Practical Chemistry, Chemical Physics, Theoretical and Practical Pharmacy, Materia Medica, and Therapeutics.

NEW CENTRAL SCHOOL OF CHEMISTRY AND PHARMACY, 173, Marylebone Rd., London.—Mr. J. Woodland, F.C.S. Lectures are given on Chemistry, Botany, Materia Medica, Pharmacy, Latin, and Physics. Laboratory instruction.

SOUTH LONDON SCHOOL OF PHARMACY, 325, Kennington Road, S.E.—Lectures on Chemistry and Physics, by Dr. John Muter, F.R.S.E., F.I.C., Daily, at 9 a.m. (Organic) and 10 a.m. (Inorganic). Lectures on Botany daily at 12 noon, and at 2 p.m. on Materia Medica and Pharmacy, by Mr. Dodd, F.C.S. The Laboratories for Qualitative and Quantitative Analysis open daily from 9 till 5, under the direction of Mr. de Koningh, F.I.C., F.C.S. The Students' Laboratory of this Institution is specially designed to accommodate 40 Students. The Technical Laboratory is open daily from 9 till 4, and is fully fitted with all apparatus for teaching the manufacture of drugs and chemicals. Periodical Examinations of the Students are held by Visiting Examiners appointed by the Council of Education, and Medals and Certificates are awarded on the results thereof. Fees for the first three months £10 10s. (junior) and £12 12s. (senior); afterwards £2 2s. and £3 3s. per month respectively, inclusive of all departments.

PEOPLE'S PALACE, Mile End Road, E. (Draper's Company's Institute).—Chemistry, Mr. D. S. Macnair, Ph.D., F.C.S., assisted by Mr. G. Pope. The session commences Monday, September 29th. The classes are open to both sexes without limit of age.

POLYTECHNIC INSTITUTE, 309, Regent Street, London, W.—Mr. R. A. Ward and Assistants.—Evening Classes in Theoretical and Practical Chemistry, &c.. The Classes are open to both sexes. The next term commences on Monday, September 29th, 1890.

MORLEY MEMORIAL COLLEGE, ROYAL VICTORIA HALL, Waterloo Bridge Road, S.E.—Science and Technical Classes, Session 1880-91. Lectures will be given in the following subjects:—Principles of Chemistry, Electricity and Magnetism, Heat, Light, and Sound, and Mechanics. The instruction given is suited to artisans and practical men, and is chiefly in connection with the Science and Art Department, South Kensington. Classes begin Wednesday, October, 1st.

UNIVERSITY CORRESPONDENCE COLLEGE, 124, Booksellers Row, W.C.—The classes held at the Chemical and Biological Laboratories of University Tutorial College during the last Session were a marked success; no less than 27 students being successful at the Intermediate Science and Preliminary Scientific Examinations, of London University. The next Session commences the first week in October.

WESTMINSTER COLLEGE OF CHEMISTRY AND PHARMACY, Trinity Square, Borough, S.E.—Messrs. Wills and Wootton.

BRISTOL MEDICAL SCHOOL.—Mr. T. Coomber, F.C.S.

MERCHANT VENTURERS' SCHOOL, BRISTOL.—Head Master, J. Wertheimer, B.Sc., B.A. The Chemical and Metallurgical Laboratories are open to students of either

sex every week-day except Saturday, and students may either devote the whole of their time to laboratory work, or they may take the complete course of chemical training. Prospectus containing full particulars can be obtained at the School, or at the Merchants' Hall, price 4d.

INSTITUTE OF CHEMICAL TECHNOLOGY, Hackney Hey, Liverpool.—Principal, Mr. A. Norman Tate, F.I.C. The course of instruction is intended more especially for students who wish to gain a knowledge of chemistry and the allied sciences in their relation to industrial and commercial pursuits, and embraces a thorough preliminary course of theoretical chemistry and practical laboratory work, followed by instruction in chemical technology fitted to the requirements of each pupil. In addition to these chemical studies, students who desire it can enter upon a special course calculated to afford them knowledge useful in the erection and arrangement of manufacturing and plant, and construction of apparatus.

LEEDS SCHOOL OF MEDICINE.—Prof. Smithells.

MANCHESTER TECHNICAL SCHOOL.—Lecturers: Dr. E. Knecht, F.I.C., E. L. Rhead, J. Grant, F.C.S., and E. Milnes. The day classes commenced on Sept. 2nd, 1890, and the evening classes will commence on Sept. 22nd. The school is equipped with two large laboratories for the practical study of Pure Chemistry and Physics, a Laboratory for Metallurgy, and one for Dyeing, Bleaching, and Printing. Special practical work in any branch of Chemical Technology, or in preparation for University Examinations, will be arranged to suit individual Students. The Evening Courses of instruction are especially designed to meet the wants of those already engaged in various industries. A syllabus, containing full particulars as to hours, fees, &c., may be obtained from Mr. J. H. Reynolds, The Technical School, Manchester.

NEWCASTLE-ON-TYNE SCHOOL OF SCIENCE AND ART AND TECHNICAL COLLEGE (Chemical Department).—Principal, P. Hawkrigge, M.A., B.Sc. Lecturers and Demonstrators, W. D. Oliver, H. Oliver, J. D. Best, W. Carr, &c.

INSTITUTE OF SCIENCE AND ART, VALPY STREET, READING.—Head Science Master: Alfred J. Shilton, F.C.S. Session begins September 29th.

SHEFFIELD BOROUGH ANALYSTS' LABORATORY, 1, Surrey Street.—Mr. A. H. Allen, F.C.S. Day and Evening Classes.

STOCKPORT TECHNICAL SCHOOL.—Chemistry and Dyeing Department.—Lecturers on Chemistry: R. J. Brown, M.Sc., and G. W. Davies, F.C.S. Lecturer on Metallurgy: G. W. Davies, F.C.S. Lecturer on Dyeing: W. M. Gardner, F.C.S. There is a Chemical Laboratory to accommodate 120 Students, and also a Metallurgical Laboratory and a Dyehouse. There will be Day and Evening Courses of Lectures on Inorganic and Organic Chemistry and on Dyeing, Bleaching, and Calico Printing, and also practical instruction in the same, and in the evening there will be, in addition, Classes in Practical and Theoretical Metallurgy. In the Evening Classes the instruction is based mainly on the lines laid down by the Department of Science and Art, but in the Day Classes a more extended Course of instruction is pursued, and opportunity is afforded for carrying on any special branch of practical work under the supervision of the teachers. A Syllabus containing full particulars of times, fees, and courses of instruction is obtainable on application.

TECHNICAL INSTITUTE, SWANSEA.—Classes in Theoretical and Practical Inorganic and Organic Chemistry will be held during the winter months, commencing Oct. 4th, 1890. Principal, W. Morgan, Ph.D., F.C.S., F.I.C.

EDINBURGH SCHOOL OF MEDICINE, 41, Chambers St.—Dr. Drinkwater, F.C.S.—The instruction here qualifies for all Medical Boards, Edinburgh University, London University, &c. Day and Evening Classes.

SCHOOL OF MEDICINE, SURGEON'S HALL, EDINBURGH.—Dr. Stevenson Macadam, F.R.S.E., Mr. Falconer King, Mr. Ivison Macadam, Mr. Drinkwater, and Mr. Rymer.

SCHOOL OF MEDICINE, EDINBURGH.—The Laboratory, India Buildings, Edinburgh, is open throughout the year for Students, under the superintendence of J. B. Readman, D.Sc. F.R.S.E., F.C.S. Attendance at this laboratory qualifies for the Degrees of Medicine, Science, and Public Health of Edinburgh University, and for the Examinations in Medicine and Public Health of the Royal Colleges of Physicians and Surgeons, Edinburgh. Hours, 10 a.m. to 4 p.m.

SCHOOL OF MEDICINE, MINTO HOUSE (NEW VETERINARY COLLEGE, EDINBURGH).—Mr. J. Falconer King, F.C.S., F.I.C., and Mr. John Hunter, F.I.C., F.C.S.

GLASGOW UNIVERSITY.—Prof. J. Ferguson.

CHEMICAL LABORATORIES AND CLASS ROOMS.—Messrs. R. R. Tatlock and Readman, City Analyst's Laboratory, 156, Bath Street, Glasgow; and India Buildings, Edinburgh. The Laboratory is open daily all the year for the reception of students, under the immediate supervision of R. R. Tatlock, F.R.S.E., F.C.S., F.I.C., the City Analyst and Gas Examiner. Hours, 10 a.m. to 4 p.m.

GLASGOW VETERINARY COLLEGE.—Professor Cooke.

STIRLING SCHOOL OF SCIENCE AND ART.—Chemical and Physical Laboratories.—Andrew Wilson, F.I.C., and Assistants. Laboratory work daily, from 10 to 1. Lectures, 2 to 4 p.m.

QUEEN'S COLLEGE, GALWAY.—Dr. Dixon.

ROYAL COLLEGE OF SURGEONS IN IRELAND, DUBLIN.—Professor of Chemistry and Hygiene: Sir Charles A. Cameron, M.D., F.R.C.S.I. Instruction is given in the College Laboratory in General, Practical, and Analytical Chemistry, and in the subjects (Physical, Chemical, and Microscopical) required for Examinations in Public Health and to educate for the position of Public Analyst.

DUBLIN, CARMICHAEL COLLEGE OF MEDICINE.—Professor of Chemistry: C. R. C. Tichborne, Ph.D., F.C.S.

DUBLIN, CATHOLIC UNIVERSITY.—Dr. Campbell.

THE DETECTION OF TRACES OF IODINE IN THE PRESENCE OF MUCH CHLORINE.

By ALEXANDER JOHNSTONE, F.G.S.,
Assistant to the Professor of Geology and Mineralogy, Edinburgh University.

HAVING experienced considerable difficulty in rapidly determining by the usual tests the presence of iodine in the company of chlorides, in the course of some recent investigations on the properties of the naturally occurring halogen salts, I was led to devise the following simple method, by the use of which I believe I have been able to prove the wider occurrence of iodine in the mineral kingdom than has hitherto been supposed. To the properly prepared solution of the substance to be tested add a single drop of a saturated solution of silver nitrate in strong pure ammonium hydrate. If iodine is present even in the minutest quantity, the characteristic pale yellow precipitate of silver iodide will instantly form. Confirm this indication by pouring in—after having mixed the precipitate through the liquid by inverting the test-tube with the thumb on the orifice—pure concentrated sulphuric acid, which first deepens the yellow of the precipitate, and then, when sufficient has been added, liberates the iodine, which is readily and infallibly recognised by its unique appearances, whether precipitated to the bottom of the tube, suspended in the liquid, or dissolved through it to form a pink solution. If not a trace of iodine is present in the chloride tested, the latter will give no precipitate, or at most only a faint whitish cloud that will immediately disappear on the first shake given to the tube in the subsequent mixing.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 7, August 18, 1890.

New Synthesis effected by means of Cyano-succinic Ether. Acetylcyanosuccinic Ether.—L. Barthe.—The author has obtained this compound,—

as a colourless oil.

Methyl Cyanosuccinate and Cyanotricarballylate. L. Barthe.—The former of these compounds has the formula—

The latter is—

Researches on Butter and Margarine.—C. Viollette.—The author distils in a confined atmosphere and in a current of watery vapour the fatty acids derived from about 50 grms. pure dry butter saponified with an aqueous solution of potassa. He collects not less than 10 litres of the condensation liquid obtained by allowing 17,000 litres of steam to bubble into the fatty acids suspended in water at 100°. An alkalimetric operation (using phenolphthalein as indicator) renders it possible to deduce the proportions of the butyric and caproic acids of the butter. The concrete volatile acids are weighed, as well as the fixed acids, after washing, desiccation in a vacuum, and fusion. The quantity of each of these groups renders it practicable to determine their equivalent, and, consequently, by calculating the glycerides, to effect the synthesis of the butter.

Researches on the Optical Analysis of Butters.—C. Viollette.—Butters and margarines have different indices of refraction, which show deviations of -33° to -27° of the oleorefractometer for butters, and of -15° to -8° for margarine. The indications of the oleorefractometer are sufficiently precise when they refer to mixtures the components of which have known deviations. It is necessary to fix, by a series of observations on different butters, the minimum deviation below which a butter may be considered as a margarine. The oleorefractometer may be useful for examining the butters of commerce, but its indications can be considered certain only when the butters show a deviation less than the lowest limit of butters.

On a Characteristic Reaction of Cocaine.—Ferreira da Silva.—The author treats a small portion of cocaine or of one of its salts in the solid state, or the residue from the evaporation of any of its solutions, with some drops of fuming nitric acid of sp. gr. 1.4. It is evaporated to dryness on the water-bath; the residue is treated with one or two drops of a strong alcoholic solution of potassa. On stirring up with a glass rod there is observed a special or distinct odour recalling that of peppermint.

No. 8, August 25, 1890.

Transformation of Melted Ammonium Nitrate.—E. Matthieu-Plessy.—According to the author, in preparing oxamic acid and oxamide by means of melted ammo-

nium nitrate there is formed a third product, the nitrate of a new fixed alkali. This fixed alkali is a substituted ammonia—a nitric monamide or nitramide. It may be named azotylamine; and its nitrate, azotylammonium nitrate.

MISCELLANEOUS.

The Chemical Laboratory of Wiesbaden.—In the Summer Term, 1890, there were 69 students on the books. Of these 42 were from Germany, 5 from Russia, 5 from North America, 4 from England, 4 from Austro-Hungary, 2 from France, 2 from Italy, 2 from Spain, 1 from Norway, 1 from Chili, 1 from South Australia. Besides the director, Geh. Hofrath Prof. Dr. R. Fresenius, there are engaged as teachers in the establishment Prof. Dr. H. Fresenius, Dr. E. Borgmann, Dr. W. Fresenius, Dr. E. Hintz, Dr. Med. G. Frank, and Architect J. Brahm. The assistants in the instruction laboratory are two in number, in the private laboratory seventeen, in the Versuchsstation three. The next Winter Term begins on the 15th of October. Besides the scientific researches, a great number of analyses were undertaken in the different departments of the Laboratory and in the Versuchsstation on behalf of manufacture, trade, mining, agriculture, and hygiene.

NOTES AND QUERIES.

* * Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertisement columns.

Paper Manufacture.—(Reply to Richmond Villas).—As authorities on the paper manufacture in all its branches, we can recommend "The Art of Paper Making," by Alex. Watt (London: Crosby Lockwood and Son); also "Spon's Encyclopedia of Industrial Arts, &c.," Division IV. (Spon, Charing Cross). Appended to the latter is a fairly complete bibliography of the subject. In the same work, Division V., is an account of the starch manufacture.

PATENTS.

Provisional Protection, from £2 2s.

Lowest cost of complete English and Foreign on application. Also, Designs and Trade Marks. Inventions financed.

VOL. LXII. No. 1609.

ON THE DETERMINATION OF OXYGEN IN THE AIR.

By J. ALFRED WANKLYN and W. J. COOPER.

FOR the last half-century the methods for the determination of oxygen in the air have been explosion with excess of hydrogen, and absorption by means of pyrogallate of potash.

There is an old method founded on the wonderful reaction between nitric oxide and oxygen, which flourished soon after the discovery of the composition of the atmosphere, and was abandoned and is now almost forgotten, and never mentioned without being condemned.

We have had to investigate this process in the course of work undertaken in order to write our just published book entitled "Air Analysis." We find that when this old process—the process of Priestley and Cavendish—is altered in a very simple and obvious manner, it is rendered accurate, and we now present it to chemists as one of the most satisfactory processes in the whole range of analytical chemistry.

We measure the sample of air and the nitric oxide separately. We bring the two together in presence of water—reaction instantly occurs, and the resulting ruddy fumes are rapidly absorbed by the water—and we read again. One-third of the contraction is the volume of the oxygen in the air.

The experimental details are given in our book.

ON THE DETERMINATION OF PHOSPHORIC ACID IN BASIC SLAGS.

By G. ARTH.

VARIOUS authors recommend precipitation by ammonium molybdate in order to determine the phosphoric acid in these slags, but without placing themselves in identical conditions. Some add the molybdic solution directly to the hydrochloric liquid obtained on attacking the slag and without removing the silica which may be in solution; others eliminate the silica, but still operate in presence of hydrochloric acid.

It is already well known that to separate phosphoric acid in the state of ammonium phospho-molybdate with accuracy the silica and the hydrochloric acid must be got rid of by transforming the bases into nitrates. Müntz evaporates the solution to dryness two or three times with nitric acid until the chlorine is expelled, and then adds the ammonium nitro-molybdate to the nitric solution.

Having had occasion to analyse one of these slags, the author treated it with hydrochloric acid, rendering the silica insoluble, and removing it in the usual manner, and he then evaporated the filtrate with nitric acid to expel chlorine. The following result was observed on operating thus with a sample containing 13.85 p.c. phosphoric acid. When the hydrochloric acid is about to disappear, generally during the second evaporation with nitric acid, there forms in the concentrated liquid a yellow, granular precipitate, which increases more and more and which cannot be re-dissolved in nitric acid, cold or hot, dilute or concentrated. As this precipitate contains phosphoric acid it is impossible to have here a nitric solution containing all the phosphorus.

The composition of the yellow deposit is that of a

hydrated ferric phosphate, $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot \text{H}_2\text{O}$, after drying at 100° — 105° . It is soluble in strong hydrochloric acid, especially with the aid of heat.

This phosphate has the same composition as the ordinary precipitated phosphate, but the latter is nearly white and dissolves readily in the mineral acids even if diluted, whilst the other is far less soluble, and has a decided yellow colour. The two phosphates in question appear to be allotropic modifications of one and the same compound, presenting differences analogous to those noticed in ferric oxide itself, *e.g.*, as regards solubility. In fact, if they are treated with a cold potassa-lye they dissolve with different degrees of readiness, and yield two oxides, the appearance of which is decidedly different, while the filtrate contains the same phosphoric acid.

This new ferric phosphate is easily prepared from pure ferric chloride and disodic phosphate, evaporating the solutions with a sufficient excess of nitric acid.

In analytical operations this compound may be formed if the ferric oxide and the phosphoric acid in the substance are in a certain proportion, as it may be the case in basic slags.

By evaporating a mixture of ferric chloride, of disodic phosphate, and nitric acid, there is sometimes formed another tetrahydrated ferric phosphate of a rosy white colour, insoluble in nitric acid. This compound may be the one which Erlenmeyer obtained under different conditions.—*Annalen der Chemie und Pharmacie*.

DISINFECTION BY BURNING SULPHUR.*

By E. R. SQUIBB, M.D.

UNDER the head of Prevention Dr. Segur asks what are the important measures of prevention, and among these may certainly be included the disinfection of infected apartments.

Perhaps the most common measure for the disinfection of apartments which have been infected by diphtheria and other contagious diseases, is the burning of sulphur. This mode of disinfection has been in active use for more than a hundred years and many epidemics of contagion are supposed to have been controlled by it. Of late years, however, its efficacy and utility have been called in question by several prominent authorities on the ground that it does not prevent the development of the spores of several microbes supposed to be pathogenic of important contagious diseases.

If it be admitted that the burning sulphur was properly applied, and that the propagation of the spores is positive proof of persistence of contagion, then the question must be considered as settled, and the practice should be abandoned. But as the first of these propositions, at least, cannot be safely admitted in the attempts at disinfection as commonly practised, and as the method is continued by Boards of Health and hospital authorities as well as in private houses, notwithstanding the evidence against it, it may be useful to re-examine the conditions to be met.

In a given locality there are particles of contagious matter so small as to float in the air, and these settle upon, or become entangled in, all surfaces to which the currents of air carrying them have access. For perfect disinfection the contagious element or virus of all such particles must be so changed as to be no longer contagious. This change must be effected either by physical or by chemical action, or by both acting together.

It seems to be absolutely proven that the one element necessary to the activity of all virus is moisture. Desiccated virus is inactive and impassive; and when desiccation is complete or perfect, as by a sufficient degree of heating for a sufficient length of time, the change is such

* *An Ephemeris of Materia Medica, Pharmacy Therapeutics, &c.* Vol. iii., No. 4.

that the re-supplying of moisture does not reproduce the contagion.

But moisture is an element of varying degree. Too much by dilution may weaken active virus to absolute inactivity, as too little may weaken it to practical destruction.

Contagious matter or virus which is only sufficiently dry to be thus rendered inactive and impassive becomes active by contact with moist surfaces, and thus moisture becomes the essential element in its contagiousness by supplying the conditions under which its molecules can resume the function of propagation or generation. This same element moisture, which is necessary to enable them to propagate contagion, is equally necessary for any reaction with agents which have the power to so change their molecular structure as to destroy their capacity for contagion.

Hence all disinfectants require the presence of moisture, and require it in a degree sufficient to enable all the molecules of contagious matter to commingle and react with the molecules of the disinfectant. If the moisture be sufficient in amount it matters little whether it be held by the virus or by the disinfectant, but the reaction will be much more sure and more prompt if each of the reacting substances be fully saturated with moisture. If either agent be dry or nearly dry, the reaction will be proportionately slow and imperfect.

The condition of the contagious material of an infected apartment, although not absolutely dry, has only the moisture of the common atmosphere, and if there was any such thing in the living animal as a dry surface there could be no infection from such air-dry contagious material.

An air dry disinfectant or antiseptic is equally inactive and impassive, and for the same reasons; namely, the absence of the physical and chemical conditions for reaction.

When sulphur is burned in air a dioxide of sulphur is formed. One atom unites with two atoms of the oxygen of the air to form an anhydrous or perfectly dry gas which occupies practically the same space as did the oxygen combined. This sulphur dioxide is therefore a heavy gas, and as it cools after being formed by the combustion, it falls, so that any enclosure in which it is formed will fill up from the bottom as it would with water, and but for the laws of diffusion of gases, an enclosure might have the pure gas at the bottom and none at the top. The laws of diffusion, and the currents of air and gas caused by the heat of combustion, do, however, carry the gas to all parts of an enclosure, and yet the gas is in greatest proportion near the floor, and any leakage there, as under the doors for example, will waste much more gas than the same openings higher up.

The sulphur dioxide formed is a perfectly anhydrous or dry gas, and is therefore called sulphurous anhydride. It is not an acid, but is an indifferent, inactive, impassive gas, showing but a feeble tendency to combine with anything, or to exert any power. It has a moderate affinity for moisture, and when one molecule of the gas combines with one molecule of water sulphurous acid is formed; when combined with more than one molecule of water a liquid sulphurous acid is formed of a strength proportionate to the amount of water. This solution of sulphurous acid is commonly called simply sulphurous acid, and as found in the markets it commonly contains from 3 to 6.5 p.c. of true sulphurous acid, or the compound molecule made up of one atom of sulphur, two atoms of oxygen, and one molecule of water. This sulphur dioxide, or sulphurous anhydride plus water, or sulphurous acid, unlike the inactive dioxide, is a very active and very potent substance, and its prominent characteristic is its affinity or appetite for oxygen, by which it is converted into sulphuric acid. This affinity for oxygen by which it takes that element from all its looser combinations, makes it a powerful deoxidising agent. And, by taking oxygen away from its looser combinations in the infective matters, it

breaks up their complex molecules, destroys their power of contagion, and thus becomes disinfectant. Again, instead of taking away oxygen from compound molecules it may unite with this oxygen and thus form sulphuric acid as a new component of the compound molecule, changing this so as necessarily to destroy it and therefore be disinfectant.

All this detail is to show that sulphur dioxide, resulting from burning sulphur in the air, is not a disinfectant, but requires the presence of moisture either with the sulphur dioxide, or with the infected matter, or with both. And, further, that in proportion to the amount of moisture up to what would be a very large dilution, the more there is present the more perfect are the conditions for thorough disinfection, and the less moisture there is present the more imperfect the disinfection.

Now, if the practice of Boards of Health and other authorities be examined, it seems to be very defective indeed, unless they use an abundance of watery vapour without thinking it worth while to mention it in their directions and practice.

The common usage seems to be to close up the infected apartments as thoroughly as practicable and to burn sulphur in them in the proportion of four pounds of sulphur to each 1000 cubic feet of space.

There are no directions to stop up the lower chinks more carefully than the upper ones, while the lower half of a door will waste twice as much gas as a window. The sulphur is usually put in an iron pot or pan, and this is set in a larger vessel of water or upon a vessel of wet ashes or sand; and this seems to be done to lessen the risk of fire rather than to supply vapour of water. The sulphur is lighted by means of alcohol poured upon it and lighted, and the apartment is then closed and watched until the sulphur is burned out. The dioxide formed finds a little moisture in the normal atmosphere of the room, and thus a small proportion of it gets converted into the active sulphurous acid. Then the heat of the burning sulphur vapourises a portion of the water in the vessel in which it is placed. Under favourable conditions the amount of water thus vapourised may equal or slightly exceed the weight of the sulphur burned. But under general conditions it will be much less. These two sources being the only ones from which moisture is supplied, and the amount supplied being very much too small, it is only reasonable that the disinfection should be proportionately incomplete, and under such conditions any condemnation of sulphurous acid as a disinfectant is unsound and irrational.

The conditions for a much better application of this agent are very easily supplied. To fumigate with the active sulphurous acid, instead of the inactive dioxide of sulphur, it is only necessary to evaporate water to the extent of three or four times the weight of the sulphur burned, or to wet the surfaces to be disinfected, or both, so that plenty of moisture may be present during the burning of the sulphur. A shallow pan of water upon a kerosene stove well started in advance of lighting the sulphur, and the floor, ceiling, and walls well sprinkled with water by means of an ordinary dust-brush, is perhaps as good a practice as any.

There is abundant evidence on record that sulphurous acid in small amount is destructive to all the lower orders of animal and vegetable life, to all fermentations both vital and chemical; and, all that the more recent elaborate investigations seem to have shown is, that the spores or germs of certain microscopic organisms were not destroyed by it as applied to them, even in the presence of abundant moisture in some of the trials. Many of the late investigations have been made with very great care and labour and by modern accurate methods. Some of the best results are, however, confusing, if not contradictory, and, therefore, are inconclusive, even in regard to the resistances of spores.

Chiefly from the above-mentioned considerations the writer reaches the conclusion that burning sulphur for

disinfection should by no means be abandoned, but should be more thoroughly and more carefully applied.

Not only in diphtheria, but in all infectious diseases, some such disinfectant is greatly needed in preventing the spread of disease, and diminishing the risks of susceptible persons, and no other method has yet been proposed that is more effective, more simple, or of easier application.

In the less convenient and more costly method of disinfecting by gaseous chlorine the same principles apply, and the same conditions are necessary. Dry chlorine gas is as inactive as sulphur dioxide, and from deficient supply of moisture the one will fail as often as the other.

When chlorine is generated from common salt by means of dioxide of manganese and sulphuric acid, the salt and manganese are commonly mixed into a thin paste with water before the acid is added. Then on adding the acid much heat is developed, and a proportionate amount of water is evaporated and disengaged with the chlorine. But this amount of water is far too small for the full effect of all the chlorine, and unless all the surfaces be well wetted, and steam be supplied, the disinfection will be defective.

If the walls and ceilings of apartments be kalsomined, or be covered with any other preparation of glue or paste, these should be scrubbed off clean with hot water before the disinfection, because disinfection does not destroy the tendency to putrescence in gelatin, glue, paste, &c.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING AUGUST 31ST, 1890.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;

and C. MEYMOTT TIDY, M.B., F.C.S., Barrister-at-Law,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, Metropolis Water Act, 1871.

London, September 6th, 1890.

SIR,—We submit herewith the results of our analyses of the 175 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from August 1st to August 31st inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 175 samples examined, one was found to be "very slightly turbid," viz., a sample collected on the 1st ultimo, the remaining 174 samples being clear, bright, and well filtered.

The generally satisfactory character of the water supply during the month of August is well indicated by a comparison of the mean and maximum proportions of organic carbon found in the Thames-derived waters distributed to the Metropolis during the months of June, July, and August, respectively, thus:—

	Means.	Maxima.	
June	0.150	0.166	} Parts per 100,000.
July	0.152	0.185	
August	0.150	0.175	

But just as the numbers for July were somewhat heightened by the occurrence during the latter part of the month of a flooded state of the rivers, brought about by the unprecedented rainfall of the 17th of July, so were the numbers for August similarly heightened by the persistence, during the early part of the month, of the previously brought-about floods, sustained as they were by a considerable rainfall in the weeks following that of the above-mentioned wholly exceptional fall.

The proportion of organic matter present in the water, as determined alike by the estimations of organic carbon found and of oxygen consumed, though affected sufficiently to render analyses made on an early day in the month no fair criterion of the character of the month's supply, was, nevertheless, influenced by the floods, but to a very inconsiderable extent only, as noted also in our previous monthly report. The degree of colour-tint of the water, however, when viewed through a thickness of two feet, was found to be more appreciably affected. Thus, while the mean ratio of brown to blue tint of the Thames-derived water was, during the first half of the month of August as 20 : 20, it was found during the last half of the month, after the subsidence of the floods, to be only as 14.1 : 20.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES.
WILLIAM ODLING.

THE DRY ASSAY OF TIN ORES.* PART I.

By HEINRICH O. HOFFMANN,
Assistant Professor of Mining and Metallurgy.

(Continued from p. 104).

(3). In assaying ores in the dry way, it has been, and still is, very common to give a salt cover. To try what effect this would have, the foregoing two sets of experiments were repeated, adding the salt.

It was found that the charges melted less rapidly and were not so thin as before; when cold, the surface of the slag was uneven and rough; the crucible was corroded, but less soaked with potassium cyanide, the upper part showing no prills of tin. The slag showed a very coarsely granular structure; it was opaque, milk-white, but somewhat dull in comparison with that of the pure cyanide. No other differences were observable.

The low results shown by the averages were startling. They could not be attributed to any action of the sodium chloride, nor to the small amount of silicate derived from the corrosion of the crucible. The salt was examined, and found to be rich in sulphuric acid; this explained the loss in tin (see Table XVI.). Fine Michigan table-salt was then tested, and sulphuric acid found to be present here also; therefore, nothing further was attempted with salt. No special advantage is apparent in its use with potassium cyanide, as the slags are thinner without it, and form a better "wash" for the sides of the crucible than the less readily fusible salt. If it is to be used at all, recourse must be had to Ohio salt, which, according to the Report of the Geological Survey of Ohio, "Economic Geology," 1888, vol. vi., p. 663, is free from sulphates, while Michigan salt always contains them.

(4). Ricketts recommends the chalk-lined crucible for the assay with potassium cyanide. He gives the charge, 10 grms. of ore and 40 grms. of potassium cyanide, with half of the flux in the bottom of the crucible and the other half mixed with the ore, then the usual cover of cyanide,

to which is added a salt cover, and heats for fifteen minutes. These directions were followed, only omitting the salt cover.

It was expected that the chalk-lining would at least partly prevent the cyanide from filtering into the crucible, but no difference could be observed, the crucible being just as black as if it had had no chalk-lining.

The structure of the slag was slightly coarser; it was more uneven in fracture, and of a bluish grey colour, instead of the usual pure milk-white.

The average of the results is 2'1 per cent lower than that obtained by the chemical analysis, and 1'75 per cent lower than the average of the corresponding 10-grm. assays, Nos. 39 to 42. The separate assays also show a difference of 1'9 per cent, which is very unfavourable. The first reason for this that suggested itself was the possible presence of gypsum in the chalk, but no sulphates

were found. There remains, therefore, only the presence of lime to account for the slagging of tin.

By a mistake in assay No. 54, the entire 40 grms. of potassium cyanide were mixed with the 10 grms. of ore, and charged with it. No button whatever was obtained. The bottom of the crucible was covered with a spongy, greenish grey mass, and this by the ordinary white slag of potassium cyanide. This shows the necessity of having a good layer of potassium cyanide on the bottom of the crucible, probably on account of the tendency the tin has not to collect in a single button. If the crucible is filled with a uniform mixture of ore and cyanide, a number of small buttons will be produced mixed with the slag. If a layer of pure potassium cyanide cover the bottom of the crucible, the particles of tin will sink into it, and form on the undisturbed bottom a nucleus, around which other particles can collect, and thus take up gradually most of

the tin. The effect is similar if charcoal be mixed with the potassium cyanide (see 5 to 7).

(5). The regular method of assay with potassium cyanide was modified in the same way as the German method; i. e., the stannic oxide was first reduced by charcoal, and the potassium cyanide then added to collect the particles of metallic tin into one button. It was expected that the iron would be taken up by the potassium cyanide instead of alloying with the tin. The result was tested by dissolving the slag in water, filtering the solution, acidulating the filtrate with hydrochloric acid, and boiling to expel the hydrocyanic acid formed. It was then tested with a mixture of ferrous and ferric salt, which gave the reactions for potassium ferro- and ferri-cyanide. Another part of the filtrate was evaporated to dryness, treated with nitro-hydrochloric acid, again evaporated to expel all cyanogen, and taken up with hydrochloric acid. On adding ammonium hydroxide, the reddish brown ferric hydroxide was precipitated, showing again the presence of iron.

In the experiments, 5 grms. of ore were mixed with 1 grm. of charcoal, placed in a naked crucible, size F, and heated for a quarter of an hour after the charge had become dark red; then 20 grms. of potassium cyanide were added; after this, thirteen minutes were required before quiet fusion was obtained.

The slags had the usual characteristics of the pure cyanide, but black patches of carbon were irregularly dispersed through them. The buttons were white, very bright, malleable, and free from iron; they were, however, rough, and covered with bead-like excrescences of tin.

These results are very unsatisfactory. The average gives 3.73 per cent less tin than is present; it is 3.20 per cent lower than that of the corresponding 5-grm. assays, Nos. 35 to 38, and 2.21 per cent lower than that of the modified German method, Nos. 23 to 25. On comparing the separate weights of the tin buttons obtained, it will be seen that the tendency of the tin not to collect in one button is enhanced by the presence of the charcoal with which the ore had been mixed. The only result of positive interest obtained by the experiments is the fact that the iron of the black tin, reduced to the metallic state, goes into the slag, and not into the button, as in the modified German assay.

Similar experiments carried on in a charcoal-lined crucible were equally unsatisfactory.

(6). The same method, only using a porcelain crucible, bears the name of Levol's method. Kerl* and Balling† give it as follows:—2 grms. of ore are mixed with 20 per cent of charcoal in a porcelain crucible, and heated for from fifteen to thirty minutes in a muffle; 0.50 to 0.75 grm. of potassium cyanide is added, and the heating continued another five minutes. They say that the results are accurate to from 0.3 to 0.5 per cent.

It was found that it is necessary to grind ore and charcoal very fine, and that an excess of charcoal must be avoided.

Two grms. of ore were mixed with 0.5 grm. of charcoal, and heated for half an hour in the muffle at a good scorification temperature. The crucibles were then removed, allowed to cool, 1 grm. of potassium cyanide added, and the crucibles returned to the muffle for ten minutes.

They were all blackened and somewhat corroded; the slag was of a light grey colour, from the charcoal, and there was a small amount of green slag. In none of the assays had the tin collected in one button; it varied in size from a button down to a fine grey powder. The crucibles were now placed in hot water, the small buttons picked out, and the fine tin separated from the charcoal and insoluble green slag by washing. This is the uncertain part of the assay. The fine tin separates with difficulty from the green slag. If this is entirely removed, some tin will be lost, and the resulting weight will be too

low; if all the tin is recovered, some slag remains with it, and the result is too high. Thus the assayer must choose between two evils, and this causes a feeling of uncertainty. Any slight mistake is multiplied by fifty when the result is expressed in percentage. This is illustrated in Table XIII.

TABLE XIII.

No. of Assay.	Resulting tin.	
	Grms.	Per cent.
59.	1.350	67.50
60.	1.335	66.75
61.	1.305	65.25
Average	1.330	66.50

The average is too low, showing loss from excessive care in washing to obtain pure tin. The greatest discrepancy between the single results is 2.25 per cent. This shows how difficult it is to effect a satisfactory separation of fine insoluble slag and fine tin. During the past two years the writer has made a number of assays according to this method. The results obtained from duplicate assays only agreed well when all the tin had collected in one or more large buttons; they were never satisfactory if the tin was present in the form of fine powder. It was not discovered why in one case a button, in another a powder, should be obtained. The statement made by Kerl and Balling, that the results of this method are accurate within 0.5 per cent, needs modification, as it certainly does not apply to all tin ores. Probably those of the Black Hills contain impurities that were not present in the ores Kerl and Balling have reference to.

(7). The last experiments made with potassium cyanide followed T. W. E. David, in his "Report on the Geology of the Vegetable Creek Tin-Mining Field," Sydney, New South Wales, 1887, p. 153. Mr. David says that at the Glen Smelting Works at Tent Hill the potassium cyanide is mixed with charcoal. The only reason that can be brought forward for this modification is, that the potassium cyanide used must have been very impure. Thus, in order to increase its reducing power, charcoal was added.

Five grms. of ore were fused with a mixture of 30 grms. of potassium cyanide and 1 grm. of charcoal; only two-thirds of the flux were mixed with the ore, one-third being rammed into the bottom of the naked crucible.

Contrary to expectation, the charge fused as readily as if it contained no charcoal, and came very quickly to a quiet fusion. On breaking the crucible, no button was to be found, but only fine prills of tin disseminated through a pumice-like dark grey slag, containing irregular streaks coloured black by carbon. This shows again the necessity, alluded to above, of having in the bottom of the crucible a layer of pure potassium cyanide for the reduced particles of tin to collect in and form a button.

In the preceding experiments, the ordinary c. p. potassium cyanide was used, as it seemed important that the results obtained should be based on a reagent whose composition was definitely known. But this pure cyanide is somewhat expensive (1.90 dollars a pound), and to see whether its use was absolutely necessary, the different commercial grades were tested. First, however, c. p. cyanide was mixed with cheaper fluxes, such as pure potassium and sodium carbonate, to obtain, if possible, a flux which would have the same action as the pure cyanide, but be considerably cheaper. The effect produced by potassium sulphate was also investigated.

(To be continued).

Determination of Starch Granules in Corn.—Z. v. Mikowski.—The author concludes that the methods of Aeböth and Marcker both give good and accordant results. In determinations of sugar either the gravimetric process of Allihn or the volumetric method of Soxhlet should be used, as the process of Reischauer gives merely approximate results.—*Zeitschrift für Analytische Chemie*, Vol. xxix., Part 2, 1890.

THE FIXATION OF ATMOSPHERIC
NITROGEN.*

PART II.

By A. A. BRENNEMAN, S.B.†

Continued from p. 103.)

An Inquiry in Regard to the Conditions under which Cyanogen is Produced by Direct Union of Nitrogen and Carbon.

THE union of nitrogen with other chemical substances is brought about with so much difficulty that it has long been the custom to speak of nitrogen as an inert substance showing little affinity for or tendency to combine with other elements, yet the very large classes of compounds in which nitrogen is an essential element show that it is not difficult to retain it in a compound once formed, or to hand it over from one compound to another in the reactions by which chemical compounds are formed or decomposed. The difficulty, then, is simply that of getting free nitrogen, as it exists in the air, to enter into direct combination with any other element, and this difficulty is so real and serious that, practically, all of the nitrogenous compounds used in the arts are obtained by the decomposition of other nitrogen compounds. Free nitrogen is one of the most abundant substances on the earth, and combined nitrogen is essential to some of the most valuable of commercial products, but the ready fixation of the nitrogen of the air on a manufacturing scale in any single compound which may be used as the starting point of a series of substances derived from it, has yet to be accomplished.

This indifference to combinations, together with the considerable degree of permanence given by nitrogen to the compounds into which it enters, lead to the conclusion that a certain quantity of work, represented by a certain quantity of heat, has to be done in order to bring free nitrogen to the condition in which combination is possible. The chemist explains this by saying that the condition of free nitrogen is that of two atoms joined to one another to form a molecule and requiring the expenditure of a certain quantity of heat to tear them apart and leave each atom free to enter into new combinations.

The most prominent source, perhaps the only true source, of nitrogenous compounds in nature is found in the union of nitrogen and oxygen of the air under the influence of the electric discharge, as in lightning, &c. Nitric acid is washed down from the air by rain during a thunderstorm, either free or as ammonium nitrate or nitrite, and these substances, and ammonia, the product of their reduction, are the starting points of mineral, vegetable, and animal compounds containing nitrogen. The conversion of nitrogen of animal and vegetable matter into ammonia and nitric acid under the influence of bacterial life is a secondary process and does not deal with free nitrogen.

Whether the union under the influence of the electric spark be purely a heat effect, or whether it results in part from a special polarity impressed upon the atoms of nitrogen by the discharge, it is now definitely proven that heat alone in presence of a strongly basic substance, like an alkali, is sufficient to effect the combination of nitrogen and carbon. The discovery, made accidentally, that the hot blast iron furnace fulfils at times the conditions necessary for the production of cyanogen from nitrogen of the air, was the beginning of a series of experiments upon the fixation of free nitrogen which have cast much light upon the nature of the problem.

Nevertheless, the conditions of the blast furnace furnish the best basis for the study of the question, and most of the early attempts to fix atmospheric nitrogen as cyanogen

have striven to imitate these conditions more or less closely. Bunsen indeed (*ante*) suggested the construction of a furnace on the plan of the blast furnace for production of cyanides only, but it is difficult to see the practicability of such a plan unless the size of the furnace were very much reduced or the yield of cyanides very small as compared with consumption of fuel. We have to inquire, then, what are the essential and what the non-essential conditions for the fixation of free nitrogen as cyanogen? The investigations of the blast furnace itself with this object has been done by Bunsen and Playfair (*ante*), and the various forms of apparatus which have been applied to the manufacture of cyanides upon this plan and the experience drawn from them furnish much additional material for such an inquiry.

We are limited here to the study of the synthesis of cyanogen, but the conversion of the nitrogen of the air into ammonia or cyanogen on the one hand, or into an oxide of nitrogen on the other, are mere phases of the great question of the fixation of nitrogen, and as the synthesis of one of these substances by the aid of atmospheric nitrogen would lead to the production of all, this limitation cannot exclude all considerations of these related substances.

The conditions essential to the fixation of nitrogen and the production of cyanides are indicated in the operation of the blast furnace, but only in the most general way. Neither observations nor experiment with the blast furnace have yet enabled any one to control it for the production of cyanides. The appearance of cyanides as a product of these furnaces, whenever observed, has occurred unexpectedly and has generally ceased as suddenly and mysteriously as it began. Bunsen's proposal, to erect a furnace similar to a blast furnace to be worked for cyanides only, has never been fully acted upon, and in the light of present experience it offers little promise of success. We have learned from the study of the blast furnace only that a high temperature, a reducing atmosphere, an alkaline flux, and an excess of nitrogen are conditions favourable to the process.

The conditions most suitable in respect to temperature, flow of nitrogen, quality and density of carbon or carbonaceous fuel, proportion and nature of base, &c., are as yet undefined.

The more manageable furnace of Possoz and Boissiere (*ante*), although holding rather closely to the principle of the blast furnace, is free from its greatest defects, in that it has no very deep column of coal to resist the flow of gases or crush the lower portions into a compact mass by its weight. The air or nitrogen is admitted at many points also, and the cross section of the furnace is not small enough to prevent access of the gases to the centre of the column of coal. Its defects are, slowness of conversion of nitrogen into cyanogen, rapid destruction of the lining of the furnace, and contamination of the cyanides with silicates thereby formed.

The process of Margueritte and Sourdeval (*ante*) and that of Romily (*ante*) are each, for a different reason, free from the chief of these defects, yet they have been no more fortunate than their predecessors in finding a practicable, commercial process.

In order to reach a conclusion as to the present aspect of the whole question, it may be well to take up and consider in detail the various conditions upon which the absorption of free hydrogen by carbon depends, to see how far the theory of chemistry may lead us in anticipating the effect of each, and to find, if possible, what combination of conditions gives, in the light of theory and past experience, most promise of success.

1. *The Influence of Temperature.*—Possoz and Boissiere (*ante*), to whom great deference is due as the authors of the most persistent as well as the most successful efforts ever made in this field, give unqualified testimony, as the result of long experience, to the necessity for very high temperatures. A white heat is said to be required, and the fixation of nitrogen, other things being equal, is

* *Journal of the American Chemical Society*, vol. xi., Nos. 1-2.

† The substance of this article was prepared as an appendix to a commercial report, but has not been printed heretofore in any scientific journal.—A. A. B.

directly proportional to temperature. On the other hand, Armengaud and Ertel both claim that lower temperatures are quite adequate to effect the combination of nitrogen and carbon. Walter Weldon, also, one of the foremost authorities in the application of chemistry to manufactures of this or of any age, stated, in 1879, as the result of his own experiments, that the limit of temperature in this operation had been placed too high and that a red heat was sufficient. Siepermann, in 1887, testified to the same effect, basing his views on a series of experiments.

The question at issue relates only to the difference between a cherry red and a white heat, but this difference is of the utmost importance in the practical operation of a plant, and may of itself be the point upon which the whole question will ultimately turn. It is possible, however, that, under conditions, either of the above views may be correct, and the question must remain an open one until the process shall have been more fully studied.

2. *The Influence of Oxygen.*—It is generally admitted as the result of all experiments upon the manufacture of cyanides, that oxygen and cyanogen cannot exist together at high temperatures. Theory leads to the same conclusion. Cyanogen is a combustible substance, and the effect of oxygen upon cyanides is either, in the case of the alkaline cyanides, to convert them, first into cyanates and then into carbonates, or in the case of cyanides of the heavy metals, to decompose them with liberation of carbon monoxide and dioxide. All processes, therefore, using air as a source of nitrogen provide for absorption of oxygen or its conversion into oxides of carbon. The mixed gases of the cyanogen furnace must be as a whole reducing, not oxidising, in character.

3. *The Influence of Water.*—Here again we have P. and B. (*ante*) with their weight of practical experience insisting upon a condition which receives little support from others. It is evident, however, that the conditions of their furnace did not prevent the exclusion of moisture to such an extent as to decide the question absolutely, and the ill effects of water when admitted purposely and in greater quantity may be ascribed, in great part, to its cooling effects merely, when we remember the great expenditure of heat under which water is decomposed by carbon. Water in excess, also, decomposes cyanides, yielding ammonia. The experiments of Langlois are quite conclusive as to the principle that water in moderate quantity does not influence the production of cyanides, and Armengaud, Ertel, and others (*ante*) speak positively as to its advantages. If the formation of ammonia is a preliminary stage in the synthesis of cyanogen, as Kuhlman suggests (*ante*), the presence of hydrogen, or, what is in effect the same, of vapour of water, is a necessary condition. Vapour of water is an oxidising agent under certain conditions of temperature and for certain elements, but it is possible that cyanogen is not attacked by it at high temperatures in presence of hot carbon, carbonic oxide, or hydrocarbons. The conclusions of several experimenters that water does not hinder the formation of cyanides is not, at any rate, definitely contradicted by theory.

4. *Time of Contact between Nitrogen and Carbon and Degree of Subdivision of Carbon.*—If we assume that the base, which is found to be necessary in production of cyanogen from nitrogen of the air, combines instantly with the nascent cyanogen, the question of time is one simply of the speed of the preceding reaction between nitrogen and carbon. Chemical action between a solid and a gas, when the temperature necessary for the reaction has been attained, depends principally upon the surface exposed. The action may be assumed to be instantaneous, like the action of oxygen upon hot and finely divided carbon, and to be retarded only because the products of combustion cannot be removed from the sphere of action at the same rate at which the action takes place.

In a process like that of Possoz and Boissiere, and when each fragment of charcoal is bathed in a film of fused potash, action is limited by the rate at which the fused cyanide circulates in the pores of the charcoal and gives

place to unchanged potash on the surface. New surfaces of carbon for attack, or of potash for absorption, are therefore exposed less frequently than is required, and complete saturation, that is, conversion into cyanide, is attained only after a long exposure and with much waste of gas and heat. The absorption of nitrogen is probably also retarded progressively as combustion proceeds, both because the pieces of carbon are reduced in size and therefore facilitate clogging of the flow of gas, and because the potash and fused cyanide are relatively more abundant as carbon decreases and lesser surface of carbon is exposed.

Both practice and theory, therefore, lean to the conclusion that, other things being equal, the process will be hastened by any arrangement that tends to increase the surface of carbon exposed. The use of pulverised fuel would seem to be the ideal condition so far as carbon is concerned, and with an excess of ammonia, the only gaseous alkali, would probably, at a proper temperature, yield ammonium cyanide readily, as shown in Romilly's experiment (*ante*), in which a smoky flame of hydrocarbon gas burning in air yields ammonium cyanide when the gas is charged with ammonia.

The effect of supplying the base also in the condition of powder would probably be to still further facilitate the action, as gaseous cyanogen would meet solid particles of highly heated base as soon as formed, and would combine with the metals of these bases to form cyanides. Alkalies would fuse and would probably tend to produce aggregations with particles of carbon, to that extent impeding access of air to them, but when we take into account the increased rapidity of chemical action under these conditions and the short time given to each group of particles in passing through the furnace, the gain by the process of pulverising will probably be greater than the loss. Solid bases, like lime or baryta, are free from the latter objection, but also have less chemical energy.

5. *Influence of Alkalies or Other Bases.*—The influence of a base upon the union of carbon and nitrogen, both being in contact with the base and at a temperature sufficiently elevated for combination to occur, is probably due merely to the fact that the base serves to remove cyanogen from the sphere of action as fast as it is formed. The belief in a predisposing affinity, a non-correlated power, acting from a given centre to bring about a reaction in which the predisposing body has no share except to combine, *subsequently*, with the products of the reaction, is an ingenious fiction of the older chemistry, which finds little support at the present time. The influence of a foreign substance in impeding the union of two bodies by lessening the opportunities for contact of their respective atoms within a given time supplies a more tangible explanation. Every chemical reaction is limited in violence after the first moment of action—is impeded and finally checked—by the products of the reaction, unless these are removed. Like any foreign substance these substances impair the freedom of access of the reacting atoms to one another and absorb heat which is necessary to the reaction. Whatever tends to remove these products quickly from the field of action tends to facilitate the reaction itself. When *a* and *b* unite to form *ab*, the presence of a third substance, *c*, capable of combining with the compound *ab* to form *abc*, but not with *a* or *b* separately, will facilitate the union of *a* and *b*, for the above reasons.

This would seem to be the function of the alkali or other base in the synthesis of cyanogen. The conclusion is sustained apparently by the experiment of Langlois and the earlier chemists (*ante*), in which ammonia passed over hot charcoal yields ammonium cyanide. Trommsdorff first suggested that it was the presence of ammonia that favoured here the formation of cyanogen by furnishing a means of fixing it as soon as formed.

The theory of the action of bases, of alkalies at least, is susceptible of another explanation. Many authorities (Bromeis, Bunsen and Playfair, Graeger, Rieken *et al.*, *ante*) believe that the union of carbon and nitrogen occurs only at or above the temperature at which potassium is

reduced from its oxide by carbon. Metallic potassium or its vapour must be taken into account upon this hypothesis when the reaction in question is studied. This view would explain the lesser activity of soda in forming cyanides, as it is less readily reducible. Graeger (*Zsb. chem. Tech.*, 1858, 81) finds that in the old fusion process for prussiates the yield is lessened in proportion as potash is replaced by soda, even at temperatures approaching the fusion point of the cast iron pot. He believes that nitrogen from the organic matter in this case is volatilised and lost before metallic sodium is formed, owing to the high temperature required for reduction of sodium. Lime and baryta, from their infusibility, are also difficult to reduce, and should be less suitable for the process. Knowing the incompatibility of cyanogen and oxygen at high temperatures and the fact that cyanogen unites directly with the metals, it is quite possible that cyanogen can only combine when the metal itself is presented to it, and cannot reduce the oxide, at least only by being itself destroyed. Bunsen and Playfair held (*ante*) that cyanogen in the upper part of the iron furnace acted as a reducing agent and was itself destroyed in reducing oxides of iron.

The theory of Berthelot (*ante*) is interesting in this connection. He holds that a direct compound of potassium and carbon (C_2K_2) is formed, and that this compound absorbs nitrogen, forming with it potassium cyanide. The theory is in perfect accord with the preceding one. Delbrück (*ante*) has also shown that cyanogen is formed when a mixture of nitrogen or ammonia with carbon dioxide is brought in contact with fused potassium.

It is possible also that potassium or other metal, under these conditions, unites directly with nitrogen to form nitrides, which then combine with carbon, yielding cyanides. The observation of Briegleb and Geuter, already referred to (*ante*), that magnesium nitride, when heated with carbonic oxide or carbonic acid, evolves cyanogen, lends colour to this view.

6. *The Nature of the Base to be Used.*—As far as experiments have gone, potash seems to be the base best suited. Its great chemical energy and ready fusibility and reducibility in presence of carbon give it advantages over all other bases. Soda, besides being somewhat less powerful as a base, fuses at a higher temperature and therefore involves increase of wear and cost in apparatus. On the other hand, it is cheaper, weight for weight, than potash, and, in addition, its lower molecular weight enables it to do more work for a given weight than potash in the proportion of 138:2 to 106.

The facility with which ammonium cyanide is formed when ammonia is passed over hot charcoal indicates that ammonia, like the fixed alkalies, combines very readily with cyanogen. It has the advantage of not acting as a flux upon the material of the furnace. The use of ammonia, itself produced from nitrogen of the air, to facilitate the synthesis of cyanogen at a lower temperature than that thought necessary for cyanogen alone, is suggested by Komily's experiment and may be a feature of future development in the fixation of nitrogen.

Of the infusible bases the alkaline earths, lime, baryta, strontia, and magnesia only, seem to have sufficiently strong basic power to form cyanides with the air. The cyanides of other metals decompose quite readily when heated. The advantages of the alkaline earths are their infusibility, which prevents clogging of the mixture of coal and basic substance and so permits perfect access of nitrogen, and their cheapness. The corresponding cyanides are soluble and easily converted into alkaline cyanides. These qualities compensate to some extent for the deficient chemical energy of the alkaline earths. Margueritte and Sourdeval (*ante*) found that baryta absorbed nitrogen rapidly and that barium cyanide yielded ammonia on treatment with steam. Siepermann (*ante*) mixes baryta with alkalies to prevent fusion and clogging. Lime, the cheapest of these bases, seems to have been little used. Armengaud speaks of using it in his apparatus in 1843 (*ante*) and Fleck (*ante*) claimed the discovery that

hot calcium hydrate could convert a mixture of nitrogen and carbonic oxide into ammonia and carbon dioxide.

(To be continued).

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, June 19th, 1890.

Dr. W. J. RUSSELL, F.R.S., President, in the Chair.

(Continued from p. 109).

59. "*Studies on the Constitution of the Tri-derivatives of Naphthalene.* No. 4. *The Constitution of α -Naphthylaminedisulphonic Acid* Dahl No. II. *Naphthalene-1:2'-disulphonic Acid.*" By HENRY E. ARMSTRONG and W. P. WYNNE.

When naphthionic acid is sulphonated with 35 percent anhydro-sulphuric acid at a temperature not exceeding 30° according to Dahl and Co.'s German patent No. 41957, 1886, two disulphonic acids are produced, which are respectively known as α -naphthylaminedisulphonic acid No. II. and No. III., the latter constituting the chief product. The constitution of acid No. III. has been given in a previous communication (*Proc. Chem. Soc.*, 1890, 16). With the object of comparing the disulphonic acids obtained by the sulphonation of α -naphthylamine with those known to be produced by the sulphonation of α -naphthol, the authors have undertaken the investigation of acids Nos. I. and II. of Dahl and Co.'s patent, and are now in a position to communicate the results obtained by the examination of acid No. II., for a liberal supply of which they are indebted to Messrs. Dahl and Co.

The product received was in the form of potassium salt, and appeared to be uniform; but on investigation it was found to contain a noteworthy quantity, perhaps 20 percent, of an α -naphthylaminetrisulphonic acid, the formation of which under the conditions above named, is especially interesting as throwing further light on the process involved in the production of isomeric disulphonic acids. When reduced by the hydrazine method, this α -naphthylaminetrisulphonic acid yields a *naphthalenetrisulphonic acid* characterised by forming a chloride, $C_{10}H_5(SO_2Cl)_3$, which crystallises from a mixture of benzene and petroleum spirit in small prisms melting at about 191°; whilst by the Sandmeyer method it is converted into a *chloronaphthalenetrisulphonic acid* characterised by forming a chloride, $C_{10}H_4Cl(SO_2Cl)_3$, which crystallises from benzene in minute prisms, from a mixture of benzene and petroleum spirit in small crystalline aggregates, and from acetic acid in small scales melting at 215°.

α -Naphthylaminedisulphonic acid No. II. on conversion into naphthalenedisulphonic acid by v. Baeyer's hydrazine method, yields a new acid, the salt of which will be described in a subsequent communication. The chloride of this acid, $C_{10}H_6(SO_2Cl)_2$, crystallises from benzene, in which it is readily soluble, in prismatic forms; from a mixture of benzene and petroleum spirit in tufts of opaque irregular needles; and from acetic acid in beautiful glistening plates; it melts at 122.5°, and on distillation with PCl_5 yields a dichloronaphthalene melting at 63–63.5°, convertible by sulphonation, &c., into a sulphochloride, crystallising in needles, which become opaque and melt at 117°. The acid is consequently the 1:2'-disulphonic acid, and is the sixth known naphthalenedisulphonic acid. By the Sandmeyer method, acid No. II. can be converted into a chlorodisulphonic acid, the chloride of which crystallises from a mixture of petroleum spirit and benzene in minute needles, and from acetic acid in small prisms; it melts at 126–127°, and, on distillation with PCl_5 , yields 1:4:3'-trichloronaphthalene,

characterised, among other properties, by melting both at 56° and 66° under the conditions already described (*loc. cit.*). Superposing these results, it follows that α -naphthylaminedisulphonic acid Dahl No. II. is, as its mode of formation would seem to indicate, a sulphonated naphthionic acid, and that it has the constitution:—

Dahl acid No. II.

The authors reserve the investigation of the properties of the 1:2'-naphthalenedisulphonic acid and its derivatives.

60. "Studies on the Constitution of the Tri-derivatives of Naphthalene. No. 5. The Constitution of the Schöllkopf α -Naphthylaminedisulphonic acid." By HENRY E. ARMSTRONG and W. P. WYNNE.

The formation of the Schöllkopf α -naphthylaminedisulphonic acid (German patent 40571) by the nitration and subsequent reduction of the authors' naphthalene-1:4'-disulphonic acid (Bernthsen, *Ber.*, 1889, 3327) renders it evident that the generally accepted view of the constitution of this acid is a correct one. Having been favoured by the Actiengesellschaft für Anilin-fabrikation with a supply of the material prepared by the method given in the Schöllkopf patent, the authors took occasion to submit this to examination. They find that it is converted by the hydrazine method into naphthalene-1:4'-disulphonic acid, which was characterised by conversion into the chloride crystallising from benzene in prisms melting at 182°, and into 1:4'-dichloronaphthalene melting at 107°. On treatment by the Sandmeyer process it gave a chlorodisulphonic acid, the chloride of which crystallised from acetic acid in very small prismatic needles which became opaque on drying, and from a mixture of petroleum spirit and benzene in sparingly soluble glistening flat plates; it melted at 135°, and, on distillation with PCl₅, was converted into δ - or 1:4:1'-trichloronaphthalene melting at 131°. These results place it beyond question that the constitution of the Schöllkopf acid is expressed by the formula—

61. "Studies on the Constitution of the Tri-derivatives of Naphthalene. No. 6. The Constitution of Cassella's β -Naphthylamine- δ -disulphonic Acid." By HENRY E. ARMSTRONG and W. P. WYNNE.

Messrs. Cassella and Co. having been good enough to furnish the authors with a supply of their β -naphthylamine- δ -disulphonic acid, prepared from the β -naphthol-disulphonic acid of their German patent No. 44079, it has been possible to determine its constitution by the hydrazine and Sandmeyer methods already described. On treatment by the hydrazine method, the amido-acid yields, in the first instance, a peculiar ropy gelatinous hydrazine, which can only be freed from tin salts with considerable difficulty. The disulphonic acid obtained from this hydrazine yields a chloride crystallising from benzene, in which it is sparingly soluble, in small flat spear-like needles; this chloride melts at 225°, and on distillation with PCl₅ yields 2:3'-dichloronaphthalene melting at 135°: it is, therefore, naphthalene-2:3'-disulphonic acid—the β -disulphonic acid of Ebert and Merz. By the Sandmeyer method, the amido acid is converted into a chlorodisulphonic acid, the chloride of which crystallises from benzene, in which it is very soluble, in small characteristic radiate groups of very slender needles, and

from a mixture of petroleum spirit and benzene in small opaque aggregates melting at 176°; on distillation with PCl₅ it yields 2:3:2'-trichloronaphthalene melting at 90°. Combining these results, it follows that Cassella's β -naphthylamine- δ -disulphonic acid and the β -naphthol-disulphonic acid of the German patent No. 44097, from which it is derived, have the formula—

and both are, therefore, tri- β -acids isomeric with the corresponding R-acids (*Proc. Chem. Soc.*, 1890, 12).

62. "Studies on the Constitution of the Tri-derivatives of Naphthalene. No. 7. The Disulphonic Acids obtained by Sulphonating the Isomeric Heteronuclear β -Naphthylaminedisulphonic Acids." (First Notice). By HENRY E. ARMSTRONG and W. P. WYNNE.

According to Gans and Co.'s German patent, No. 35019, 1884, β -naphthylamine is converted into the amido-G-disulphonic acid by heating its sulphate with thrice its weight of 20–30 per cent anhydrosulphuric acid at 110–140° until soluble in water; and the same product is said to result when " β -naphthylaminedisulphonic acid" is similarly treated. But inasmuch as four monosulphonic acids are obtainable from β -naphthylamine, to determine the law of sulphonation, it was obviously necessary to examine the behaviour of each of these and to avoid the occurrence of secondary changes as far as possible; experiments with this object in view were commenced several years ago: meanwhile an account of the behaviour of the Brönner acid under conditions similar to those specified by Gans and Co. have been published by Forsling (*Berichte*, 1888, 3496).

(1). 2:1'- β -Naphthylamine- α -sulphonic Acid (Badische Acid):—When the Badische acid is stirred into four times its weight of 20 per cent anhydrosulphuric acid at a temperature not exceeding 20°, and the mixture is allowed to stand, sulphonation proceeds slowly and is not entirely complete even at the end of three months. The product is found to consist almost entirely of an acid recognised as amido-G-disulphonic acid, inasmuch as it gave by the hydrazine and Sandmeyer methods all the products already described as characteristic of this acid (*Proc. Chem. Soc.*, 1890, 12). The naphthalenedisulphochloride prepared from it melted at 137°, and on distillation with PCl₅ gave 1:3-dichloronaphthalene melting at 61·5°; the chloronaphthalenedisulphochloride from it melted at 169°, and on distillation with PCl₅ gave 1:3:2'-trichloronaphthalene melting at 113°. The subsidiary product formed on sulphonating the Badische acid has not yet been prepared in sufficient quantity to admit of its examination.

(2). 2:4'- β -Naphthylamine- α -sulphonic Acid (Dahl Acid).—When stirred into four times its weight of 20 per cent anhydrosulphuric acid at a temperature not exceeding 20°, the Dahl acid gradually undergoes further sulphonation, the process being usually completed in 116–120 hours. The product is found to consist of two isomeric acids, which are readily separated by crystallising out the minor product as normal potassium salt, and subsequently purifying the chief product by repeated crystallisation of its acid potassium salt.

Chief Product.—The acid potassium salt of the chief product crystallises in thistle-down like aggregates, and is very soluble in water; on reduction by the hydrazine method it gave naphthalene-1:3-disulphonic acid which was characterised by means of the chloride melting at 137°; on distillation with PCl₅, this gave 1:3-dichloronaphthalene melting at 61·5° (*loc. cit.*). On treatment by the Sandmeyer process, it was converted into a chlorodisulphonic acid, the chloride of which is very soluble in benzene, and crystallised from a mixture of benzene and petroleum spirit in radiate groups of small prisms, from acetic acid in elongated prismatic needles showing good

end faces; this chloride melted at 156°, and on distillation with PCl_5 gave 2:2':4'-trichloronaphthalene crystallising in radiate groups of very slender characteristic needles melting at 80°. It follows, therefore, that the chief product obtained by the further sulphonation of the Dahl acid under the conditions named has the constitution—

Minor Product.—The normal potassium salt of this acid was obtained in well formed rectangular tablets. The quantity prepared has not sufficed for its complete investigation by both methods, and it has therefore been examined by the Sandmeyer method alone. The corresponding chlorodisulphonic acid yields a *chloride* which crystallises from benzene, in which it is sparingly soluble in the cold, either in prismatic needles or well formed prisms, from a mixture of benzene and petroleum spirit in flat needles, and from acetic acid in long prismatic flat needles; it melts at 158°, and on distillation with PCl_5 is converted into 1:2:4'-trichloronaphthalene crystallising from alcohol in long slender flat needles melting at 78–78.5° (*Proc. Chem. Soc.*, 1889, 49). It follows, therefore, that this amido-acid has the constitution—

(3). 2:3'-β-Naphthylamine-β-sulphonic Acid (Brønner Acid).—When stirred into four times its weight of 20 per cent anhydrosulphuric acid at a temperature not exceeding 20°, the Brønner acid is readily further sulphonated, the process being completed in from 16–20 hours. The product is found to consist of two isomeric acids; the minor product, perhaps 20 per cent, has been identified as G-amidosulphonic acid by the hydrazine and Sandmeyer methods (*o. supra*).

Chief Product.—The acid potassium salt of this acid crystallises in opaque white radiate aggregates of short needles, difficultly soluble in water; but the crystalline form and solubility are much influenced by the presence of small quantities of amido-G-acid, and there is every reason to regard it as identical with the acid obtained by Forsling (*Ber.*, 1888, 3496) by heating Brønner acid with 3 to 4 parts of "fuming sulphuric acid" (percentage of added SO_3 not stated) at 110° until the product was soluble in water. When reduced by the hydrazine process, the amido-acid constituting the chief product gave naphthalene 1:3'-disulphonic acid, which was characterised by means of its sulphochloride melting at 127°, and the derived 1:3'-dichloronaphthalene melting at 48.5°. On treatment by the Sandmeyer process, it was converted into a chlorodisulphonic acid, the *chloride* of which crystallised from benzene, in which it was readily soluble, in well formed prisms, from a mixture of benzene and light petroleum in small prisms showing good faces, and from acetic acid in prismatic needles; it melted at 124.5–125°, and on distillation with PCl_5 gave 1:2:3'-trichloronaphthalene crystallising from alcohol in tufts of short very slender needles melting at 92° (*Proc. Chem. Soc.*, 1889, 52). Combining these results, the amido-acid constituting the chief product, and presumably Forsling's acid, has the constitution—

By operating at higher temperatures the yield of this

acid is diminished, and that of the amido-G-acid increased.

(4). 2:2'-β-Naphthylamine-β-sulphonic Acid (Bayer and Duisberg's Delta-acid).—When stirred into four times its weight of 20 per cent anhydrosulphuric acid at a temperature not exceeding 25°, delta-acid yields a complex product, which has not yet been satisfactorily separated into its constituents. Although the acid was very carefully purified and, it is believed, was freed from Brønner acid, one of the disulphonic acids obtained from it and forming a considerable proportion of the product, had the constitution and properties of the β-naphthylamine-1:3'-disulphonic acid prepared from pure Brønner acid. Two other products were obtained and are at present under investigation; one of these is converted by the Sandmeyer process into a chlorodisulphonic acid which seems to be identical with that derived from the sulphonated Dahl acid of the constitution—

The investigation of the changes which occur in the conversion of these various acids into amido-R-acid on the one hand, and the Cassella β-naphthylamine-δ-sulphonic acid on the other are at present under investigation, and the authors hope to be in a position shortly to communicate in a final form results indicating the influence exercised by NH_2 , as compared with Cl and OH in a β-position on the formation of disulphonic acids.

63. "Studies on the Constitution of the Tri-derivatives of Naphthalene. No. 8. β-Chloronaphthalenedisulphonic Acids." (First Notice). By HENRY E. ARMSTRONG and W. P. WYNNE.

As already indicated in a previous communication, the study of the disulphonic acids obtained by sulphonating chloronaphthalenesulphonic acids of known constitution is being carried on *pari passu* with that of the acids derived from the various naphthylaminesulphonic acids (*Proc. Chem. Soc.*, 1890, 18). A brief account of the results obtained with the four heteronuclear β-chloronaphthalenesulphonic acids under like conditions is now given, details with reference to the composition of the salts, &c., being reserved for a full communication. Sulphonation was effected by adding the theoretical quantity of sulphuric anhydride, employed in the form of 20 per cent anhydrosulphuric acid, to the dry potassium β-chloronaphthalenesulphonate and heating the warm mixture at 100° for an hour, the potassium sulphate formed being removed by treatment with alcohol and the excess of sulphuric acid by means of barium carbonate.

(1). 2:1'-β-Chloronaphthalene-α-sulphonic Acid.—This acid, under the conditions named, gives a uniform chloronaphthalenedisulphonic acid, the *chloride*,—

of which crystallises from benzene, in which it is comparatively sparingly soluble, in beautiful radiate groups of long slender lustrous needles; it melts at 170°, and on distillation with PCl_5 gives 1:3:2'-trichloronaphthalene melting at 113°. The constitution of the acid is therefore—

and corresponds with the G-amido acid obtainable from the 2:1'-β-naphthylamine-α-sulphonic acid.

(2). 2:4'-β-Chloronaphthalene-α-sulphonic Acid.—This acid gives what seems to be a uniform product. The potassium salt of the chlorodisulphonic acid is particularly well characterised since it crystallises in prismatic forms,

whereas the corresponding salts of the isomeric acids crystallise in slender needles. The chloride,—

is apparently dimorphous and crystallises from benzene for the most part in very lustrous scales, but occasionally in prismatic forms, both of which melt at $156-156.5^\circ$, and on distillation with PCl_5 give the same trichloronaphthalene melting at 79° . This trichloronaphthalene has not yet been compared by sulphonation, &c., with the 1:2:4'- and the 1:3:3'-trichloronaphthalenes, with one of which it must be identical, owing to the insufficient supply of material; most probably it has the constitution 1:3:3' and corresponds with that derived from the amido-acid constituting the chief product of the further sulphonation of the 2:4'- β -naphthylamine- α -sulphonic acid.

(3). 2:3'- β -Chloronaphthalene- β -sulphonic Acid.—Under the conditions named, this acid gives two chlorodisulphonic acids which are best separated by the fractional crystallisation of the potassium salts. The less soluble potassium salt constituting the minor product yields a chloride, $\text{C}_{10}\text{H}_7\text{Cl}(\text{SO}_2\text{Cl})_2$, which crystallises from benzene in aggregates of what at first sight seemed to be radiate prisms, but under a lens were found to be composed of bundles of very slender needles aggregated in prismatic forms, having a silky lustre; it melts at 148° , and on distillation with PCl_5 gives 1:3:2'-trichloronaphthalene, crystallising from alcohol in characteristic tufts of needles melting at 113° .

The more soluble potassium salt constituting the major product was found to give products identical with those obtained from the chlorodisulphonic acid derived from 2:1'- β -chloronaphthalene- α -sulphonic acid (*v. supra*). The chloride crystallises from benzene in radiate groups of needles melting at 169° , and on distillation with PCl_5 yields 1:3:2'-trichloronaphthalene melting at 113° . The constitution of the two acids is represented by the formulæ—

(4). 2:2'- β -Chloronaphthalene- β -sulphonic Acid.—This acid, under the above conditions, yields a uniform chlorodisulphonic acid, the chloride of which,—

crystallises in beautiful radiate groups of flat prismatic needles melting at 174° . On distillation with PCl_5 , the chloride is converted into 1:3:3'-trichloronaphthalene, crystallising from alcohol in radiate groups of long slender needles melting at 80.5° . The acid has, therefore, the constitution—

(To be continued).

CORRESPONDENCE.

THE ORIGIN OF MELINITE AND LYDDITE (PICRIC ACID).

To the Editor of the Chemical News.

SIR,—In your issue of the 12th inst. there occurs, page 131, the following sentence:—

"Although picric acid compounds were long since experimented with as explosive agents, it was not until a

very serious accident occurred, in 1887, at some works near Manchester, where the dye had been for some time manufactured, that public attention was directed in England to the powerfully explosive nature of this substance itself."

As this sentence forms part of this year's great annual scientific manifesto, with which Presidents of the British Association for the Advancement of Science are wont to favour your readers, I trust your love of scientific precision will help me to point out that, "*prior*" to the very serious accident near Manchester, public attention "*was*" directed in England to the powerfully explosive nature of this substance itself through the medium of a very serious publication in London—or rather through the medium of two very serious publications—viz., a patent and a paper read before the Chemical Society, as you will see from the following statement, which I drew up last spring at the request of, and as I hoped for the use of, my distinguished fellow-inventor—the President of the Government Committee on Explosives, and now President of the British Association for the Advancement of Science.—I am, &c.

H. SPRENGEL.

54, Denbigh Street, S.W.
May 5th, 1890.

Dear Sir Frederick,—Having had the advantage of Dr. Dupré's friendly advice, I now beg to send you the simple statement, accompanied by all the documentary evidence at my disposal, for which you were good enough to ask in your note of the 29th ult.—Yours very truly and respectfully,

H. SPRENGEL.

Sir F. Abel, C.B., F.R.S., &c.,

President of Government Committee on Explosives.

SIMPLE STATEMENT.

Picric Acid, "*as a powerful Explosive when fired by a detonator*," was discovered and used by me early in 1871. I patented this substance in England in conjunction with a number of other explosive agents.

As this patent (2nd edition) is unfortunately out of print and now older than fourteen years, I am unable to procure and enclose a copy. Be it mentioned, however, that in the complete specification of this patent, No. 2642, of October 5th, 1871, I say, page 5, lines 5 to 8:—

"This invention relates to the preparation and use of explosive compounds, and is partly based on the principle of keeping separate the "*oxydising*" from the "*combustible*" agent until such time as the effect of their chemical combination is required."

Picric acid, being neither an oxidising nor a combustible agent, but partaking of the character of both, already combined, viz., a complete explosive by itself, I separated it from the rest of the substances mentioned in the patent, and placed it alone in a detached sentence, page 6, lines 17 and 18, thus:—"I also employ Picric Acid."

August, 1873, I published a paper in explanation of this patent in the *Journal of the Chemical Society of London*, of which paper I am able to enclose a copy. There I say, page 10 (marked in red):—

"Be it noticed here that picric acid alone contains a sufficient amount of available oxygen to render it, without the help of foreign oxydisers, a powerful explosive, when fired by a detonator. Its explosion is almost unaccompanied by smoke."

(In other words:—It is almost completely gasified by detonation in spite of its excess of carbon, necessitating; as was obvious to every F.C.S., the formation of carbonic oxide. See my table and analysis, pp. 5 and 7.)

A copy of both this patent and paper I sent to M. Eugène Turpin of Paris, February 9th, 1884. Twelve months later this gentleman patented* my statements of 1871 and 1873, respecting Picric Acid, without mentioning the source of his information; and that in spite of the

* Brevet No. 167512 of February 7th, 1885.

sharp reprimand which he had previously received from Sir F. Abel for having brought out, as his own, another invention of mine with much flourish of trumpets. (See my enclosed pamphlet,* pp. 17 to 26.)

Finally it may be recorded, that the first Picric Acid shot was fired by me early in March, 1871, at Faversham in Kent, forming part of a piece of work which want of encouragement and the hostility of gunpowder makers obliged me to put aside.

H. SPRENGEL

London, May 5th, 1890.

ESTIMATION OF AMMONIA.

To the Editor of the Chemical News.

SIR,—I have read a note in the CHEMICAL NEWS of last week, page 126, upon an apparatus for the estimation of ammonia in sewage and sand; the apparatus is also figured.

I should like to draw the attention of your readers to the fact that I employed, while at Bonn, an apparatus almost identical with that described by Mr. Hazen, the only difference being that I used in place of the long, and often inconvenient, Liebig's condenser, a spiral worm of glass, and which I found to answer equally as well. I have occasionally used the method since my return for the determination of ammonia in products obtained from bituminous and petroleum shales, and I cannot say that I have been so favourably impressed with the method as Mr. Hazen appears to be. The method is more complicated, takes up more room, and necessitates the expenditure of more care and considerably more time than the process of simple boiling of the liquid to be examined.

Besides, when using concentrated solutions of ammonia, unless the small flask be continuously heated, my experience has been that it is almost impossible to drive over the last traces of ammonia, thus, of course, yielding results which in most cases are found to be too low. The method, as described is, as Mr. Hazen remarks, useless and inapplicable to water analysis.—I am, &c.,

ARTHUR R. HASLAM, Ph.D.

The Laboratory, Wellington Quay,

Determination of Acetone in Methyllic Alcohol and the Methylenes of Denaturation.—Leo Vignon.—The crude methyllic spirit used for rendering ethylic alcohols

* "The Hell-Gate Explosion, near New York, and so-called 'Rack-rocks,' with a few words on so-called 'Panclastite,'" by H. Sprengel, London; E. & F. N. Spon, 1886.

undrinkable is known in France as methylene. The author finds that Kraemer's method commonly used may serve for the determination of very small quantities of acetone in methyllic alcohol; it cannot be employed for estimating the acetone in the methylenes used for denaturation, which contain 20 to 25 per cent of acetone. Zieben's method is applicable only to methylenes which contain neither aldehyd nor ethylic alcohol, nor, in general, any substance other than acetone capable of yielding iodoform.

On Oxytetric Acid.—Ch. Cloëz.—The author assigns to this acid the formula $C_5H_6O_4$.

Identity of the Oxytetric and Mesaconic Acids.—Ch. Cloëz.—The result of this paper appears from the title.

The Determination of Hydrochloric Acid in a Solution of Hydroxylamine Hydrochlorate.—J. A. Muller.—This determination can be made with a solution of soda quite free from carbonate, using phenolphthalein as the indicator.

Action of Oxygenated Water on the Oxy-compounds of Manganese.—A. Gorgen.—This memoir does not admit of useful abstraction.

THE CHEMICAL NEWS.

VOL. LXII. No. 1610.

THE RIVER AIRE: A STUDY IN RIVER POLLUTION.*

By T. H. EASTERFIELD and J. MITCHELL WILSON, M.D.

THE following paper endeavours by a series of analyses to show the amount and probable sources of the pollution of the river Aire, from its origin until it reaches the estuary of the Humber. (It had been proposed to treat of the Calder also in this communication; we reserve, however, the results of our investigations upon this river for publication at another time.) In the autumn of 1889 we were engaged in a similar inquiry, but then only with reference to that portion of the Aire which lies at some distance below Leeds, and after it is joined by the river Calder. The facts then ascertained formed the basis of a report to the Goole Local Board by one of the authors of this memoir (J. M. Wilson).

On previous occasions, in dealing with the question of river pollution above Leeds, analyses have been made, chiefly, if not only, of such contributory streams, or becks, as discharge the largest amount of polluting matter into the river. These inquiries doubtless served the purpose of tracing the source of these gross pollutions, but gave little or no idea of the extent to which the whole volume of the river was thereby affected. Our object has been to supply this information.

The points selected by us, in taking samples for analysis, have been chosen with reference to possible pollutions from large centres of population on the banks of the river or of contributing streams, but only at such a distance below the discharge of such pollutions that their average effect upon the river could be properly estimated.

It is notorious that the river Aire has been, and is still being, polluted with every kind of manufacturing refuse and with domestic sewage. A large part of the solid portion of these polluting matters settles in the bed of the river, and there remains during the ordinary flow of the water. The result, however, of a heavy or long-continued rain-fall is to increase enormously the volume of the stream, scouring out the upper parts of the river, and sending the polluting matters nearer the outfall. This action may be a partial one, only affecting a few miles of the river, or it may be so general as to cause a thorough cleansing of the river bed. In each case the deposit on the sides and bed of the river is carried onwards only so far as the force of the current permits; in the one case the solid matter again settles, causing a large increase in the total impurities in the lower parts of the river; in the other case the mass of the impurities is carried to the sea. It therefore follows that the condition of the water at any given point cannot be entirely due to pollutions poured in by any district immediately above that point; rather may we ascribe this condition to local influences, together with impurities originating nearer the source. The coating of the river bed is also broken up through the fermentation of the deposited filth, and the consequent evolution of gas. This action is especially noticeable below Leeds, and is one cause of the offensive odours with respect to which so many complaints have justly arisen. The same cause may also to some extent explain the fact that the amount of suspended solids varies somewhat irregularly in the different analyses.

Since the present paper does not pretend to furnish any-

thing like complete and exhaustive analyses of the samples of water, it became a matter of importance to select which of the impurities present should be estimated in each case. After careful consideration we decided only to have regard to the constituents enumerated upon the wall diagrams, and we believe that the results there presented give a very fair idea of the condition of the river. In all cases we have stated our results in grains per gallon rather than in parts per million, believing that results so stated are much more comprehensible to most Englishmen, and especially to those with whom the metric system is not in daily use.

In any investigation of river pollution it is necessary to bear in mind the state of the river at the time when the research was being carried out; since the impurities in the water vary greatly in quality and quantity, according as the season is wet or dry; while, further, the physiography of the river basin must, at the same time be considered; for, clearly, constituents, which in one case are to be regarded as results of concomitants to pollution, may in other cases be natural to the water, and be no sign whatever of contamination from artificial sources.

In connection with the latter consideration, we venture to submit to you a concise account of the geology of the river basin. Malham Tarn itself rests upon Cambrian states, but the surrounding fells, from which it no doubt receives its chief supplies of water, consist of Yoredale shales, capped by millstone grit. After leaving the town, the river flows about one mile underground through carboniferous limestone, until it emerges at Malham Cove. It then passes still over carboniferous limestone for about another two miles, when it reaches the outcrop of the Yoredale shales, through which it runs until it reaches Skipton. From this point the river directs its course over millstone grit, succeeded by coal measures, until at Castleford it is joined by the Calder, and is now some sixty miles from its source. Here it enters the magnesian limestone district, through which it makes its way for about five miles, then descends for about sixteen miles over new red sandstone, after which it reaches the warpland, where it falls into the Ouse. It will be noticed that the samples of water, of which the analyses are given, were collected on two separate days, August 5th and 20th. The reason for allowing so long a time to elapse between the collection of samples was that, during a portion of this interval, the river was considerably swollen by heavy rains, and it would have served no useful purpose to present analyses of the river when in such an abnormal condition. The first effect of a flood is, no doubt, to bring down an increased quantity of filth, but after the waters have subsided the river is found to be purged from a good deal of its former impurity; hence, in the second series of analyses, the water immediately below Shipley was found to be upon the whole far less objectionable than in the first series, though some of the constituents have remained constant. This is most graphically shown in the series of curves presented to you. Upon these curves the impurities are quantitatively represented by the ordinates, while the abscissæ show the distance from the source of the river at which each sample was taken.

As there is always a certain amount of difficulty in deciding which is the actual source of a river, we have considered Malham Cove as the river head, because here the river first emerges in considerable volume from the foot of the rocks, is easily accessible, and is of such a state of purity that it forms a very convenient standard of comparison. It is true that, even here, the amount of dissolved solids and albumenoid ammonia is considerable but this is not to be wondered at when we consider that the water has originally flowed from peaty fells, and then found its way through and over limestone rocks for a very considerable time before its emergence at Malham. Though the amount of suspended matter in this water was too small for estimation, the colour of the water was distinctly brown when seen even in small bulk, as is so often the case with waters derived from peaty and moorland

* Read before the British Association for the Advancement of Science, Leeds Meeting, 1890, Section B.

Results of Analysis.

	Date.	Suspended solids.	Dissolved solids.	Chlorine.	Free ammonia.	Organic ammonia.	Oxygen required.	Sulphuric acid.

sources. This accounts for the enormous reducing power of the Malham water upon permanganate, the water having been collected at a later date than the other samples, when the stream was swollen with brown peaty water from the fells.

Coming now to the consideration of the individual results as recorded in the curves and diagrams, we notice that, in the case of all the impurities, a gradual rise takes place until Skipton is reached, but that a slight fall takes place in the water taken from immediately above Keighley. This is easily explained by the fact that the Aire between Skipton and Keighley receives a considerable volume of clean soft water from the millstone grit. At Keighley the Worth Beck, itself a foul stream, discharges its contents into the river, bringing down a large quantity of trade sewage, and one is surprised that its influence upon the river is so slight. At Saltaire Park the water is nearly of the same quality as at Keighley, but in nearly all impurities there is a slight reduction. One and a half miles lower, however, the river has received the effect of the Saltaire, Shipley, and Bradford districts, and it is here that for the first time the river assumes that objectionable aspect and foul smell which has made the name of the Aire a bye-word in the districts through which it passes. At Shipley the first series of analyses ends. In respect of most of the foreign constituents the second sample is decidedly better than the first; but the difference in the case of the albumenoid ammonia is but small, whilst the sulphates have remained constant. The river was about two inches higher on this occasion than upon the first, but was considerably lower than it had been five days previously. In every case there is a marked increase in the impurities between Shipley and Kirkstall; but from Kirkstall to half a mile below the Leeds Sewage Works at Knostrop, the rise in every constituent is found to be excessive, and in nearly every case the impurities are here found to be at a maximum. This result is of importance, and scarcely confirms a recent statement, "that the river is very much purer when it leaves Leeds than when it enters it." At Allerton the sulphuric acid is at its highest, while the suspended solids are abnormally low. Below the junction of the Aire and Calder the suspended solids have again risen, and a small increase has taken place in the chlorides. Thus, it will be noticed that with the exception of suspended solids, chlorine, and sulphates, the maximum point is just below Leeds; the rise in chlorine and sulphates after passing Leeds is, we believe, chiefly due to chemical works on the river bank, and to a foul beck entering the river at Methley. The abnormal fall in the suspended matters at Allerton is to us inexplicable, for the sample was taken by one of us; we have, however, no reason to doubt the results of our analyses. It cannot be expected that the curves should follow one another with rhythmic constancy. Indeed, if it were so, this paper would be superfluous.

The figures given under the head of suspended solids will, we think, emphatically support the generally accepted

view that the warp—or what may be termed the only non-objectionable foreign ingredient in the river—is not the result of fluvial denudation, but has its origin in marine action on the Yorkshire coast north of the Humber, whence it is carried into the Ouse and Humber by the tide. The largest amount of suspended solids in the river, before it was influenced by tidal action, was 7'5 grains per gallon, and other analyses have shown that other Yorkshire rivers do exceed this, while in the Ouse, near Goole, there were 64 grains per gallon of suspended matter at low tide, and in the same river in October, 1889, during a "fresh" and at flood tide, the suspended matter equalled 263 grains per gallon. Comparing now the Leeds and Bradford areas, we may say that upon August 5th the water after leaving Shipley contained—

5 times as much	suspended matter
1½ "	" dissolved solids
1½ "	" chlorides
3½ "	" free ammonia
2½ "	" organic ammonia
1½ "	" sulphates

as when the water passed from Saltaire Park into the Shipley and Bradford district. In the case of Leeds, the water below Knostrop sewage outlet on August 20th contained—

1½ times as much	dissolved matter
3 "	" suspended matter
1½ "	" chlorine
2½ "	" free ammonia
1½ "	" organic ammonia
1½ "	" sulphuric acid

as in the case of the same water at Kirkstall Abbey. We do not, however, feel able to act as judges in the case of Leeds *versus* Bradford. Our facts show that both districts are responsible for excessive pollution.

Our results may be summed up as follows:—(1) That the river, originally a limpid stream, receives pollution from all the townships on its banks until it passes Leeds, when the pollution has become so great that the effect of smaller towns below it becomes appreciable; (2) that between each centre of population the river appears to cleanse itself to a small extent by natural causes; (3) that nearly all the impurities rise and fall simultaneously, but not in the same proportion; (4) that there is no evidence that the "warp" is chiefly brought down by the rivers, but rather that it is brought up the river by the tide.

If we consider all the results of our inquiry from a practical aspect, it will be admitted that the provisions of the Pollution of Rivers Act, have not been, and are not being, much enforced in the water-shed of the Aire. Each gallon of the filtered water taken throughout the whole length of the river has been shown to contain mineral and organic impurities in ever-increasing amounts. Even the comparatively minute masses of the impurities, which we have shown to be present in each gallon of water

analysed, must, if measured by the daily flow of many thousand gallons of river water, represent enormous quantities of waste material, which might perhaps be more profitably utilised, or serve some other end than that of converting the natural blessing of a pure stream into the doubtful advantage of a navigable sewer.

DETECTION OF IODINE IN THE PRESENCE OF CHLORINE.

(ADDITIONAL NOTE).

By ALEX. JOHNSTONE.

AFTER the iodine has been liberated, as described in my previous note (see CHEMICAL NEWS, vol. lxii., p. 153), by the action of strong H_2SO_4 , the minutest trace of its free presence can be made self-evident by at once pouring into the tube a drop or two of CS_2 , when the well-known characteristic change to pink in the colour of the latter will result from its absorption of the iodine.

Edinburgh University.

THE DRY ASSAY OF TIN ORES.*

PART I.

By HEINRICH O. HOFFMANN,
Assistant Professor of Mining and Metallurgy.

(Concluded from p. 159).

(8). THE effect of potassium carbonate on the cyanide assay was tested by fusing in a naked crucible 5 grms. of ore with 30 grms. of potassium cyanide, to which had been added different quantities of this flux. One-third of the flux mixture was rammed into the bottom of the crucible, and the rest mixed with the ore, except a small quantity kept to be used as a cover. The average time required to complete the assay was ten minutes from the time the charge began to fuse.

TABLE XIV.

No. of Assay.	Charge.				Resulting tin.	
	Ore.	KCy.	K_2CO_3 .	P.c. in mixt.		
	Grms.	Grms.	Grms.	P.c. in mixt.	Grms.	Per cent.
62.	5	30	3	9.09	3.325	66.50
63.	5	30	6	16.66	3.300	66.00
64.	5	30	9	23.07	3.275	65.50
65.	5	30	12	28.57	3.263	65.26
66.	5	30	15	33.33	3.235	64.70
67.	5	30	18	37.50	3.230	64.60
68.	5	30	21	41.17	3.190	63.80

The charges behaved during the fusion just as if pure cyanide had been used. The crucibles remained uncorroded. On breaking, it was found that with the increase of potash in the mixture the crucible was less soaked with cyanide; in the last assay, with 41.17 per cent potassium carbonate, the bottom was blackened only to the depth of $\frac{1}{4}$ inch. The top of the slag was, in all the assays, as smooth as with pure cyanide. The colour had, however, changed; with small quantities of potash, the slag, on the surface as well as on the fracture, had a bluish tinge, which grew deeper, until, in the last assay, it became of a decided blue-grey colour. The structure of the slag became more and more granular, until it was so coarse as to have the appearance of granulated sugar cemented together. Finally, with the increase of potash the lustre of the slag decreased, while at the same time

it grew harder and tougher. The buttons of tin obtained did not differ in appearance from those with pure cyanide.

In Table XIV. two points are striking: first, that the amount of tin obtained grows smaller with the increase of potassium carbonate; and, secondly, that no tin is recovered in the slags or in the crucible. Both facts are probably due to the same cause,* namely, that metallic tin decomposes alkali carbonates, forming stannates which are not readily fusible. In fact, Berthier† says: "By fusing one part of metallic tin with four or five parts of potassium carbonate, a substance is obtained which is liquid, compact, opaque, yellow like wax, and crystalline." In the assays given in the table, the quantity of flux was increased in proportion to the percentage of potash added. As this alone might have had a bad effect on the result, a number of assays were made in which the percentage of potash was the same as in Nos. 64 to 68, the total amount of flux, however, not exceeding 30 grms. They were all very unsatisfactory. Over fifteen minutes were required for the fusion, and there was no regularity in the results. To counteract this, assays were made, to which charcoal had been added to strengthen somewhat the weakened action of the diluted fluxes, placing, however, fluxes free from charcoal in the bottom of the crucibles. The buttons gave higher results, but the irregularity in their weights was the same as before. It would appear, therefore, that the potassium cyanide needs to be practically free from potassium carbonate; 9.09 per cent of the latter showing already a loss of 1.34 per cent in the result obtained.

(9). The effect of sodium carbonate was tried in the same way. Although this alkali is not common with potassium cyanide, it was thought advisable to test it, as, when potassium cyanide is used in blowpipe experiments, it is generally mixed with an equal weight of sodium carbonate.

The mixtures were not so readily fusible as the corresponding potassium charges, and required fifteen minutes, instead of ten as before. They were, however, just as thin when once melted. When cold, the slags were similar to the potassium slags, only more vitreous and harder. The bluish grey shades of colour were missing; the slags were white, but had no lustre whatever; the buttons were, on the whole, the same as above, but showed bead-like excrescences.

TABLE XV.

No. of Assay.	Charge.				Resulting tin.	
	Ore.	KCy.	Na_2CO_3 .	P.c. in mixt.		
	Grms.	Grms.	Grms.	P.c. in mixt.	Grms.	Per cent.
69.	5	30	3	9.09	3.315	66.30
70.	5	30	6	16.66	3.280	65.60
71.	5	30	9	23.07	3.270	65.40
72.	5	30	12	28.57	3.110	62.20
73.	5	30	15	33.33	3.055	61.10
74.	5	30	18	37.50	3.025	60.50
75.	5	30	21	41.17	2.910	58.20

Table XV., it will be seen, contains no columns for tin in slags or crucible, and the percentage of tin extracted is smaller than with the potassium salt, the inevitable

conclusion being that an admixture of soda has a still more deleterious effect on the result than one of potash.

(10). The influence of potassium sulphate is a very bad one. Bloxam* states that, in the presence of potassium sulphate, stannous and stannic sulphides are formed; the former if the proportion of sulphate be small, the latter if sufficiently large, the stannous sulphide remaining undissolved as a black powder if the slag be treated with water, the stannic sulphide going into solution, and being precipitated as yellow sulphide upon acidulating.

In the experiments, different amounts of potassium sulphate were added to 30 grms. of potassium cyanide, and two-thirds of the new flux mixed with the ore, one-third being placed in the bottom of the naked crucible. The time required for tranquil fusion was ten minutes.

The charges fused readily, and the crucibles were not attacked; the surface of all the slags was smooth, the colour deepening with the percentage of potassium sulphate from light red, with a dark rim, to black. The fracture was at first similar to that of pure cyanide, and grew finer until it became stony; the colour, at first very light peach blossom, became darker, till it reached, with the last assay, a dark flesh-colour. The hardness and toughness of the slags also increased with the percentage of potassium sulphate.

The results obtained show a gradual decrease in the percentage of tin. One per cent of potassium sulphate causes already a loss of 4'14 per cent tin. In assay No. 76 some stannous sulphide was present; it decreased in No. 77, and was absent in No. 78, which, when acidulated, gave a copious precipitate of stannic sulphide. The deleterious influence of potassium sulphate, which was first shown by Bloxam, is thus verified by a series of systematic figures.

(11). Various grades of the commercial potassium cyanide were obtained and tested. The grade of the cyanide can be judged from its general appearance, the pure being coarsely crystalline, soft, and snow-white. The lowest grade—"or mining purposes"—is reached when the structure becomes stony, and strongly resists pulverisation; the colour is a decided grey, resulting from finely divided iron.

In each experiment 20 grms. of the special brand of cyanide were mixed with 5 grms. of ore, 5 grms. being reserved for the bottom of the crucible, and 5 grms. for a cover. The average time required for tranquil fusion was ten minutes.

a. "Granular Purified"—86 to 90 per cent KCy, with some KOCy and K_2CO_3 —1'25 dollars per pound.

The upper slag did not have the beautiful crystalline structure nor the strong lustre of the pure cyanide. It was white, but showed a bluish tinge near the top. The average result is 4'18 per cent too low, and the greatest discrepancy between the single results is 2'50 per cent.

b. "Pure for Gold Platers"—92 per cent KCy, 5 per cent KOCy, and 3 per cent other salts—1'25 dollars per pound.

The general characteristics are the same as those of Nos. 83 to 85, but the results are higher and more uniform.

c. "Common Fused"—85 per cent KCy—0'55 dollar per pound.

* *Journal of the Chemical Society, New Series, 1865, vol. iii., p. 97.*

The upper slag has a stony fracture, and is of a dull white colour. The results are very low and very irregular.

d. "Common for Mining Purposes"—65 per cent KCy—0'50 dollar per pound.

The surface of the slag is smooth, has a dark blue colour with grey and yellow streaks passing through it. The fracture is stony, the slag is hard and tough, and is flesh-coloured. The results are as bad as those from Nos. 89 to 91.

It will be seen that, of the different grades, only the brand "Pure for Gold Platers" produces results—0'74 per cent too low—which are sufficiently accurate for every-day purposes. As these brands represent each a certain definite grade of a particular firm, it will be seen that the assayer is obliged to test each separately, making the ordinary chemically pure potassium cyanide—98 per cent KCy and 2 per cent KOCy—his standard.

THE FIXATION OF ATMOSPHERIC NITROGEN.*

PART II.

By A. A. BRENNEMAN, S.B.†

(Concluded from p. 162.)

7. *The Relation of Ammonia to Cyanogen and the Conditions which Determine the Formation of One or the Other.*—The production of ammonia by bringing together at a high temperature carbon, air or nitrogen, steam, and a basic substance has long been known. The history of the subject, although closely related in many respects to the question in hand, has been omitted in this discussion for want of time. It is, however, difficult to separate two questions which deal, in a certain sense, with different phases of the same reaction. If any definite conclusion can be drawn from the results of industrial experiments it is that higher temperatures favour the production of cyanides and lower temperatures, of ammonia, with the addition also that vapour of water in excess is certainly unfavourable to the productions of cyanides but probably favourable to the production of ammonia. It is possible even that, for a temperature sufficiently high, supposing that it could be maintained against the cooling effect involved in the decomposition of water by hot carbon, the proportion of water above or below a given limit might be the condition determining the production of ammonia in one case or cyanides in the other. It is difficult in the present state of our knowledge upon the subject to mention any conditions, other than variation in temperature and variation in quantity of water, which can account for the production at one time of ammonia and at another of cyanides in a furnace using in both cases precisely similar materials. The belief of Berzelius, Wöhler, Bromelius, and others (*ante*), that formation of ammonia was the preliminary stage in the synthesis of cyanides and that water acted as an intermediary, accords with this view. An

* *Journal of the American Chemical Society, vol. xi., Nos. 1-2.*

† The substance of this article was prepared as an appendix to a commercial report, but has not been printed heretofore in any scientific journal.—A. A. B.

excess of water, both by lowering the temperature and by impeding contact of nitrogen and carbon, would retard the formation of cyanides and proportionally increase the ammonia.

The extraordinary permanence of ammonium cyanide, in comparison with other ammonium salts, at high temperatures (*ante*), taken in connection with the fact that ammonia by itself is dissociated at high temperatures, may indicate that at very high temperatures ammonia can resist dissociation only in presence of a more refractory substance, hydrocyanic acid, with which it can combine. Ammonia in contact with coal, at a very high temperature, forms ammonium cyanide (*ante*). This may be taken to mean that ammonia is more unstable in presence of hot carbon at that temperature than when merely heated alone, and that the portion first decomposed forms hydrocyanic acid, which unites at once with a portion of ammonia not yet decomposed (because not yet in contact with carbon), and thus, in forming the stable compound ammonium cyanide, the ammonia is protected from dissociation or chemical decomposition. But if ammonia is decomposed at these temperatures it is unlikely that it can form under the same condition, while it is evident that cyanogen not only can but does form. We are led then to the hypothesis that, other conditions remaining unchanged, temperature is an important, if not the leading condition, which determines the production, respectively, of ammonia or cyanogen.

With respect to water as a determining cause, it may now be said that while an excess of water probably tends more and more to oxidise or otherwise decompose cyanogen* as fast as it is formed at very high temperature its influence would be merely mechanical in retarding the formation of ammonia at a temperature somewhat lower. When the temperature is sufficiently high to enable carbon to decompose water one of the products of decomposition (CO) is without influence upon the formation of ammonia, while the other, hydrogen, is in the nascent state and therefore in the condition most favourable for union with nitrogen irrespective of the presence of carbon. If water were in a state of dissociation due to heat alone, oxygen coming from water could not, under those conditions, act upon ammonia, since it could unite neither with hydrogen or nitrogen. The case may be stated as follows:—

a. Ammonia is not permanent at very high temperature, except in combination with cyanogen, but is permanent at somewhat lower temperatures, still above a red heat. It is not decomposed by water at any temperature, but at certain temperatures its formation will be favoured by the very conditions that make water an unstable compound, i.e., high temperature and presence of carbon.

b. Cyanogen is permanent at very high temperatures with or without presence of ammonia. Cyanides are probably decomposed by water in excess at very high temperatures.

Finally, the presence of water in moderate quantity at certain elevated temperatures may favour the production of cyanides by permitting a certain formation of ammonia, which is then converted into cyanides, the temperature being lower on the whole than that required for the formation of cyanogen without water. Here ammonia clearly acts as an intermediary, but the temperature, being above a certain limit, favours the production of cyanides rather than ammonia as the final product. At a slightly lower temperature—still, however, above the point at which water is decomposed by carbon—ammonia would form in preference to cyanides and in greater quantity; with an excess of steam ammonia would be the sole product. This may suggest the possibility of working a furnace intermittently with changes of temperature for the production in succession of cyanogen and ammonia, or, what is the same in principle, the working of two furnaces in

conjunction, one to produce ammonia and the other to convert this ammonia into cyanides.

8. *The Influence of Other Gases upon the Absorption of Nitrogen by Carbon.*—The influence of carbon monoxide and carbon dioxide cannot be definitely stated. Bramwell expressed a preference for the latter in his cyanogen retorts, along with nitrogen, but it is hard to find any reason in theory for this preference, since the higher oxide of carbon is always reduced to the lower in presence of hot carbon, and must be so changed in the cyanogen furnace. As it is therefore, an oxidising agent, it should in theory be more objectionable than carbon monoxide. It is more probable that foreign gases, provided they have no oxidising character, merely impede the access of nitrogen to carbon and only act mechanically to retard the union of carbon and nitrogen.

It may perhaps be expected that the above theory should also explain why cyanogen is not formed in a coal fire by simple union of carbon and nitrogen. In the first place it has never been definitely settled that it does not. Many authorities (Binks, R. Wagner, Brunquill) have held with greater or less force to the belief that it does, or at least that it may so form under certain conditions. That it does not form readily or abundantly must, however, be conceded. Again, the instability of cyanogen itself may be such, under the conditions of an ordinary fire, that it is decomposed as fast as formed, and its instant fixation by combination may be essential to its formation in appreciable quantities. The effect of fire gases, carbon dioxide or monoxide, sulphur dioxide, &c., upon free cyanogen has never been investigated, although several of the authorities already quoted have, from their own experience in the synthesis of cyanides, indicated a belief in the influence of one or other of these gases upon the process (*ante*).

9. *The Influence of Hydrocarbons in the Preparation of Cyanogen or Ammonia.*—If hydrocarbon gases or vapours of heavy hydrocarbons were brought into a furnace containing the materials for production of cyanides or ammonia, namely, hot coal, nitrogen, water in greater or less quantity, and an alkali or other basic substance, the result would be a partial decomposition or dissociation in which carbon and hydrogen would be set free, and fixed gases having the composition of the lower paraffines or olefines would remain. Heavy hydrocarbons, oils like crude petroleum, might be used in part to supply the carbon necessary to the reaction; being in a condition of most minute subdivision as set free from combination, it would be most suitable for rapid combination. It is possible also that hydrogen liberated at the same time and in the nascent state would be better adapted to the synthesis of ammonia than at any other time, and further, this hydrogen would be obtained at less expenditure of heat than hydrogen from decomposition of water by carbon. The condition of a furnace fed with hydrocarbon vapours would resemble to a great extent the smoky gas flames of Levoir and Romily (*ante*), in which ammonium cyanide was produced even without the intervention of a base other than ammonia.

10. *The Influence of Pressure.*—The data derived from experiment on the large scale give little information upon this point. Newton remarks (*ante*) that the production of cyanides is improved by a certain pressure and by friction between the solids and gases of the furnace, but this remark applies to very low pressures such as depend merely upon friction in retarding the gases as they are drawn or forced through the alkalis charcoal by a pump. There is no evidence of systematic use of high pressures, exceeding one atmosphere for example, and the furnaces thus far designed for making cyanides or ammonia are none of them adapted to the use of pressure. It is possible that the necessary reaction would be much assisted by pressure. There is every analogy indeed to favour this view. Combustion in compressed air or oxygen is more rapid than at normal pressure; and the union of nitrogen and carbon should be also accelerated. More of the

* Karmrod found that steam passed over hot potassium cyanide caused evolution of ammonia and the heated residue no longer contained cyanogen.

unlike particles are brought in contact in a given time, and the opportunities for combination being multiplied combination should occur in the same proportion. Moreover the heat lost in expansion of gases is lessened and the temperature within the furnace should be more readily maintained.

If it were possible to maintain a pressure of several atmospheres within a furnace while the gaseous contents of the furnace were continually supplied and discharged, there is every reason to believe that the furnace would be more economical and more effective in the production of cyanides or ammonia.

Summary.

The present aspect of the question may be summarised as follows:—

The manufacture of cyanides and ammonia from the nitrogen of the air, while quite possible on the small scale, is beset with difficulties in its economical and commercial application, which, up to this time, have been insurmountable. These difficulties are probably matters relating mainly to construction and to endurance of materials.

At the same time there is still much uncertainty in regard to the chemical and physical conditions most favourable to the fixation of nitrogen.

The following conclusions are the result of the foregoing inquiry:—

1. The temperature necessary for formation of cyanogen may be lower than at first supposed, but certainly not below a high red heat. For ammonia a low red heat is sufficient.

2. The presence of free oxygen is deleterious in all cases.

3. Water in very small quantities is not prejudicial to production of cyanogen, and an excess is probably necessary in the synthesis of ammonia.

4. The long-continued contact of carbon and nitrogen is of less importance than thorough commingling of all reacting materials.

5. The presence of a strong base is essential, but under certain conditions ammonia, produced synthetically, may serve the purpose of a base and effect the synthesis of ammonium cyanide.

6. Alkaline bases are preferable, potash especially, and because of the intermediate action of metallic potassium which is reduced at a lower temperature than sodium. Baryta is the best of the alkaline earths for the purpose.

7. Ammonia and cyanogen are probably formed under conditions differing in respect to temperature and moisture, but otherwise similar, as already indicated. (2.)

8. The presence of carbonic oxide and of reducing gases in general is probably favourable, while oxygen, carbonic acid, and steam in excess (the latter only in the case of cyanogen) are probably injurious. Nothing is known as to the influence of sulphurous acid or hydrogen sulphide, but they are probably undesirable.

9. The presence of hydrocarbon vapours is favourable, and may, under certain conditions, permit the formation of both cyanogen and ammonia without the presence of a base.

10. There are no direct data for estimating the influence of pressure upon the reactions in question. The application of pressure is at least worthy of trial.

Discussion.

Dr. WALLER said that the so-called "catalytic action" afforded no explanation of the effect of certain elements in the cyanogen forming process, and mentioned the apparent inducements offered for the production of a salt by the presence of a base, as, for instance, the formation of calcium chromate by heating chrome iron ore with lime.

Dr. ALSBERG called attention to the fact that addition of lime would in some cases contribute merely physical conditions which would aid in the reaction, such as porosity, infusibility, &c. Also that frequently in such

instances of so-called catalytic action the temperature of formation and of dissociation of the new compound are so nearly the same that unless a base is present to unite with and retain it, as a salt not dissociated at that temperature, no reaction results. He expressed it as his opinion that not even a momentary formation of such compounds takes place under such temperature conditions unless in the presence of a base to retain them. The addition of iron in the cyanogen process has something to do with its success—as in the Castner sodium process.

Dr. DOREMUS referred to the production of oxygen from KClO_3 and MnO_2 , and to a paper published in the CHEMICAL NEWS intended to show the existence of a number of definite successive reactions between these substances. Experiments made with indifferent substances—*e.g.*, sand—substituted for MnO_2 , gave dissimilar results.

Mr. SABIN—The escape of nitrogen as ammonia in the old prussiate process may be very great if the management is unskilful. A cyanide is first formed, and then, at a higher temperature or on prolonged heating, ammonia is produced. I believe that in a properly constructed and continuously acting furnace all of the nitrogen of leather scrap could be converted into ammonia in presence of caustic soda and moisture, although the process might not be economical. I doubt whether any cyanide manufacturers in this country, with one exception, are making a paying business of it, as such large quantities of cyanides and ferrocyanides are imported. The exception, a firm in Newark, are using an improved pear-shaped retort heated only at the central wide portion.

Dr. ALSBERG—We are on the eve of a complete revolution in prussiate processes; cyanides and ferrocyanides are manufactured in Germany from gas purifier waste in such quantities as to have reduced the price 25 per cent. The process of making cyanides from sulphocyanides is not easy because of difficulty of eliminating sulphur. The only practical process at present is by heating sulphocyanides and finely divided iron under pressure at 120–140° C., whereby ferrocyanide and ferrous sulphide are formed. It is also stated that if a sulphocyanide and ferrous sulphate are mixed and exposed to air, that sulphur is gradually taken up in presence of free alkali, but it seems somewhat doubtful. The old method of making cyanides will have to be abandoned for cheaper methods. Sodium ferrocyanide is now made in large quantities to replace potassium ferrocyanide using gas house wastes and commercial soda-ash. More of sodium bichromate is used in dyeing and calico printing than of potassium bichromate, but certain colours, it is claimed, will not permit of this substitution.

Dr. DOREMUS said the Wilkinson process for manufacturing wood gas produced little cyanogen and no ammonia; in fact he had never heard of either as impurities requiring any attention.

Prof. BRENNEMAN—The formation of ammonia by an ordinary coal fire may not be impossible. In the gas retort the amount of ammonia and cyanides produced is very large, possibly larger than that due to the nitrogen in the coal alone, although the access of atmospheric nitrogen, through leakage and attime of charging, cannot be very free.

NOTE.—In regard to the question of action by presence or predisposing affinity, the case, in its strictest sense, is inconceivable. It involves action for a purpose by inanimate things. Also, the supposition that action of a certain kind cannot take place, even momentarily, under conditions in which decomposition also occurs, is a necessity only in theory. It presupposes that every newly formed molecule is instantly solicited by all of the conditions, chemical and physical, that affect the mass, whereas in a reacting mass of solids (less so in the case of liquids or gases, although still existing) there are difficulties in the way of instant diffusion of all conditions. Heat may be locally increased or decreased momentarily by

chemical action, and *vice versa*, and these changes may favour the local formation of products which are instantly fixed by active substances present in excess, and has been already explained (*ante*).—A. A. B.

DETERMINATION OF LITHIA IN MINERAL WATERS.*

By E. WALLER, Ph.D.

PRACTICALLY three methods are now available. (1) The phosphate method (Mayer's modification) (*Ann. Chem. u. Pharm.*, xcvi., 193). (2) The amyl alcohol method (Gooch, *Am. Chem. Jour.*, ix., 33). (3) The fluoride method (Carnot, *Bull. Soc. Chim.* [3], i., 280).

Rammelsberg's method (*Pogg. Ann.*, lxi., 79), somewhat similar in principle to that of Gooch, in that it depends upon the comparatively greater solubility of lithium chloride in an organic solvent, has been comparatively little used, on account of the difficulty and expense involved in obtaining the pure anhydrous alcohol and ether necessary for the process. Moreover the experiments of J. L. Smith (*Am. Jour. Sci.*, [2], xvi., 56), rearranged in convenient form for reference by Gooch (*loc. cit.*), do not indicate that it is very satisfactory in its application, even with the best of care. Some indirect processes, such as the weighing of mixed chlorides of sodium, potassium, and lithium, and then determining the chlorine and potassium (Bunsen, *Ann. Chem. u. Pharm.*, cxxiii., 348), have been also proposed, but they are troublesome in execution and likely to be unsatisfactory in result.

For all of these processes it is necessary to obtain from some known quantity of the water the alkalies as chlorides free from admixture with other bases, and in most cases a considerable proportion of the sodium and potassium salts, which usually predominate largely over those of lithium, must be removed. To accomplish this the usual method may be followed, acidification with hydrochloric acid, evaporation, treatment with barium hydrate solution, removal of the excess of baryta by ammonium carbonate, driving off the ammonium salts, and extraction with alcohol or alcohol and ether to take out the lithium chloride, which is inevitably accompanied by some sodium and potassium chlorides. Throughout this treatment the spectroscopic method must constantly be used to determine when the extraction or washing is complete, and these preliminary operations often prove very tedious. Some suggestions in this connection may be of value. The small platinum wires used to test the precipitates, solutions, &c., need critical examination. A wire which has been once used with lithium salts may perhaps be held in the flame until it will give no trace of colour to the flame, nor show the lithium line by the spectroscopic, but on moistening with hydrochloric acid and inserting in the flame the line will show almost as brightly and distinctly as if no lithium had been removed from it. Repeated scouring, immersion in acid and insertion in the flame, or long soaking in acid may be necessary to remove this trace of lithium from the wires. It has been found convenient to keep several wires dipping into a test-tube partially filled with dilute hydrochloric acid, and to use them in succession, so that each wire shall have a tolerably long immersion in the acid, before being tested again, as a preliminary to using it for a test on a precipitate, &c.

Barium precipitates (BaCO_3 and BaSO_4), when formed in the presence of lithium compounds, carry down and retain perceptible quantities of lithia (by spectroscopic test) with great persistency. The well-known tendency of the barium sulphate to drag other salts with it seems to be greater in the case of lithia than in that of other alkali

line salts, although this may perhaps be due to the exceeding delicacy of the spectroscopic reaction. Precipitation in a rather dilute solution and rather liberal washing is usually the most convenient course to pursue in the case of the precipitation of BaSO_4 in presence of lithium salts. With BaCO_3 a re-solution in HCl and re-precipitation with ammonia and ammonium carbonate is most effective. If the proportion of lithium is large, re-solution and re-precipitation a third time may be advisable. The precipitate produced by barium hydrate, unless consisting largely of sulphate, does not give so much difficulty in the washing out of the lithia, except when it has been exposed for some time to the air of the laboratory containing CO_2 .

A word further as to the decomposition of LiCl by heat. Direct quantitative estimations upon the subject were not made in this investigation, but the phenomena noted tend to confirm Mayer's remark, that under the influence of heat in presence of water, lithium chloride has a tendency to exchange chlorine for oxygen.

A solution containing lithium chloride is evaporated to dryness with difficulty when placed on the water-bath, and if it finally is made to appear dry after prolonged treatment in this manner, more of the material is slow to re-dissolve in water (apparently because of the formation of lithium hydrate) than if the same solution is evaporated nearly to dryness and the moisture driven out by careful ignition over a naked flame.

Assuming in every case that one has obtained a concentrated aqueous solution from a known quantity of the water, containing all of the lithium and some of the potassium and sodium as chlorides, but no other bases, the phosphate method would be as follows:—

Add an excess of hydro-disodium phosphate, and then a moderate excess of pure sodium hydrate, evaporate to dryness, re-dissolve in water by the aid of a gentle heat, add an equal volume of strong ammonia, digest warm for some time, allow to stand for twelve hours, filter, and wash with a mixture of equal volumes of ammonia and water, and finally ignite and weigh as Li_3PO_4 . A second or third portion of precipitate may be recovered by evaporating the filtrate and washings, adding ammonia, and allowing to stand as before, filtering, &c. The chief difficulty with the accuracy of the process consists in the practical impossibility of obtaining all the lithium as phosphate, free from any other alkaline salts. Too much washing will cause appreciable amounts of lithium phosphate to go into solution. Indeed, in my experience the filtrate and washings have always showed a decided lithia line in the spectroscopic from the start. On the other hand, too little washing leaves some alkaline salt along with the lithium phosphate—shown by its tendency to cake on ignition—but whether it cakes or not, lithium phosphate separated by this method, when tested by the flame, almost invariably gives so strong a sodium flame as practically to obscure the red of the lithium to the naked eye. Consequently it becomes to a considerable extent a matter of judgment to decide when the washing is completed, and then the amount of lithium phosphate obtained is a compromise between the precipitate dissolved off by washing and alkaline salts left with it. However, by the aid of a little experience the error can be usually brought within moderate limits, if the proportion of water which the chlorides represent is sufficiently large (ordinarily 10 to 20 litres). The use of such large quantities of water is naturally attended with more or less labour in evaporation, removal of bases, &c., and is in itself objectionable aside from the sources of error inherent in the method of determination. This method has, however, until recently been practically the only one in general use.

The method of Gooch (*loc. cit.*) used by him in the examination of the waters of the Yellowstone Park ("Bull. U.S. Geol. Survey," No. 47; also *CHEM. NEWS*, lix., 113 *et seq.*), may be described as follows:—The concentrated solution of the alkaline chlorides should con-

* *Journal of the American Chemical Society*, xii., No. 6.

tain only about 0.2 grm. of salts in all. To this solution, in a casserole or dish, is added 30 to 50 c.c. of pure *anhydrous* amyl alcohol. The vessel is then heated on a sand-bath over a low flame, so as to boil off the water through the amyl alcohol, leaving the undissolved salts adhering to the sides of the dish. The heat is kept up until the volume of amyl alcohol has been reduced to about 15 or 18 c.c. after cooling. A few drops of hydrochloric acid are added to restore to the form of chloride any lithium oxide or hydrate which may have been formed, and the heating is repeated for a short time. The amyl alcohol is then filtered through paper, or through a Gooch crucible, into a measuring cylinder, and its volume noted (usually 10 to 15 c.c.). In case the proportion of lithium is large the undissolved salts should be taken up with a little water, and the treatment repeated in the same way as just described, the amount of amyl alcohol which has been heated with the chlorides being measured as before. The salts are then washed with cold amyl alcohol until no trace of lithium is perceptible in them by the spectro-scope; the filtrate and washings are evaporated in a weighed platinum dish, and the chlorides converted into sulphates, ignited, and weighed. From this weight, for every 10 c.c. of amyl alcohol which remained in contact with the chlorides after heating, the following deduction is made:—

When only sodium and lithium chlorides were present . . .	0.00050 grm.
When only potassium and lithium chlorides were present . . .	0.00059 "
When both sodium and potassium as well as lithium chlorides were present . . .	0.00109 "

The cold amyl alcohol used for washing dissolves so little that it is needless to take it into account.

The relative solubilities of NaCl, KCl, and LiCl in amyl alcohol, as determined by Gooch, are essentially:—

NaCl	1 in 30,000, or 0.0041 grm. in 100 c.c.
KCl	1 " 24,000, or 0.0051 " 100 "
LiCl	1 " 15, or 6.60 " 100 "

Temperature seems to have but little influence upon the solubility of NaCl and KCl.

Pure amyl alcohol freed from water by boiling, if necessary, is indispensable.

(To be continued).

Ordinary Meeting, June 19th, 1890.

Dr. W. J. RUSSELL, F.R.S., President, in the Chair.

(Concluded from p. 165).

64. "The Comparative Influence Exercised by the Radicles Cl, OH, and NH₂ in Naphthalene derivatives on the Formation of Disulphonic Acids." By HENRY E. ARMSTRONG and W. P. WYNNE.

The results obtained by the comparative study of the influence exercised by radicles such as Cl, OH, and NH₂ on the formation of disulphonic acids, of which an account has been given in the foregoing notes and in previous communications by the authors, are such as to throw much light on the laws which govern substitution in the naphthalene series, and are moreover highly suggestive. The results obtained in the case of the chloro- and amido-acids are collected in the following diagram:—

One fact to which attention may be directed, which appears to be most clearly established by the investigation of a very large number of disulphonic acids, is the "invincible objection" of two sulphonic radicles to remain in either contiguous or para- or peri-positions. The expression "remain in" is used advisedly, as the authors believe that, inasmuch as action more often than not takes place in the first instance in accordance with the so-called α -law to which they have repeatedly directed attention, such positions are sometimes initially assumed by two sulphonic groups. It is a question whether the final acquisition of other positions than α -positions is a consequence of direct isomeric change, or of the formation of higher sulphonic acids and their subsequent partial hydrolysis.

Different radicles undoubtedly exercise a very different and most important influence in determining such secondary changes. Thus β -naphthol on treatment with sulphonating agents is converted into a sulphate which very readily undergoes isomeric change into the 2:3'-sulphonic acid; β -naphthylamine sulphate undergoes a similar change, but much less readily, being converted into the 2:3'-sulphonic acid only after long heating at a high temperature: in this latter case the formation of the sulphamic acid probably precedes that of the sulphonic acid, and either the sulphamic acid is formed with difficulty from the sulphate, or, when formed, does not readily undergo isomeric change.

α -Naphthylamine and α -naphthol differ in a similar manner.

When excess of sulphuric acid is used, opportunity is given for sulphonation to pursue a different course: the characteristic properties of the phenol and amine are, in a sense, obliterated owing to the formation of sulphates, and these sulphates behave much as do corresponding derivatives containing a neutral radicle-chlorine, for example. Then, if β -naphthyl sulphate be sulphonated by SO₃HCl without application of heat, a disulphonic acid is at once obtained which, there is reason to believe, has the constitution—

(cf. *Berichte*, 1882, 204); the formation of this compound affords the most significant indication of the course of change: evidently the *homo- α* -hydrogen atom contiguous

to the $\text{O}\cdot\text{SO}_3\text{H}$ -group of the sulphate is first displaced; the resulting sulpho-sulphate, however, spontaneously undergoes isomeric change. β -Naphthylamine sulphate, apparently, behaves somewhat differently, yielding the 2:1'- and 2:4'-monosulphonic acids: in this case the $\text{NH}_2\cdot\text{H}_2\text{SO}_4$ -group may be supposed to remain unchanged; but it is not improbable that the homo- α -hydrogen atom contiguous to this group is primarily displaced by SO_3H , which then passes spontaneously into the contiguous peri- α -position, giving rise to the 2:1'-acid: the formation from the 2:3'- and 2:4'-monosulphonic acids of disulphonic acids containing the SO_3H -group in the homo- α -position contiguous to the NH_2 affords the strongest support to this view. The formation of the 2:4'-monosulphonic acid from β -naphthylamine sulphate is perhaps the outcome of an independent action.

In the case of β -chloronaphthalene, it is conceivable that the 2:1-sulphonic acid is the immediate product, and that this spontaneously changes into the 2:1'-acid which is actually obtained as chief product; the 2:3'-acid which is obtained as subsidiary product may be formed by spontaneous isomeric change from 2:4'-acid initially produced on sulphonation rather than by the isomeric change of the 2:1'-acid at the moment of formation; this view being supported by the fact that β -iodonaphthalene affords a small proportion of 2:4'-acid (cf. *Proc. Chem. Soc.*, 1889, 120).

In short, it is not impossible that the β -mono-derivatives all behave similarly on sulphonation, acting in a minor degree as naphthalene itself would, but chiefly as mono-derivatives: and that the differences in the structure of the ultimate products are due to the different manner in which secondary change takes place under the diverse influences of various β -radicals. The same argument would apply to α -compounds.

The peculiar differences manifest in the case of monosulphonic compounds are also to be noticed in the case of disulphonic (cf. diagram, above)—the product of further sulphonation is, as a rule, simpler in the case of the chloro-acid than in the case of the amido-acid; and change proceeds further in the case of the hydroxy- than in that of the NH_2 -compound, as is evidenced by the formation of R- together with G-disulphohydroxy-acid under conditions which do not give rise to R-amidodisulphonic acid.

In the case of the 2:1'-amidodisulphonic acid, the homo- α -position contiguous to the NH_2 is, perhaps, screened from attack; and either a 1:4-disulphonic acid is first formed, or, under the dehydrating influence of the sulphuric acid present in excess, a *sulphamic-sulphonic* acid is gradually produced, which then undergoes isomeric change: it appears not improbable, from the exceptionally slow manner in which sulphonation takes place, that the latter is the correct explanation. The remaining three isomeric β -amidodisulphonic acids, are in all probability, at an early stage—for it is possible that a sulphamic acid is the first product of sulphonation—if not initially converted into 2:1-homosulpho-derivatives; but it is a question whether these then undergo a simple isomeric change, or whether the final products are formed from them by their conversion into higher sulphonic acids which then suffer hydrolysis. The behaviour of 1:2-chloro- β -naphthylamine on sulphonation (cf. *Proc. Chem. Soc.*, 1889, 36, 48) appears rather to support this latter view, as the passage of the sulpho-group through the positions $1 \rightarrow 2 \rightarrow 3$ takes place with a much greater facility than is usual in cases of non-spontaneous isomeric change. It is true that the conditions under which sulphonation is effected are such that no water is present; but, bearing in mind the tendency of H_2SO_4 to combine with SO_3 , it is by no means improbable that H_2SO_4 itself may effect the hydrolysis.

Lastly, attention may be called to the occurrence of "homo-sulphonation" in the case of the two chloro- β -sulphonic acids; the products in question are, perhaps, direct sulphonation-products, but it is also conceivable

that the 2:1-chloro-sulphonic acid is first formed and that this undergoes isomeric change to the 2:4-acid in consequence of the guarding influence exercised by the hetero- β -sulphonic radical.

The results obtained in the case of the Dahl No. II. acid are of special interest, as one of the sulpho-groups is in the β -position alternative to that occupied in the acid which yields naphthol-yellow S; it is, hence, possible that, in the first instance, naphthionic acid yields a per-disulphonic acid, and not the Schöllkopf acid.

The solution of these various problems will necessitate much further study; but obviously their settlement is of importance in relation to the theory of the formation of substitution-derivatives generally.

65. "Note on the Action of Potash on Naphthalene-1:3-disulphonic Acid." By HENRY E. ARMSTRONG and W. P. WYNNE.

When the authors' naphthalenemetadisulphonic acid (*Proc. Chem. Soc.*, 1890, 13) is fused with 3—4 times its weight of caustic potash at $280\text{--}300^\circ$ for several hours, it gives a product which consists chiefly of a trihydroxy-naphthalene, $\text{C}_{10}\text{H}_5(\text{OH})_3$ (C = 67.7 per cent, H = 4.6 per cent). This crystallises from water in minute scales, from light petroleum (b. p. = 30°) in small white aggregates of no definite form, and melts at $120\text{--}121^\circ$. It sublimes in lustrous thin scales; is extremely soluble in ether, chloroform, carbon bisulphide, acetone, and benzene; and gives no characteristic colouration with ferric chloride. The study of the action of potash on naphthalenemetadisulphonic acid is being continued.

66. "The Action of Zinc on Dilute Sulphuric Acid." By F. PULLINGER, B.A., B.Sc., late Scholar of Corpus Christi College, Oxford.

The author has carried out a series of experiments with zinc prepared by thrice distilling *in vacuo* zinc purchased as "chemically pure," and has arrived at the following conclusions:—

(i.) That zinc with a perfectly smooth surface is not acted on by dilute sulphuric acid which has been submitted to prolonged boiling.

(ii.) That zinc with a rough surface is readily acted on by acids, but in a less degree by those which have been boiled than by those which have not.

(iii.) That oxidising agents, such as electrolysed sulphuric acid, hydrogen peroxide, and nitric acid, increase the rate of dissolution.

(iv.) That a reducing agent such as hydrogen iodide almost entirely prevents dissolution; but that those containing sulphur, such as sulphur dioxide, are without effect.

(v.) That in all probability persulphuric acid is the *vera causa* of the dissolution of zinc in the so-called "pure" sulphuric acid.

(vi.) That pure dilute sulphuric acid would, at ordinary temperatures, be entirely without action on zinc, whether the surface of the latter were rough or smooth.

67. "Acetyltrimethylenecarboxylic Acid." By T. RHYMER MARSHALL, D.Sc., and W. H. PERKIN, jun., Ph.D., F.R.S.

When ethylene bromide acts on ethylic sodacetacetate, an oil, $\text{C}_8\text{H}_{12}\text{O}_3$, is formed which boils at 196° ; on hydrolysis this yields an oily acid, $\text{C}_6\text{H}_8\text{O}_3$, to which the name Acetyltrimethylenecarboxylic acid and the formula—

were assigned (*Chem. Soc. Trans.*, 1885, xlvii., 834). In a research published a short time since, Lipp (*Ber.*, xxii., 1201) states, as the results of some experiments on acetopropyl alcohol, that this formula is incorrect, and must be replaced by—

The authors have very carefully re-investigated the subject with the following results:—

Acetyltrimethylenecarboxylic acid and hydroxylamine readily interact, forming a crystalline hydroxime,—

which melts at 145° . On reduction with sodium amalgam, the acid is converted into α -ethyl- β -hydroxybutyric acid, $\text{CH}_3\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{C}_2\text{H}_5)\cdot\text{COOH}$; this forms a thick colourless syrup, yielding on distillation α -ethylcrotonic acid, $\text{CH}_3\cdot\text{CH}:\text{C}(\text{C}_2\text{H}_5)\cdot\text{COOH}$.

A drop of a solution of potassium permanganate added to a solution of acetyltrimethylenecarboxylic acid in a dilute solution of sodium carbonate is not decolourised, even on long standing—a proof that the acid is a saturated compound, and cannot have the formula ascribed to it by Lipp (compare Baeyer, *Annalen*, ccliv., 146).

Acetyltrimethylenecarboxylic acid readily splits up on heating into acetyltrimethylene,—

and carbon dioxide.

Acetyltrimethylene and hydroxylamine interact to form a hydroxime, $\text{C}_6\text{H}_9\text{NO}$, which crystallises from petroleum spirit in beautiful glittering prisms. When reduced by means of sodium (in moist ethereal solution), acetyltrimethylene yields methylpropylcarbinol,—

which boils at 119.5° (compare Saytzev, Wagner, *Annalen*, clxxix., 313).

Methylpropylcarbonyl acetate, $\text{CH}_3\cdot\text{CH}(\text{C}_2\text{H}_5\text{O}_2)\cdot\text{C}_2\text{H}_5$, obtained by boiling the alcohol with acetic anhydride, boiled constantly at 133.5° .

Dimethylidipropylglycol,—

is produced, together with methylpropylcarbinol, by the reduction of acetyltrimethylene. It is a thick oil which boils at 220 – 225° (Friedel, *Jahresb.*, 1869, 513). Fuming solution of hydrogen bromide converts acetyltrimethylene, at ordinary temperatures, quantitatively into acetopropyl bromide, $\text{CH}_3\cdot\text{CO}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\text{Br}$ (b. p. 120° at 75 m.m.), a proof that acetyltrimethylene cannot have the formula—

Methyldehydropentonecarboxylic acid,—

is always formed in small quantities, together with acetyltrimethylenecarboxylic acid, by the action of ethylenbromide on ethyl sodacetacetate (Freer and Perkin, *Chem. Soc. Trans.*, 1887, li., 822). In one experiment, this acid was obtained in large quantities and free from acetyltrimethylenecarboxylic acid. It crystallises from benzene in large apparently monoclinic prisms which melt at 150° . It does not interact with hydroxylamine; its alkaline solution decolorises permanganate instantly, in which respects it differs very markedly from acetyltrimethylenecarboxylic acid.

When boiled with water, methyldehydropentonecarboxylic acid is entirely converted into acetopropyl alcohol, carbon dioxide being evolved.

Methyldehydropentone,—

is formed when the acid is distilled. It is a colourless

ethereal liquid; b. p. 82° , rel. den. at $15^\circ = 0.9107$; magnetic rotation, 5.391 . When shaken with water it rapidly dissolves, forming acetopropyl alcohol.

A careful study of these results shows that acetyltrimethylenecarboxylic acid is a saturated ketonic acid, and that it cannot have the constitution proposed by Lipp. Lipp's formula represents an acid which may be identical with methyldehydropentonecarboxylic acid, but which in any case must possess properties closely allied to those observed in this acid, and which are entirely distinct from the properties of acetyltrimethylenecarboxylic acid.

NOTICES OF BOOKS.

The Metallurgy of Steel. By H. MARION HOWE, A.M., S.B. Vol. I. New York: The Scientific Publishing Co.

THE object of the author is to give metallurgists a systematic account of the American steel works and their present practice. In his preface he remarks somewhat dryly that the important thing for the reader is to know that certain practice exists, or is possible; for the manufacturer that it be not known as his particular practice. Probably even the close-mouthed Krupp would object relatively little to having his practice revealed, provided it were not known as his.

The work itself is simply enormous, unmatched in its minute and thorough going comprehensiveness. As a whole it is intelligible only to the rare individuals who are at once thorough chemists and thorough engineers, and who have studied both these disciplines from the point of view of the practical metallurgist. The author, after defining steel—no very easy task—examines the mutual behaviour of carbon and iron, with especial reference to hardening, tempering, and annealing. He discusses at some length the evidence of the state of combination of carbon with iron. It appears that in addition to the graphitic state combined carbon may exist in iron in a more or less soluble modification. He considers, however, that each of these modifications may comprise varieties not as yet distinguished.

In successive chapters the author discusses the behaviour of iron with silicon, manganese, sulphur, phosphorus, chromium, tungsten and copper, and the metals occurring but sparingly in iron. He believes that chrome steel is preferable to carbon steel where extreme hardness is required coupled with a fair degree of forgeableness. Its neglect he ascribes to the fact that its manufacture, which requires unusual skill and intelligence, has largely fallen into careless, incompetent hands.

On the merits of the alloys of iron and aluminium he is sceptical. He notices that some of the most experienced analysts, amongst others Rammelsberg, fail to detect aluminium in wootz, whilst the alloys of iron with larger proportion "appear to be little and hold out little promise." Neither is he satisfied with the evidence of the improvement effected in the Mitis process. He maintains that it is not shown that the melting-point is actually lowered in the Mitis process, that there is reason to doubt if aluminium even tends to produce this specific effect of lowering the melting-point; that were it known to lower the melting-point too little of it is present to explain a fall of the melting-point sufficient to account for the startling effects produced, whilst a fall in the melting-point is incompetent to explain all the phenomena.

An authority quoted has examined many irons and steels for aluminium and finds it commonly present in steel, though in such small proportions as 0.032 p.c. The results of Faraday and Stodart on the alloys of steel with silver, gold, and platinum, have not been confirmed by recent researches nor by practical observations.

Chapters ix., x., xi., and xii. discuss the effects upon

iron of non-metallic bodies, especially in a gaseous or liquid state. Polluted waters corrode iron much more rapidly than clear water. In Thompson's observations while the waste of gas-works does not appear to augment the corrosive action of pond-water initially somewhat polluted by stables, &c., sewage increased it 37 per cent in case of wrought-iron and 76 per cent in case of cast-iron. In these days of iron ships and sewage polluted rivers and harbours the practical meaning of these observations is perfectly plain.

The absorption and escape of gases from iron with the accompanying formation of "blow-holes" and the means for their prevention are very fully discussed. It is considered practically certain that in the cases which have been studied the gases which form blow-holes are chiefly hydrogen and nitrogen escaping from solution; carbonic oxide probably co-operates and doubtless comes in large part from solution. Still air may be drawn down mechanically in "teeming," under conditions which require to be studied, and may thus be an important cause of the blow-holes.

Amongst the methods proposed for the prevention of blow-holes several of the most interesting depend on gaseous pressure applied to the molten steel. Krupp is said to use liquid carbon dioxide at a pressure of 5 tons per square inch. In discussing the value of liquid compression the author writes: "It has seemed to many that Whitworth's attitude has not been one of confidence in the value of his compression." It is admitted, however, that "in proper hands the liquid compression of large masses, if powerful enough, according to our present evidence, does prevent pipes, blow-holes, and cracks almost completely."

The structure of iron as observed on microscopic examination is compared to that of granite. Seven distinct crystalline minerals have been recognised chiefly by the researches of Mr. Sorby. To these the author has given names more brief and of a more mineralogical type than those proposed by Sorby.

Another method of ascertaining the structure of steels is the examination of the fracture, which has been especially studied by Brinnell. This inquirer recognises nine distinct types of fracture which he supposes to result from nine corresponding types of structure. These types of fracture and the conditions under which they are acquired and lost are considered in detail.

The remainder of the volume is devoted to the effects of different kinds of working and to the various processes for conversion.

An appendix describes certain compound steels shown at the Paris Exhibition of 1889.

The Student's Chemistry (Inorganic). In Two Volumes. Poona: The "Orphanage Press."

THE work before us differs from the ordinary small or middle-sized chemical manuals chiefly in two respects; what may be called the philosophy of chemistry has been expounded at greater length, and the physiological action of elements and compounds is brought into prominence. We miss, however, any systematic reference to the spectroscopy and its revelations as well as to electrolysis and to thermo-chemistry.

The arrangement of the work is as follows:—After the introductory discussion of the general principles of the science, in which the bold hope is expressed that before long the synthesis of albumen will have become possible, the author proceeds to a classification of the elements. These he divides into three main classes, non-metals, metalloids, and metals. He is fully aware of the error of applying the term "metalloid," as it is too often done by French chemists, to bodies which are eminently unlike metals. But we fear that by applying it to such elements as tin he will merely increase confusion.

On the addition of alum to impure waters for the purpose of removing organic matter in suspension—it might

have been added "or in solution"—the author thinks the remedy may possibly be worse than the disease, as alum attacks the tissues of the stomach. But the alum, if not added in excess, is decomposed, the precipitate formed carrying down with it most of the microbia which may be present in the water. Since this method has been adopted by the French troops in Tonquin they have enjoyed a nearly complete exemption from dysentery. Facilities for boiling a suspected water are not always at hand.

The use of phosphorus, ordinary or amorphous, for the production of lucifer matches is here rightly objected to. The only legitimate uses of phosphorus, indeed, are in agriculture and medicine.

To the statement that PH_3 in marshy places gives rise to will-o-the-wisp we must demur. The presence of this gas in the air or in the emanations from decomposing animal matter has never been satisfactorily demonstrated.

The author justly objects to the use of boric and salicylic acids for the preservation of articles of food.

Aluminium scarcely receives full justice: the only processes mentioned for its production are those of Deville and Webster, and only one of its alloys is described.

We must congratulate the author on the manner in which he keeps his readers at the level of the most recent discoveries. It is not often in a work of the bulk of the one before us that we find mention of so recent and still questioned a discovery as that of the metal found by Dr. Krüss in commercial nickel and cobalt. We find, too, a notice of the announcement made at the October meeting (1889) of the Vienna Academy of Sciences that sulphur is not a simple body, but a compound of carbon. We must add, however, that this strange result has not hitherto received the necessary verification.

The chief defect of the work is the want of an index, which is the more to be regretted as the arrangement of the book is somewhat complicated.

The second volume is a brief summary of qualitative analysis, and does not call for any special remarks.

CORRESPONDENCE.

M. BARTHE'S NEW SYNTHESSES.

To the Editor of the Chemical News.

SIR,—I am at a loss to understand the following difficulties in M. Barthe's syntheses (CHEM. NEWS, vol. lxii., p. 153):—

Apart from the acetyl constituent, cyanosuccinic ether appears to contain $\text{C}_5\text{H}_6\text{O}_2 + \text{Cy}$ and E_2 ; but cyanosuccinic methers, called methylcyanosuccinate, apparently contains $\text{C}_4\text{H}_3\text{O}_4 + \text{Cy}$ and Me_2 .

In methylcyanotricarballylate, called cyanotricarballylate, what does CA_2 mean?

Information will greatly oblige.—I am, &c.,

S. E. P.

[M. Barthe does not use the expression cyanosuccinic methers. CA_2 is a misprint in the original for CN_2 .]

REFERENCES TO ORIGINAL PAPERS.

To the Editor of the Chemical News.

SIR,—Will you allow me through your columns to make an appeal on behalf of those who have constantly to refer to original papers quoted by authors? The usual method adopted by authors in referring to papers already published is to quote the number of the volume in which the paper or papers occurred; this may seem at first sight to be all that is necessary, and indeed it would be so if everyone had immediate access to a library round whose walls all journals ever published were properly ranged.

I submit, however, that this method renders the ever-

increasing mass of "abstracts" published by the Chemical and other Societies practically useless for reference, and for this reason:—The method gives no clue as to the year in which the paper was published, unless the reader happens to remember what is the number of the current volume of the journal in question, and also how many volumes of it are issued per annum; if he know this, then a few seconds' calculation will enable him to turn to that volume of the "abstracts" published some 4 to 6 months later than the original paper. But as it is impossible for anyone to remember these facts, the absence in the reference of the date of the volume in which the paper occurred makes it exceedingly difficult to find the abstract of that paper.

Inasmuch as it has frequently taken me ten minutes to find the abstract of a paper when only the number of the volume in which it occurred has been given, you will, I feel sure, Sir, make room for this protest against the waste of time suffered by, among others, your obedient servant,

AN ABTRACTOR.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 10, September 8, 1890.

On a Platinum Sulphocarbide.—P. Schutzenberger.—On slowly passing a current of an inert gas, such as dry nitrogen charged with vapours of carbon disulphide, through a column of platinum sponge fixed in a glass tube between two plugs of asbestos, and heated by means of a gas burner to a temperature below dull redness—400° to 450°—the carbon disulphide is entirely absorbed and the platinum sponge is gradually converted, from the entrance-point of the gas to its exit, into a fine black powder. On continuing the experiment as long as there was any increase of weight, exactly 1 mol. of carbon disulphide was absorbed by 2 atoms of platinum. The product had the composition $\text{Pt}_2\text{S}_2\text{C}$. From its behaviour it was found not to be a mixture, but a definite compound, and may be regarded as methane in which the four atoms of hydrogen have been replaced by two bivalent groups, $=\text{Pt}=\text{S}$.

New Researches on the Gadolinia of M. de Marignac.—Lecoq de Boisbaudran.—Last year I had the honour to submit to the Academy the results of a qualitative examination and a quantitative analysis of a gadolinia prepared by M. de Marignac. The results show that nine-tenths of the earth cannot be ascribed to substances previously known. Taking, on the other hand, into consideration the existence of a special electric spectrum, we easily obtain a clear confirmation of the discovery of M. de Marignac, if the researches of this illustrious chemist had not rendered the novelty of gadolinia indisputable. Having been courteously placed by M. de Marignac in full possession of the gadolinia which had served for my above-mentioned experiments, I proceeded to a fractionation of this matter by means of very dilute ammonia. The minuteness of the mass operated upon (1.5 grms.) rendered this research tedious and delicate. In fact, I obtained 14 portions (Nos. -4 to +9); but as the examination of the absorption-spectra requires a certain quantity of concentrated liquid, I was obliged to collect all the matter into the numbers -4, 0, +6, and +9, by the gradual and cautious reduction of the intermediate numbers. In this manner the difference of composition existing between each of these five final numbers and its neighbour (e.g., between numbers 6 and 9) is that which would have been the case if, the earth being more abundant, it had been possible to obtain fourteen portions

of sufficient volume to admit of the examination of each. By absorption, it was found that samarium (characterised by its blue bands) was strongly concentrated in the first precipitates. It is very well marked in No. -4, feeble in No. 6, and scarcely perceptible in No. 9. Thus, samaria shows a basicity less than that of gadolinia. The didymia is naturally concentrated at the tail of the precipitates; it is not perceptible in No. 3, it is very moderate in No. 6, and easily visible in No. 9. By reversal we see that the fluorescence ZB is strongly marked at the head of the series; it is fine in No. -4, moderate in No. 3, doubtful in No. 6, and null in No. 9. Further, the earth No. -4 is very yellow, whilst the earths Nos. 6 and 9 are very pale. The fluorescence of samarium (by reversal) is seen very faintly in No. -4, and not in the other numbers. By the direct spark (not condensed) the spectrum of gadolinium is fine in all the numbers, which is intelligible since the quantity of Gd_2O_3 contained in No. -4, the most impure of all, is still very considerable. In fine, Nos. 6 and 9 contain the smallest quantity of foreign bodies, these consisting principally of Sm, Di, and ZB. There is a little more of Sm but less of Di in No. 6 than in No. 9. I think that the sum of the impurities in each of these two numbers can scarcely reach 2–3 per cent. These are certainly the purest gadolinias which have yet been obtained. No. 6 is a yellowish white; No. 9 is decidedly paler, though not quite white. Professor Clève has kindly permitted me to publish one of the principal results of his long and important researches on gadolinia. He finds that the principal mass is not split up on fractionation. Impurities, very difficult to eliminate, but of known nature, are distributed unequally among the various fractions, altering but little the value of the equivalent, as it will be seen on examining the numbers obtained by M. Clève for the atomic weight of Gd. I will here point out a fact which does not seem to have been noticed; its knowledge will, perhaps, prevent regrettable mistakes among persons who study the rare earths. It is the decidedly great temporary solubility of the rare earths, and especially of gadolinia, in ammonium acetate in presence of an excess of free ammonia. A solution of Gd_2Cl_6 containing from 0.5 to 1 grm. Gd_2O_3 per litre, being mixed, at first with acetic acid and then with an excess of ammonia, remains limpid for a long time, and the precipitation is complete only after the lapse of a day or two days. Heat expedites the formation of the deposit, but in this case it is only partial, since a liquid which has already become spontaneously turbid clears up on heating and becomes turbid when cold. Analogous effects are observed with the salts of Yt, La, and Di. The deposit is formed more slowly with La than with the other two earths. The precipitation is delayed with cerous oxide, but very slightly.

NOTES AND QUERIES.

. Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertisement columns.

THE CHEMICAL NEWS.

VOL. LXII. No. 1611.

NOTES ON OXYGEN.

By J. A. WANKLYN and W. J. COOPER.

Our modification of the Priestley and Cavendish method has given the following results:—

Pure Oxygen Gas.

	Expt. I.	Expt. II.
Oxygen taken	30.0 c.c.	40.0 c.c.
NO added	82.6	97.8
	112.6	137.8
Vol. after reaction ..	20.8	20.0
Therefore contraction..	91.8	117.8
„ oxygen	30.6	39.27

The results obtained on operating on atmospheric air were as follows:—

	I.	II.	III.
Air taken	80.0	50.0	70.0
NO added.. ..	45.0	25.0	54.0
	125.0	75.0	124.0
Vol. after reaction ..	75.6	44.2	80.6
Therefore contraction ..	49.4	30.8	43.4
„ oxygen	16.47	10.27	14.47
Percentage of oxygen ..	20.59	20.54	20.67

We have made experiments on a variety of reagents for the absorption of oxygen. Thus hydrated protoxide of manganese has been tried. This reagent absorbs oxygen from the air, and employing it in a Hempel's absorption pipette, we are able to remove all the oxygen from a specimen of air in the course of twenty-four hours. We do not, however, recommend it for general use.

Alkaline sulphurets, as is well known, were resorted to in years gone by for this purpose. We are using a convenient reagent of this kind made by boiling 18 grms. of sulphur with 24 grms. of caustic potash and 150 c.c. of water. The mixture is boiled in a flask, allowed to cool, and then shaken up with a small volume of air and introduced into the absorption bulbs, a little fresh potash being added. This reagent absorbs oxygen very readily. In about an hour 40 c.c. of pure oxygen may be almost completely absorbed, and very satisfactory results are obtained with air.

EXAMINATION OF OILS, FATS, AND ALLIED SUBSTANCES.

By THOMAS T. P. BRUCE WARREN.

M. CAILLETET showed that the percentage composition of a mixture of two oils could be calculated when we knew the bromine absorptions of the mixture and of its two constituents. The principle of his procedure was this:—A known weight of bromine was added to an oil, and, after digestion, the unabsorbed bromine was estimated. The result was that the higher the bromine-absorption, the smaller was the quantity left free. To render his method clearer, I give his experimental result on a mixture of olive and sesame oils, quoted by Chateau (*Corps Gras Industriels*, Paris, 1864). The solution of turpentine required to decolourise 10 grms. bromine liquor, after digesting with 5 grms. olive oil, is 10.7 grms., and with

sesame oil 4.03 grms., and for a mixture of the two oils is 7 grms.

Difference between 7 and 4.03 = 2.97 } sum of diffs. =
 „ „ 7 and 10.7 = 3.70 } 6.67

$$\frac{10.7 \times 2.97}{6.67} = 4.76 \quad \frac{4.03 \times 3.70}{6.67} = 2.24$$

10.7 : 100 :: 4.76 : 44.53 olive oil
 4.03 : 100 :: 2.24 : 55.47 sesame oil.

100.00

This is simplified by the following proportions:—

$$10.7 - 4.03 : 7 - 4.03 :: 100 : x = 44.53$$

$$10.7 - 4.03 : 10.7 - 7 :: 100 : y = 55.47$$

Writers on oils have recorded the iodine-absorption per cent, which, unfortunately, is not well adapted for these calculations, and considering that the *unabsorbed* iodine has to be estimated to obtain the percentage figures, there is no reason why the results could not be tabulated so as to render Cailletet's method of calculating available. The Hubl figures form an ascending series; whereas Cailletet's process involves a descending series; consequently, if we have two oils to deal with, we have simply to reverse the figures for the iodine-absorption thus: call olive oil 106, and sesame oil 84.5; lard oil 170, and linseed oil 52.5.

I have taken Cailletet's mixture and adapted it to the known and accepted iodine-absorption in accordance with this arrangement. The Hubl being used in the usual way.

106 - 84.5 : 106 - 96.4 :: 100 : 44.65 olive oil
 106 - 84.5 : 96.4 - 84.5 :: 100 : 55.35 sesame oil
 170 - 52.5 : 170 - 84.5 :: 100 : 72.7 lard oil
 170 - 52.5 : 84.5 - 52.5 :: 100 : 27.2 linseed oil.

$$100 \times 96.4 = (100 - x) 84.5 + 106x \quad (1).$$

$$100 \times 96.4 = (100 - y) 106 + 84.5y \quad (2).$$

Solving, &c., $x = 55.35$ sesame oil
 $y = 44.65$ olive „

$$100 \times 84.5 = (100 - x) 52.5 + 170x \quad (3).$$

$$100 \times 84.5 = (100 - y) 170 + 84.5x \quad (4).$$

$x = 27.2$ linseed oil
 $y = 72.8$ lard oil.

Taking the results of (3) and (4):—

$$27.2 \times 170 \text{ (iodine-absorption for linseed oil)} = 4634$$

$$72.8 \times 52.5 \text{ „ „ lard „} = 3822$$

$$\text{Adding and dividing by } 100 \quad \dots = 84.56$$

we obtain the number corresponding to the iodine-absorption of the mixture.

The method of calculating by proportional parts is recognised, and no doubt admits of extensive application in chemical analysis, where a separation is tedious. Thus, a mixture of sodium and potassium chlorides can be arithmetically determined by first chemically fixing on the quantity of Cl and dividing this between Na and K proportionally to their atomic weights (Thorpe's "Inorganic Analysis," art. Indirect Estimation of Na and K). I take the examples given in CHEM. NEWS, vol. lxii., p. 125:—

42.8 iodine-absorption due to olive oil and 53.6 due to sesame oil.

$$\frac{96.4}{42.8} = 2.252 \quad \frac{96.4}{53.6} = 1.798$$

Adding these ratios = 4.05.

$$\frac{2.252 \times 100}{4.05} = 55.6 = \text{sesame for olive.}$$

$$\frac{1.798 \times 100}{4.05} = 44.4 = \text{olive for sesame.}$$

In order to follow the line of reasoning which forms the basis of these calculations, we must bear in mind that the

figure given as the iodine-absorption is really for 100 parts of that oil, and we must not confound the iodine-absorption as the weight of oil required, although, of necessity, it is a measure of the ratio of that oil.

The general result is, that in the case of a mixture of two oils, if we use the Hubl figure or value of absorption, we must reverse the proportion as regards weights, unless we use the equations 1, 2, 3, 4, which are sufficiently self-evident as to require no further explanation. The advantage here is that we can use the Hubl figure as at present understood; and, so far as I can see at present, the figure is independent of the quantity of Hubl reagent used.

ON THE PRESERVATION OF SOLUTION OF SULPHURETTED HYDROGEN.

By A. J. SHILTON, F.C.S.

ON the 15th of November last I published in the *CHEMICAL NEWS* a note on the use of glycerin in preserving sulphuretted hydrogen in solution. The experiments I quoted showed most conclusively that glycerin is most beneficial in this way, and it occurred to me that certain other analogous substances would probably act in a similar manner.

I have made rough qualitative trials, which prove this to be the case.

About five months ago I sealed up bottles containing respectively—

- (a) Sulphuretted hydrogen water.
- (b) " " " with sugar.
- (c) " " " " salicylic acid.

I have opened these to-day, and I find that solution (a) gives no reaction with lead acetate, and is entirely free from odour; whilst solutions (b) and (c) have a strong odour of the gas, and yield copious precipitates with lead acetate. I am at present engaged in further experiments as regards the action of other bodies, not only on sulphuretted hydrogen, but also on other gaseous solutions. The amount of sugar used was 2 per cent, and of salicylic acid 1 per cent.

AN APPARATUS FOR VAPOUR-DENSITY DETERMINATIONS.

By J. A. HARKER,

Research Student in the Owens College, Manchester.

HAVING repeatedly noticed in the laboratory exceedingly cumbersome arrangements for vapour-density determinations according to Victor Meyer's method, I thought it worth while designing a convenient portable form of apparatus for this purpose. The stand consists of an iron rod 1 metre high, screwed into a heavy rectangular iron base about 25 × 17 c.m. near the edge, and in the middle of the longer side. This form of stand gives the greatest stability. Instead of the usual copper cylinder, a small air-bath, similar to those described by Lothar Meyer, serves as the source of heat. A convenient size is 30 c.m. high, having the inner space of 60 m.m. diameter. The pipe of the ring burner is 16 m.m. diameter, and has 20 one-m.m. holes, at a distance of 18 m.m. apart. The air-bath, which is built up of three concentric cylinders, is mounted on an iron plate, having a screw by which it can be clamped on to the stand at any height. This is much more convenient than the usual tripod. The air-bath, when intended for ordinary use, is better without an asbestos jacket. The temperature without a jacket may, with the burner described, be varied from 80° to 360° C., and with a jacket of asbestos $\frac{3}{8}$ in. thick from 140°

to 460°. With the small flames used it is unnecessary to mix the gas with air before burning. No smoking takes place, the gas consumption at the highest temperature being only about 2 feet per hour. For lower temperatures than 80° C. a burner with fewer holes must be used. As a test of constancy the air-bath was lit, and the temperature rose in ten minutes to 201° C. It remained for an hour between this temperature and 202.5° without any screening from draughts, and without either regulator or governor on the gas supply. The rest of the apparatus consists of an iron table, 13 c.m. diameter, fastened to a rod, fitting the boss of an ordinary clamp. This supports a crystallising dish of 12 c.m. diameter and 5 c.m. deep, holding water, in which is immersed the graduated tube for measuring the evolved gas, held by a small clamp. A second clamp holds the vapour-density tube, which should have the capillary limb, on which a small bulb is blown, fastened by indiarubber, and not rigid as usually supplied. The apparatus has been tested by several people and found satisfactory, and the air-bath described has been found useful for many purposes. It may be provided with rings to partially close the hole at the top when necessary. The complete apparatus may be obtained from Mr. E. Hargreaves, Booth Street West, Manchester.

NEW CALEDONIAN NICKEL ORES.

By THOMAS MOORE.

AMONGST the many ore deposits and formations of this island few are probably of greater interest, either from a chemical or commercial point of view, than those of nickel. The nickeliferous ore commonly known as garnierite, is almost invariably found either in, or at least in close proximity to, those huge masses and mountains of serpentine which form a characteristic feature of the place, and are as diversified in their extent as in their richness. With but one or two rare exceptions it is found only on elevated positions, often at the very summits of the mountains, not unusually accompanied by chrome iron ore, and surrounded by a peculiar red earth rich in iron, which by being alternately deluged by the rains and baked by the sun has become hardened together into a compact mass. The nickeliferous mountains present a very bare, sombre, and uninviting appearance; vegetation is extremely sparse and scanty, and the few stunted shrubs growing there seem only to intensify the barrenness of the dull and monotonous region, contrasting strangely with the profuse tropical growth on the lower levels. The colour of the ore varies from the blue-green in the poorer specimens to a warm dark green in the richer, and passing by almost imperceptible shades to a light brown, and, finally, to a fine chocolate colour. The rich ore is generally a mechanical mixture of apparently homogeneous green or brown substance, with rounded pebbles of serpentine, forming a kind of agglomerate, or it is interstitially deposited between thin layers of quartz, steatite, and various hydrated silicates of magnesium.

Miners recognise three varieties of the ore, *i.e.*, quartz rich green, magnesia rich green, and the brown ore. The first is characterised by the large amount of silica it contains, generally as minute glistening crystals of quartz or in the amorphous condition. The magnesia ore contains only a small quantity of quartz, but a very considerable amount of magnesian silicates, and has a paler green colour than the former. The brown ore is the least common variety, is very soft, and as a rule contains only small quantities of quartz and magnesia, but much ferric oxide. Generally speaking, however, they are classified into the green and the brown minerals.

From time to time analyses of the ore have been published, leading to a variety of formulæ with this feature

only in common, that it is a hydrated silicate of nickel, in which the nickel is replaced to a greater or lesser extent by magnesia or oxide of iron. Perhaps the various complicated and somewhat contradictory formulæ devised may be accounted for by the difficulty in obtaining pure pieces, and that the finely intermixed quartz may have escaped observation, thus giving a percentage which does not truly represent the combined silica, but rather that of silica+quartz, for pieces of the ore which to the eye appear thoroughly homogeneous in the great majority of cases give an amount of insoluble silica varying from 2 to 10 per cent. Nevertheless, I have frequently observed that those ores containing much magnesia give differences in analysis which do not agree relatively to any distinct formulæ, but seem rather to indicate a mixture of silicates; as, however, the magnesia diminishes these differences are gradually reduced, and the composition then becomes more constant, and more closely complies with the calculated numbers, except for the combined water, for which I have been unable to find a constant factor. Having excellent opportunities for procuring pure specimens, and from the many hundreds of analyses made of the same, there seems to be no doubt that both kinds of ore approach very nearly to hydrated sesqui-silicates of nickel, giving a formula of $7NiO \cdot 6SiO_2 \cdot xH_2O$, part of the nickel in the green ore being replaced by magnesia, oxide of iron, or alumina, the magnesia predominating, whilst in the brown the oxide of iron is in excess. The following carefully executed analyses of both ores give only the amount of soluble silica, as in those cases when quartz was present it has been calculated out:—

	1.	2.	3.	4.	5.	6.
SiO ₂ ..	35'55	36'24	35'25	34'78	35'80	20'57
NiO ..	48'38	44'94	46'30	43'79	43'54	15'56
MgO ..	5'02	8'75	—	2'75	2'65	0'87
Fe ₂ O ₃ ..	1'41	0'21	0'00	6'30	10'73	49'03
Al ₂ O ₃ ..	1'09	1'03	—	—	—	—
Cr ₂ O ₃ ..	0'15	—	0'14	—	—	3'82
MnO ..	—	—	—	—	0'19	trace
H ₂ O ..	8'85	8'98	9'20	12'40	8'00	10'32
	100'45	100'15	99'89	100'02	100'91	100'17

Nos. 1 and 2 represent the composition of the green ore. The colour is a fine brilliant grass-green. Hardness, 2–3. Specific gravity, 3'00. Streak light green, waxy lustre, and slightly translucent at the thin edges. Before the blowpipe the colour darkens, becoming dark olive green; in presence of much ferric oxide, red.

Nos. 3, 4, 5, and 6 give the composition of different brown ores. The colour varies from light brown to a deep sometimes slightly translucent chocolate; streak yellow or brownish yellow; the fracture is conchoidal, with a very strong resinous lustre. Hardness and specific gravity about the same as the green ore, and rather more brittle. The very light brown species (No. 6) bear a great resemblance to limonite, and are so soft as to be easily marked by the nail. They, however, do not appear to belong to the same class of ores as mentioned above, as the silica fluctuates with the nickel and magnesium oxides, and is sometimes very low, as little as 5 per cent is not unusual. A fact worth noting in connection with oxide of iron deposits is, that although containing oxide of chromium up to 8 per cent, they are easily and entirely soluble in warm dilute hydrochloric acid.

Exposed to the action of the weather all these ores gradually crumble to a powder, the brown exhibiting this to a more marked extent than the green. They are easily dissolved by hot hydrochloric acid, and the silica which separates out does not take the gelatinous condition. Up to the present no trace of crystalline character has been found, although some magnesia-rich specimens occasionally present an appearance similar to asbestos.

Thio, New Caledonia, July 20, 1890.

THE PREPARATION OF BORAX GLASS BY THE ACTION OF BORACIC ACID UPON SODIUM CHLORIDE.

By H. N. WARREN, Research Analyst.

BORACIC acid, as is well known, when in solution is readily replaced by all other acids, but when in a fused condition existing as boric anhydride, an almost exactly reversed action is presented, replacing even to a considerable extent such acids as sulphuric, phosphoric, and others of a similar stability. The action obtained thus by introducing boric anhydride into fused sodium chloride is attended by the slow expulsion of gaseous hydrochloric acid, together with an equivalent of fused borax. This reaction is in every way more productive, however, when boracic acid is introduced in place of the anhydrous compound; and in conducting the experiments a pound of common salt was maintained in the fused condition, while about half its quantity of boracic acid was generally thrown on to its surface. On each fresh addition of acid clouds of HCl were evolved, and a considerable quantity of apparently fused borax was left floating upon the surface of the remaining salt. This after cooling was readily detached from the surrounding salt by breaking the crust, leaving a large fused glassy nucleus absolutely free from sodium chloride, but containing besides borax upwards of 50 per cent of fused boric anhydride. Since apparently the moist acid afforded the best results, the addition of steam was resorted to, and injected during the process of fusion. This undoubtedly raised the percentage of borax to about 80 per cent, still leaving a considerable excess of boric anhydride, and mechanically volatilising a considerable quantity of boracic acid. The remaining experiments, which were carried out more elaborately, consisted mainly in exposing to different grades of temperature mixtures in different proportions of the two compounds, and supplying superheated steam. With these, as in the former, however, too large a quantity of boracic acid, together with the difficulties in regulating the process, have up to the present prevented its practical use.

18, Albion Street, Everton, Liverpool.

DETERMINATION OF LITHIA IN MINERAL WATERS.*

By E. WALLER, Ph.D

(Concluded from p. 174).

GOOCH'S test experiments with mixtures of pure salts may be here quoted, arranged in a form slightly different from that given in his paper. The Li_2SO_4 obtained was calculated back to LiCl in every case. The error is noticeably greater in the presence of potassium chloride.

Ex. pt. No.	Conditions.	LiCl taken.	Errors in corrected weight of LiCl found.
23 ..	NaCl only	Single 0'1298 grm.	0'0002— grm.
24 ..	" "	extr'n 0'1227 "	0'0002— "
32 ..	" "	Double 0'1287 "	0'0007— "
33 ..	" "	extr'n 0'1347 "	0'0006+ "
26 ..	KCl only	Single 0'1256 "	0'0008— "
27 ..	" "	extr'n 0'1287 "	0'0010— "
34 ..	" "	Double 0'1125 "	0'0003+ "
35 ..	" "	extr'n 0'1251 "	0'0011+ "

The average of these errors is 0'0001— with a range from 0'001— to 0'0011+, or if we calculate to the equivalent in $LiHCO_3$ from 0'0016— to 0'00176+, a difference of 0'00376 grm.

* Journal the American Chemical Society, xii., No. 6.

The process has the advantage that the sodium and potassium chlorides are left in a condition for the determination of those bases, in which case, however, an allowance must be made for the small amounts dissolved by the amyl alcohol which was heated with the chlorides. One disadvantage of the process is to be found in the fumes of the amyl alcohol, which, even in a well-ventilated laboratory, is a source of great discomfort to most analysts.

The small amount of water, 100 to 200 c.c., that can be used for this process is advantageous, though for those accustomed to the use of the phosphate process, the amount seems hardly large enough to give a fair average, and to average on a larger amount requires the concentration of the LiCl by extraction with alcohol or alcohol and ether. In some of the first trials made with the process, the amount of mixed chlorides experimented upon considerably exceeded 0.2 grm., probably nearer 1.0 grm., and in some cases more. This was because Prof. Gooch's paper seemed to imply that the operation might be reasonably expected to be successful when applied to quantities ordinarily handled in analytical work. In the case of one water it did prove so, but with another water, containing more lithia as well as alkaline salts, it was not. The removal of all the water in the manner described was a matter of extreme difficulty, and curiously enough, a limit seemed to be reached, beyond which the LiCl was extracted, but slowly and with great difficulty. The results may prove interesting.

The alkaline salts from two equal quantities of a water, each lot amounting to between one and two grms., were treated as described:—

Obtained from A 0.2400 grm. Li_2SO_4 , from B 0.2354 Li_2SO_4 .
Found in insoluble part. f. A 0.0974 " " 0.0943 "

Total .. 0.3374 " " 0.3297 "

The control process used in this case was Carnot's fluoride method, which cannot, however, be regarded as absolutely free from imperfections. It is as follows:—The mixed alkaline chlorides, after evaporation nearly to dryness, are extracted with a mixture of about equal volumes of alcohol (of 90 per cent or over) and ether, so as to obtain the LiCl comparatively free from the others. It was found most convenient to add the alcohol ether mixture, and allow to stand for some time with frequent stirring, and then after standing over night to filter through a small filter and wash with alcohol; one extraction will often suffice. A second extraction may, however, be necessary, the work being of course controlled by the indications of the spectroscope. After evaporating off the alcohol and ether, the salts are dissolved in the least possible quantity of water, and filtered into a weighed platinum dish. The filtrate and washings should then be concentrated to small bulk (5 or 10 c.c.) and pure ammonium fluoride and ammonia added; after thorough mixing, the dish is set aside over night for the LiF to precipitate. The solution is then decanted through a small filter, and the precipitate is washed by decantation three or four times (5 to 7 c.c. at a time) with a solution consisting of the reagent mixed with 5 to 10 times its bulk of ammonia; between decantations the solution must be allowed to stand some little time with stirring. The bulk of filtrate and washing (30 to 50 c.c.) is noted, the filter-paper and contents placed in the dish, sulphuric acid added, and heat applied until the paper has been incinerated, and the lithium converted to sulphate, in which form it is weighed. To this weight is added 0.0040 grm. for every 7 c.c. of filtrate and washings, and the result estimated as Li_2SO_4 is calculated to Li , LiHCO_3 , &c., according to the requirements of the case.

Care is necessary in preparing the reagent and wash liquor.

Carnot seems to have found that the ammonium fluoride ordinarily supplied for laboratory use is the only

member of the combination liable to contain impurities which would interfere (chiefly fluosilicic acid, which might precipitate alkaline fluosilicates), but experiments have shown that ammonia which has been standing for some time in contact with glass will give a cloud (presumably ammonium fluosilicate) with a mixture of solutions of ammonium fluoride and ammonia after boiling and filtering clear. This solution, so long as it contains a fair amount of free ammonia, appears to be without action upon glass. It has been found advisable, therefore, to make up (and cork up) the reagent and washing solution some time beforehand, and to filter off such portions as may be required at the time of using. Naturally, it is necessary to use for the final filtration a filter-paper which has been extracted with hydrofluoric acid. Schleicher and Schull's papers were found satisfactory in this connection. Carnot also recommends that the resulting Li_2SO_4 should be dissolved in 40 to 50 c.c. of water, and a test made for the presence of magnesium, which may have remained with the alkaline chlorides. If any is found to be present, it must be determined as phosphate, and a correction made accordingly.

In connection with this process it was observed that lithium sulphate ignited in contact with the carbon of the filter-paper is especially prone to reduce to sulphide, and especial caution is necessary at this stage of the operation. The sulphide, when heated in contact with the platinum, attacks it in a very marked manner.

The process seems to be very good, although not rapid. Its tendency is to yield results a little high, apparently because the allowance for solubility is usually larger than the actual amounts of precipitate dissolved. Test analysis tended to show also that unless the amounts of potassium and sodium chlorides present with the lithia are kept within narrow limits, the results will be high.

Unfortunately a number of the tests and comparison experiments with these methods have not yet been completed, and will have to be deferred to a second communication.

In order to test these methods upon water containing lithia, samples of several of the best known and widely advertised waters were purchased and submitted to examination.

The results were somewhat surprising, and showed unquestionably that either the original analyses, on the strength of which those waters are now sold, were erroneous on account of imperfection in the methods used, or, what is more probable, that the proportions of lithium in those waters are liable to great fluctuations.

The results given were chiefly obtained by Carnot's fluoride method, but were in several cases confirmed by the use of other methods. The most scrupulous care was exercised to be sure of obtaining *all* of the lithium in the waters under examination, the spectroscopic indications having been used at every stage of the process.

In the Farmville Lithia Water, purchased at the office of the company, no lithium could be detected by the spectroscope on moderate amounts of the water. On evaporating eight litres of the water, and treating in the manner described for the concentration of the lithia into a solution of small bulk, a lithia line was obtained in the spectroscope, but the amount was found to be too small to permit of a quantitative estimation. The experiment was repeated with ten litres of the water, with essentially the same result.

With the Buffalo Lithia Water the reaction for lithium was more distinct, when considerable quantities of the water were concentrated. From twenty litres of the water was obtained lithium sulphate corresponding to 0.0185 part LiHCO_3 per 100,000.

In Londonderry Water the lithia reaction could be obtained without great difficulty. Analysis of the water purchased by myself showed a little over 4 parts per 100,000. The company puts up some of the water in half-gallon bottles not charged with CO_2 , and also some in

pint bottles (called in their circulars "sulpho-carbonated"), which is charged with CO_2 , and has also received the addition of some salts. The amounts of salts added appears to somewhat irregular. For instance, the following results were obtained (results given in parts per 100,000):—

	Total	Loss on
	solids.	ignition.
Londonderry, half-gallon bottles (aver.)	37'35	2'25
„ pint bottle, A	149'4	4'9
„ „ B	104'2	4'5
Average of eleven others	224'7	6'4

The variations in the eleven bottles were 221.3 to 231.4 for total solids. The proportion of lithium was essentially the same as for the still water.

I was told that several lots of water, purporting to come from these springs, had at times appeared on the market in which no lithia could be detected. As I learned that Dr. Endemann had obtained some water of that kind, I requested him to send me a bottle. He complied, and although the bottle bore all the labels and marks similar to those purchased by myself, no lithia could be detected in it. The water contained 5.2 parts total solids per 100,000. I have heard of others who had similar experiences.

I naturally desired to obtain samples of these waters direct from the springs, taken by some one whom I knew to be disinterested. Attempts thus far have been unsuccessful. In the case of the Londonderry springs, all access is denied to visitors, and applications for water are referred to the bottling establishment in Nashua.

Of all the waters examined purporting to be natural, the Saratoga Hathorn proved to be the strongest in lithia. The result of tests on this water are not at present in such form that they can be here recorded, but it suffices to say that the water contains fully as much as the analyses call for (12 to 14 parts LiHCO_3 per 100,000, corresponding to 7 or 8 grains per U.S. gallon).

Tests were also made on the waters manufactured and sold by Carl H. Schultz as containing lithia. They were found to contain a little more lithia than claimed. *E.g.*, the formula on his "Vichy with Lithia," calls for an amount corresponding to about 57 parts LiHCO_3 per 100,000. The analyses showed 60 to 62 parts.

The results enumerated may be tabulated as above.

NOTES ON HIGH VACUA.*

By J. SWINBURNE.

I.

In a series of Papers on "Incandescent Lamp Manufacture," contributed to *The Electrician* in 1887, I called attention to the great superiority of the Geisler to the Sprengel form of mercury pump. Several kinds of Sprengel

pump were successively connected to a Geissler, and both were worked at the same time. The Sprengel invariably stopped taking air down before the Geissler, in fact the Geissler never stops. It acts as its own McLeod gauge, and never indicates a perfect vacuum. The probable reason why the merits of the Geissler have been so underrated is that it needs the greatest care in securing perfect dryness of the bulb and valve. Not only will traces of water-vapour condense under the floating valve instead of lifting it and going through, but it is probable air does so too. About a century ago Davy showed that if the mercury were allowed to run up gently in an imperfect Torricellian vacuum, a bubble was left; but if allowed to rise suddenly, it indicated a perfect vacuum, the air being condensed against the glass. In the lamp Papers I described a form of pump which avoids the difficulties due

FIG. 1.

FIG. 2.

to small condensations. The main bulb discharges into a small chamber sealed by a little V tube, so that a pressure of $1/100$ A would move the mercury. This chamber exhausts into a larger globe, exhausted mechanically and sealed by a floating valve. The small chamber is thus as thoroughly exhausted as an ordinary pump can pump it; but the pump proper, exhausting into high vacuum, can thus work better. The condensed air and water cannot expand back into it. It is thus really a double pump, or two mercury pumps in series. The only drawback is that it needs some pressure to open the first valve or sealing, so that there might, after all, be some condensation under it. I have lately devised and used a pump made as follows :—A (see Fig. 1) is the body or chamber of the pump proper. This exhausts into the small chamber B, sealed by the valve C, and this exhausts into the chamber G, sealed by the floating valve, H. G is connected to a reservoir and mechanical air-pump. The valve C has a long thin glass rod passing down through

* Read before the British Association for the Advancement of Science, Leeds Meeting, 1860, Section A.

A into the lower tube, which acts as a guide. A loose sleeve, F, is strung on this rod. There is a swelling at E which fits the lower end of the sleeve, and is small enough to pass through the neck in putting the pump together. When the mercury rises in the globe A it lifts the sleeve till the lower end catches on E, which closes it. The mercury rises and floats the sleeve, thus lifting the valve C. The mercury that sealed C then runs out, and there is a clear passage through into B; so no condensation takes place in A. The mercury rises till it floats H. When it falls, the valve C acts again, for the mercury has filled the sleeve F over the top, and C is heavy enough to sink the sleeve and rod when the sleeve is full of mercury. I have tried electro-magnetic and other arrangements, but this is the best as far as I have gone.

When using a pump it is best not to let air, and perhaps moisture, run through it more than can be helped. By the use of a sort of syphon it is possible to seal on new work to be exhausted without letting the air-pressure into the pump.

The point K (see Fig. 2.) is the barometric height at which the mercury normally stands in the tube R. There is then a clear passage between L, which is connected to the tubes to be exhausted, and M, which goes to the drying tubes and pump. When a tube has been sealed off and a new one is to be put on, the mercury reservoir at the foot of the arrangement is raised so that the bulb N is filled. A tap at the foot of the tube R is closed and the vacuum in L is broken. The mercury then runs up to the new barometric height P. The new tube is then sealed on and exhausted by a mechanical pump, the connection being then sealed off. The mercury in the long tube then stands only half an inch or so above that in N, and on opening the tap at the foot of R, the communication is made again to the pump. The small bulb O, and the trap at the top are to prevent a plug of mercury from going round into the phosphoric tubes.

The pump is driven by water so as to be self-acting, and can be left running for any length of time. Those who have worked much with mercury pumps will realise the value of this. Nothing makes one feel the futility of life more than to exhaust something by hand which cracks at the last stage, when five hours of life have been ticked off.

II.

In the same Papers on lamp-making I urged that the methods of measuring high vacua were inaccurate and completely misleading. The McLeod gauge and the induction coil are usually relied on for testing vacua. In incandescent lamp work the induction coil is almost exclusively used. With the test by induction sparks, I have at present nothing new to add, and will confine myself to the McLeod gauge. In measuring vacua with this gauge it is assumed that the mercury itself has no vapour tension. The vapour tension of mercury has been given by Regnault as about 50 millionths of an atmosphere. If it is anything like this, of course a vacuum of one millionth, or of 0.005 millionth, as some experimenters profess to have reached, is absurd. When discussing this subject, at the Society of Arts after Dr. S. P. Thompson's well-known Paper on "Mercury Pumps," Prof. Ramsay gave 0.25 millionth of an atmosphere, or, as I shall write it shortly, 0.25M, as the vapour tension of mercury at ordinary temperatures.

The whole action of a pump is consistent with a vapour tension of from 25 to 50M. A Geissler does not reduce the pressure in geometrical progression; but when it gets a good vacuum it takes out very little air each stroke, worked fast, and much more if worked slowly. This looks as if when the tension of mercury vapour was nearly reached, the air taken out at each stroke was what diffused into the mercury vapour. This would also explain why a Geissler, which goes on long after a Sprengel stops, does not so readily make a sparkless tube. A Sprengel stirs up the mercury, and gives the tube, being exhausted,

more chances of getting filled with mercury vapour, which is a non-conductor. This also explains why so many experimenters get better vacua with hot mercury. Of course a new pump should be heated to get the moisture off the glass, but not when it is in ordinary use.

To test this more directly I attached two McLeod gauges to the same pump. They communicated till a fair vacuum was reached. One was then sealed by raising the mercury past the elbow tube. The gauges were allowed to communicate by lowering the mercury every now and then, and it was always lowered before taking a reading. By this arrangement, when the pressure was reduced nearly to the vapour pressure of mercury, one gauge might have little but mercury vapour, and show a good vacuum; while the other had air at the same pressure, and showed a pressure equal to the vapour tension of mercury, or nearly so. The gauges are graduated by finding p corresponding to one-millionth of an atmosphere, and graduating accordingly. The pressure in millionths is then the product of the reading on the closed tube and the difference in the column. Each reading is thus readily taken at several pressures to make sure there is no condensation of any vapours or gases. The readings obtained varied in an extraordinary way. When the exhaustion was carried so far that the open gauge registered 2M or 3M, the closed registered from 20M to 60M. The least difference in temperature seems to make a large difference in the readings. In some cases, when the vacuum was still low, the open gauge was heated till the mercury sputtered, and condensed about the bulb. The bulb was then warmed to evaporate the mercury and drive all the air out, and the elbow tube sealed by raising the mercury. When the gauge was cool both were unsealed and readings taken. The gauge that had been warmed sometimes gave 1M against no less than 230M in the other. Ten minutes' connection generally brought the readings equal. Obviously the movement of the air need not depend on diffusion only; for a very small difference of temperature would cause mercury to evaporate in one gauge and condense in the other, driving the air with it.

I made a gauge with an alloy of about equal parts of potassium and sodium, which is liquid at ordinary temperatures. It would, of course, absorb any mercury vapour, and has probably a low-vapour tension. It was very troublesome, for it could not be exposed to the air for a moment, and heavy hydrocarbons would prevent the pump's working. The alloy always gets some moisture, and gets coated with a thin film of oxide which prevents drops from uniting, and they can only be run together by heating under a hydrocarbon of low boiling-point. I eventually got the gauge fitted up, but the alloy acted on the film of moisture on the glass, and the bubbles formed seemed to drive plugs of it about. It has a very low specific gravity, and pistons of it began to stray about inside the pump, and I was afraid they might get to the mercury, and by combining explosively, smash the pump, so the experiment was abandoned. In one experiment a plug of the alloy wandered into the mercury in R and cracked the tube.

Fusible alloy was next tried. It worked better, but the vapours of some sulphur that was used to trap any mercury vapour blackened the surface, and only two readings were obtained. These gave a pressure of only 13.5M as the vapour tension of mercury.

Whether it is really 13M or 50M is of comparatively little importance; but there seems to be quite enough evidence that the readings of 0.001M and higher vacua that have been given are inaccurate to the extent of some hundreds of thousands per cent. This is important in many investigations pursued by means of mercury pumps; for instance, experiments on the "Fourth State of Matter." The question is also important in lamp making, as it shows that better vacua are possible, and they may be an advantage. I do not know whether pumps worked with alloy of sodium and potassium will come into commercial use.

THE PRESENT POSITION OF THE HYDRATE THEORY OF SOLUTION.*

By SPENCER UMPREVILLE PICKERING, M.A., F.R.S.

It is but four years since this Section devoted a day to the discussion of the Nature of Solution;† since then, however, the general aspect of the question and the position of the advocates of the two rival theories have undergone such a complete change, that in renewing the discussion we shall run but little risk of going over the same ground which we then trod. At Birmingham, Dr. Tilden opened the discussion by passing in review all the well-known and long-known facts which might by any possibility throw some light on the nature of solution, and those who followed him in the discussion each gave the interpretation of these facts which harmonised best with his own views, and, as the facts themselves were susceptible of several different interpretations, the not surprising result followed that each disputant departed holding precisely the same opinions which he had brought with him. Since then, however, each party has obtained, or thinks that he has obtained, positive evidence in favour of his own views; evidence which, if upheld, must be accepted as conclusive, or which must be overthrown before his opponents can claim the victory. The supporters of the hydrate theory claim that the curved figures representing the properties of solutions of various strengths show sudden changes of curvature at certain points, which are the same whatever be the property examined, which correspond to the composition of definite hydrates, and which, therefore, can only be explained by the presence of these hydrates in these solutions; while the supporters of the physical theory, now identified with the supporters of the osmotic pressure theory, claim to have shown that, with weak solutions at any rate, the dissolved substance obeys all the laws which are applicable to gases, and that, therefore, its molecules must be uninfluenced by, and uncombined with, those of the solvent.

In another respect also I may notice that our position to-day differs considerably from what it was four years ago; for instead of having to argue the matter out amongst ourselves, as we did then, we are now favoured with the presence of some of those whose work in this very subject has made their names familiar household words with every physicist and chemist throughout the scientific world.

I propose in the first place to give a brief summary of the evidence which has lately been adduced in favour of the hydrate theory, and in the second place to inquire whether the conclusions drawn from this evidence are invalidated by the important facts elucidated by Raoult, van't Hoff, Arrhenius, and Ostwald.

In one respect the supporters of the hydrate theory start now under a distinct advantage, namely, that their most active opponents do not altogether deny the existence of hydrates in solution, although it is only in the case of strong solutions that they will admit their presence; in such solutions, indeed, it is difficult to see how their presence could possibly be denied. The only means which we have of proving that a liquid is a definite compound is by ascertaining whether its composition remains unaltered by its passage through the gaseous or solid condition—by fractionating it by means of distillation or crystallisation. With liquids of comparatively small stability, such as hydrates, crystallisation is the only method available; the results of crystallisation have led us to conclude that the liquid represented by H_2SO_4 is a definite compound, and precisely similar results must force us to accept the definiteness of the liquids $\text{H}_2\text{SO}_4\text{SO}_3$, $\text{H}_2\text{SO}_4\text{H}_2\text{O}$, and $\text{H}_2\text{SO}_4\text{H}_2\text{O}$; in the case of each of them the liquid freezes as a whole, and without change of composition; the temperature remains constant through-

out the solidification, and any excess of either water or sulphuric anhydride which may have been added may be separated from the pure compound, which alone crystallises from the mixture. Thus, in the instance taken, between the anhydride on the one hand and water on the other, we have four definite compounds, all existing in the liquid condition.

It does not follow, however, that every hydrate which exists in solution can necessarily be obtained in the solid condition; probably no solution, even when it possesses the exact composition of some existing hydrate, consists of that hydrate only, but of a mixture of it with the products of its dissociation (though the amount of these may be very small), and whether the hydrate or one of these dissociation products crystallises out on cooling must depend on the relative ease with which the bodies in question assume the solid condition; when the hydrate does not crystallise easily we can hope to obtain evidence of its presence by indirect means only.

Mendeléeff's conclusions respecting the densities of solutions of sulphuric acid and alcohol,* mistaken though I believe they were, led to the discovery of the means whereby such evidence might be obtained.

He stated that on plotting out the rate of change of the densities with the percentage composition of the solution (the first differential coefficient) he got a series of straight lines, forming figures with well-marked breaks, at points corresponding to definite molecular proportions; but on plotting out the experimental points which he said formed these figures, it is impossible to see any justification for this statement; in the case of sulphuric acid the points and Mendeléeff's drawing of them have been given side by side in the *Trans. Chem. Soc.*, 1890, p. 81, and in the case of alcohol they will be found in the *Zeit. f. Phys. Chem.*, vi., i., 10. Crompton then showed,† from an examination of Kohlrausch's values for the electric conductivity of sulphuric acid solutions, that a second differentiation might in some cases be necessary before rectilinear figures with breaks in them were obtained. In my own work on various properties of solutions of the acid I have made free use of this process of differentiation, but I have combined it with, and now nearly entirely rely on, an examination of the original curves with the help of a bent ruler.

In the *Phil. Mag.*, 1890, vol. i., p. 430, will be found rough sketches of the figures representing the densities, contraction on formation, electric conductivity, expansion by heat, heat of dissolution, and heat capacity of the solutions, and in the *Trans. Chem. Soc.*, 1890, p. 338, that representing the freezing-points. In some cases, such as the freezing-points of solutions of near 58 and 100 per cent. strength, a mere inspection of the figure enables us to locate the position of abrupt changes of curvature; in general, however, the recognition of such changes is more difficult. On attempting to draw any of these figures with the help of a bent ruler it was found that the whole figure could only be drawn in several sections, and it was also found that each section thus drawn consisted of a single curve of a parabolic nature, although a ruler, when bent by the pressure exerted by the two hands, by no means necessarily forms a parabola; and, moreover—and this is the most important part of the evidence—it was found that these figures, though differing so greatly in their general appearance, all split up into the same number of sections, indicating the existence of changes of curvature at the same points; and, further still, these points corresponded to solutions of definite molecular composition in all cases where the ratio of the acid to the water was sufficiently large to render any such comparison possible; the average difference between the composition indicated by the changes of curvature and that of definite hydrates was only 0.057 H_2O . With weak solutions it is, of course, impossible to assert that the changes occur at definite molecular proportions owing to the smallness of the change

* Read before the British Association for the Advancement of Science, Leeds Meeting, 1890, Section B.
† *Report*, 1886, p. 444.

* *Zeit. f. Phys. Chem.*, i., p. 275; *Chem. Soc. Trans.*, 1887, p. 77.
† *Chem. Soc. Trans.*, 1888, p. 116.

in percentage composition which would be caused by an additional molecule of water to each H_2SO_4 , but the changes with these weak solutions are of precisely the same character as those with strong solutions, and, unless some strong evidence to the contrary be forthcoming, we must attribute them to the same cause.

To discuss fully the value of the evidence thus obtained would take me more hours than I can now afford minutes; but I think that I may say that these results stand at present unquestioned and uncontroverted, and that unless they can be controverted we must accept the presence of hydrates in solution as having been proved. I may also add that my results with sulphuric acid solutions have been strengthened by obtaining analogous results with solutions of several other substances: that one of the hydrates indicated by them has been proved to exist by isolating it in the crystalline condition: and lastly, that a law governing the freezing-points of solutions has been formulated, according to which we can calculate within experimental error the freezing-point of any solution, whatever its strength may be, provided we acknowledge the existence of every hydrate which my work has indicated; whereas, if we deny the existence of these, the freezing-points calculated according to this or any other law show such divergences from the found values that all semblance of agreement disappears. I am indeed labouring under no small disadvantage in attempting to support the hydrate theory when the greater part of the evidence existing in favour of it is as yet unpublished.

Before proceeding to the second part of my subject I wish to draw attention to the great complexity of some of the hydrates which my work has indicated, as well as to the fact that the indications of sudden changes are nowhere more marked than they are with these very weak solutions. The changes, which are observed in the heat of dissolution curve from 5 per cent downwards,* afford a good illustration of this latter fact; or, again, the freezing-points of weak solutions may be instanced† where the rate of fall from 0 to 0.7 per cent is a quarter as great again as it is from 0.07 to 1.0 per cent. The complexity of the hydrates indicated is so great that in the extreme cases they must be represented as containing several thousand H_2O molecules, and the suggestion of such complexity will no doubt prejudice many against my conclusions in general—though on what grounds I know not, for we are entirely in ignorance at present as to the possible complexity of liquid molecules. It is interesting to note that a similar complexity of molecular grouping must be admitted if we accept Raoult's original statement that one molecule of any substance dissolved in 100 molecules of a solvent lowers the freezing-point of this latter by about 0.63° : for, if this be so, we must assign to the molecules of the various substances entered in the second column of Table I. the magnitude there indicated when they are dissolved in the solvent named in the first column, for it requires that proportion of these bodies to lower the freezing-point of 100 molecules of the solvent by 0.63° ; and, amongst these few instances which I have collected from my own determinations, we find molecular aggregates containing as many as 200 of the fundamental molecules, and even this number, I may mention, probably understates the complexity to a very considerable extent; for the depression in this and some of the other cases had to be estimated from that observed with solutions containing as much as 10 grms. molecular proportions to 100 of the solvent, and the molecular depression increased rapidly with the strength of the solution: 1000 H_2O would probably be a low estimate of the complexity of the molecules of water when dissolved in a large excess of the hexhydrate of calcium chloride, a complexity comparable with that of the hydrates, which my other work has indicated, and that too in the case of that very substance which these hydrates contain—water.

TABLE I.

Molecular Weights of Substances in various Solvents.*

Solvent	Dissolved substance producing 0.63° depression.†
100 $\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}$	32 H_2O 63 H_2SO_4
100 $\text{H}_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$	8 H_2O 15 H_2SO_4
100 $(\text{CaNO}_3)_{24} \cdot \text{H}_2\text{O}$	90 H_2O 42 $\text{Ca}(\text{NO}_3)_2$
100 $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$	210 H_2O 63 CaCl_2

Now as to the question of how far the theory of osmotic pressure, and the results on which it is based, are antagonistic to the hydrate theory: and let me first define clearly the position which I take in this matter. I do not for one moment call in question any of Raoult's classical work, which is now so familiar to us, nor do I question that these results reveal the existence of a depression of the freezing-point which is approximately and generally constant; and I consequently admit that we can generally obtain an approximately correct value for the molecular weight of the substance by observing the depression which it causes; nor, again, do I wish to question the correctness of the mathematical relationship which van't Hoff and Arrhenius have shown to exist between osmotic pressure, the lowering of the freezing-point, and other properties, provided we accept the fundamental assumptions on which their calculations are based—the truly gaseous nature of dissolved matter, and the dissociation of salts into their ions. But what I do question is that the facts of the case warrant such assumptions, and that the constancy and regularity of the results are so rigorous as to justify the conclusion that the solvent has no action on the dissolved substance, and that there are no irregularities such as would be caused by the presence of hydrates.

According to the osmotic pressure theory, the dissolved matter, so long, at any rate, as it is not present in greater quantity than it would be in the same volume of its gas, if it were gasified under normal conditions, is really in the gaseous condition, and obeys all those laws which apply to gases. According to the hydrate theory this will be but partially true. That the dissolved substance is in a condition comparable with that of a gas in so far as the separation of its own particles from each other is concerned, must be admitted—indeed, I arrived independently at this same conclusion from a study of thermo-chemical data—but inasmuch as there is present the solvent, which we believe is *not* an inactive medium, its molecules cannot have the same freedom as if they were truly gaseous, and will, therefore, obey the laws of gases imperfectly only.

It will be well to confine our attention to but one of those properties connected with osmotic pressure, and to select for that purpose the one which has been most fully investigated—the lowering of the freezing-point of a solvent: and the tests which may be applied to ascertain whether in producing this lowering the dissolved substance behaves as a perfect gas or not, may be grouped under three principal headings:—

1. Is the molecular depression (i.e. that produced as calculated for one molecule dissolved in 100 molecules) constant independent of the nature of the solvent?
2. Is it independent of the strength of the solution, so long as this strength does not exceed the limits ("gas" strength) above mentioned? (Boyle's law.)
3. Is it independent of the nature of the dissolved substance? (Avogadro's law.)

In the *Phil. Mag.*, 1890, vol. i. p. 495, will be found instances of the variation in the molecular depression which may be noticed by altering the solvent (see also Table I. above). With water in six different solvents it varied

* Other instances of high molecular weights are mentioned by Brown and Morris (*Chem. Soc. Trans.*, 1888), and Gladstone and Hibbert (*Phil. Mag.*, 1889, vol. ii., p. 38).

† Determined from the freezing-points of very weak solutions.

FIG. 1.—DEVIATION FROM REGULARITY OF THE FREEZING-POINTS OF VERY WEAK SOLUTIONS.

FIG. 2.—FREEZING-POINTS OF SULPHURIC ACID AND ALCOHOL SOLUTIONS.

between 1.072° and 0.003° ; with sulphuric acid in four different solvents between 2.15° and 0.01° ; with calcium chloride in two different solvents, from 2.773° to 0.01° ; and with calcium nitrate in two solvents, from 2.5° to 0.015° ; while many instances may be collected from Raoult's data showing that the same substance which acts normally in one solvent may act abnormally (give only half the usual depression) in another. Such variations are so great—from 100 to 35,600 per cent.—that there can be no doubt but that the solvent is *not* that inert medium which the supporters of the physical theory would have it to be, but that it has a very great influence on the results obtained. It must be noted, however, that this objection, though applying to Raoult's original views, does not, or, at any rate, may not, apply to van't Hoff's theory, for, according to this theory the nature of the solvent has an influence in determining the lowering of the freezing-point, W in van't Hoff's equation,—

$$\Delta T = \frac{0.02 T^2}{W},$$

representing the heat capacity of the solvent. But the lowering is according to this equation independent of the nature or the amount of the dissolved substance, so that the two following objections will apply to van't Hoff's theory as well as to Raoult's statement.

Secondly, as to the influence of the strength of the solution. It is remarkable that although the osmotic pressure theory depends on the behaviour of solutions below a certain strength, no attempt whatever has been made by its supporters to obtain any data respecting such solutions. The data on which their views were founded referred to solutions considerably stronger than the requisite "gas strength," and though, no doubt, it was convenient to work with data which afforded a ready excuse for any awkward irregularities which might be met with, such data must lack the conclusiveness which is so eminently desirable. The few data which I have accumulated as to solutions of an "ideal" strength can leave no doubt that, even in their case, the depression is not a constant independent of the strength.

A solution of sulphuric acid containing $0.08\text{H}_2\text{SO}_4$,

100H₂O would be of a strength comparable with the gas from the acid if it could be gasified at normal pressure and temperature, and the molecular depression should be constant for all solutions below this strength: it should be represented by a horizontal line such as AB in Fig. 1, whereas the observed deviations from constancy are very great, being represented by the lines marked H₂SO₄; and, moreover, these deviations are by no means regular, and cannot therefore be attributed to imperfect gasification; they possess none of the characteristics of the deviations of gases from Boyle's law. The determinations on which these results are based are very numerous; there are about sixty experimental points on the portion here shown, and the mean error of each point as determined in two different ways was only 0.0005°, a quantity represented by one-tenth of one of the divisions of the paper; and the deviations from the regularity amount to thirteen times this quantity, and to as much as 16 per cent of the total depression measured.

The other lines in Fig. 1 represent the deviations from regularity in the case of calcium chloride, calcium nitrate, and alcohol respectively, and these, though they are smaller than in the case of sulphuric acid, are far too great to be attributed to experimental error; and the fact that they occur sometimes in one direction, sometimes in the other, precludes the possibility of attributing them to any constant source of error in the instruments used or in the method adopted.

Remembering that these are the only data which we have at present respecting very weak solutions, we must conclude that the hypothesis that such solutions exhibit perfect regularity is wholly untenable.

It is important to observe that when we pass on to stronger solutions, where the actual magnitude of the deviations becomes so great that they would be revealed by the roughest experiments—deviations of even 70°—and where, I believe, even the supporters of the osmotic pressure theory would not hesitate to attribute them to the disturbing influence of hydrates; these deviations occur in precisely the same irregular manner as they do in the case of weak solutions, and must evidently be attributed to the same cause. The results with alcohol given in Fig. 2 illustrate these irregularities in a very striking manner. It must also be pointed out that, apart from the irregularity of these deviations, their very direction shows that they cannot be attributed to the dissolved particles being brought within the sphere of each other's attraction, as in the case of the deviation of gases from Boyle's law, for the result of this would be that their attraction on the particles of the solvent would be diminished and the freezing-point of this latter would consequently be lowered to an abnormally small extent, whereas precisely the reverse is the case in nearly every instance at present investigated: the freezing-points of strong solutions are abnormally low. Various instances of this will be found in the *Phil. Mag.*, 1890, vol. i., p. 500, that of sulphuric acid, which is illustrated here in Fig. 2, being by no means the most prominent; while the case of alcohol, now for the first time displayed (Fig. 2), is the only exception which has, so far, been met with, and that is an exception only in the case of excessively strong solutions.

From the instances above mentioned, some answer may be obtained to the third question, whether the molecular depression is independent of the nature of the dissolved substance. The values obtained with these four substances, taking solutions of a strength corresponding to that of their gases, are:—

Calcium chloride		2.850°
Calcium nitrate		2.744°
Sulphuric acid		2.313°
Alcohol		2.180°

a variation of 30 per cent, which must give an emphatic denial to the idea of absolute constancy; and if we take instances from other substances, where the data available

refer to solutions of somewhat greater strength, we find that the very substances on which the idea of constancy was originally founded show variations reaching 60 per cent (*Phil. Mag.*, 1890, vol. i., p. 492), while in other cases, which I have quoted elsewhere (*loc. cit.*, p. 493),* the variation attains the still larger dimensions of 260 per cent.

To every one, therefore, of the three test questions as to constancy and regularity, the experimental results give an unhesitating negative.

In the instances quoted above the depression actually found for alcohol has been doubled in order to simplify the comparison of it with the other substances. Alcohol belongs to that class of bodies which give just half the value in water that the majority do, and of which there are some instances in the case of every solvent yet examined. The explanations which the supporters of the chemical and physical theories give of these half values differ so radically from each other that it is hopeless to attempt to arrive at any agreement as to the nature of solution till this difference is settled. The chemists say that these half values are in all cases the abnormal ones, just as Raoult did originally, and explain them by representing the molecules of the dissolved substances which give them to consist of two fundamental molecules. The physicists give exactly the same explanation in the case of every solvent except water, but in this case they say that the smaller values are the normal ones, and the larger the abnormal, the double magnitude of these being caused by the dissociation of the dissolved molecule into its two ions, whereby two molecules or acting units are formed from every one originally added.

(To be continued).

NOTICES OF BOOKS.

Book D; or, Arithmetical Physics. Part I. B. Acoustics, Light, and Heat (Degree and Honours Stages). By C. J. WOODWARD, B.Sc. London: Simpkin and Marshall. Birmingham: Cornish Brothers.

THIS work is most distinctly examinational, and as such it must excite in the mind of the critic, not "alarm," but regret and disappointment. We feel anxious to know the real value of the method of teaching chemistry and physics which the author is carrying out in his series of "Educational Works." We feel very dubious in how far it can train the student in the art of observing rightly and of drawing correct inferences from the phenomena thus observed. We fear that this system of teaching science is one of the many results of examinationism. We cannot by any examination questions hitherto devised test the power of the student in detecting phenomena, observing them correctly, and tracing them to their causes. Hence examinationists, if they must teach the physical sciences, enter upon a bye-path better suited to their entire system. We fear that this is a mere trifling with the demand for scientific education. The first point surely should be to perfect the student as an observer; the second, to train him up in the art of tracing effects to their causes, or rather, perhaps, of harmonising the phenomena observed. But this does not lend itself to the examinational system. Hence the demand of the age is evaded. We entertain grave doubts whether works of the type in question are calculated to train students either in the acute observation or in the accurate interpretation of phenomena. But if the examinational system is to be retained at all hazards, they will, of course, have their value.

* The depression produced by H₂O in 100H₂SO₄ is 1.07° instead of 0.07° as there given.

CORRESPONDENCE.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—A circular, signed by Messrs. F. J. Lloyd and F. L. Teed, has been sent round to the members of the Chemical Society. It calls attention to the fact that the Fellowship of the Society has in the past been given to persons who have very small title to be considered chemists. The circular goes on to state that in consequence of this action on the part of the Electors of the Chemical Society, the Fellowship, regarded as a professional qualification, has fallen into disrepute, and is likely in the future to become less and less considered as an evidence of its holder's scientific training and ability.

To remedy this state of affairs, it is proposed that in future more stringent regulations shall be enforced by the present members, which shall exclude the election of any candidates for the Fellowship unless they can show what may be considered, on broad grounds, suitable qualifications; and by the general tone of the circular, it is evident that these suitable qualifications are intended to be of a scientific nature, and not the more ordinary qualifications as to character and ability to pay the Society's subscription.

I hope that you will afford me room to express some objections which I hold to the position Messrs. Lloyd and Teed have taken on this question.

The chief advantages which the Chemical Society offers to its Fellows may, I think, be found in the admirable Journal, the library, and the opportunity afforded for the reading and discussion of papers, and for intercourse between men interested in the science of chemistry; it was for these or similar purposes that the Society was formed, and I believe it was never intended that its Fellowship should be in any way regarded as a scientific qualification. The chief object was the advancement of the science. Now, the library and, above all, the Journal, which improves, one might almost say, from month to month, cannot be conducted without money, and as this money is obtained from the subscription of the Fellows, any limitation of their numbers on any other ground than that of character and financial ability to pay the subscriptions is, from this point of view, most unwise. If people having small, or even absolutely no, scientific qualifications, but who are able to pay their subscriptions, and do not fall short of the ordinary requirements as to character, wish to become members of the Chemical Society, it is certainly an advantage rather than otherwise to the scientific member who appreciates his Journal and the library.

It is no doubt quite true that persons having practically no knowledge of chemistry have joined the Society merely with the intention of using the mystic letters F.C.S. as an advertisement. This is an abuse, and several courses of action which might be taken to nullify the evil readily suggest themselves. The method proposed in the circular will certainly not succeed. Action of this kind will confirm the position of any unqualified persons who may already be Fellows. The Chemical Society having committed itself to the policy of considering the conferment of its Fellowship as a recognition of scientific training (for this is what the proposed action must do), individuals of this class already holding it will benefit immensely: unless, indeed, it is proposed to proceed to the drastic measure of turning out present members, a course which I presume is hardly contemplated. It is, perhaps, not generally known that there is at present no legal means by which any person can be prevented from placing the letters F.C.S. after his name, and, moreover, as any one can become a Fellow of the Berlin Chemical Society by merely paying his subscription, he is then able to place

F.C.S. Berlin, after his name, which probably will have quite as much, or perhaps even greater, weight with the outside public than the more sober F.C.S. It is particularly for the protection of the outside public that these new regulations are proposed. The scientific man knows very well how to take care of himself.

If means are taken to make it as widely known as possible that the Fellowship of the Chemical Society is no guarantee whatever of the attainments of the holder, the resignation of some few who look upon its possession as having a merely commercial value in return for their £2 per annum, may follow; but the many who, as students or amateurs, would be excluded by the more rigorous tests proposed will remain members, and it is sincerely to be hoped that in the future they will, as they have done in the past, continue to join the Society. Surely persons sufficiently interested in chemistry to value the Chemical Society's Library and Journal possess all the qualifications which should be required for the spread and advancement of the science.

If there were any danger that the class of persons to whom the circular refers could at any time obtain a management of the affairs of the Society it certainly would be a matter of the greatest importance: but surely a danger of this kind cannot be seriously considered as ever likely to occur.

Lastly, what class of persons can consider themselves aggrieved if the Fellowship of the Chemical Society comes to be no longer considered as a qualification? The pure scientist or professional man of any status depends to a certain extent perhaps upon his college degrees, but chiefly upon his actual position, the practical or theoretical work he has undertaken, and upon his past record generally. The practical analyst or technologist has the Institute of Chemistry, which gives a qualification that cannot be assumed by outsiders without they lay themselves open to legal action, which the officers of the Institute would be prompt to initiate. The Institute has been formed to discharge the very functions with which now it is sought to burden the Chemical Society (which has very different aims and duties). The qualifications demanded by the Institute from applicants for the Associateship or Fellowship are not unduly stiff, certainly not more so than those required from the medical student before he is permitted to practise. In short, chemists who are interested in this matter will do well to exert themselves to uphold the Fellowship of the Institute of Chemistry as being a guarantee of scientific training; whilst every means must be taken to spread among the public the knowledge that the Fellowship of the Chemical Society is no evidence whatever (nor was ever intended as such) of an individual's training or capacity.—I am, &c.,

ARNOLD PHILIP.

Royal Indian Engineering College,
Cooper's Hill, Oct. 4, 1890.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 11, September 15, 1890.

On the Equivalent of Gadolinia.—Lecoq de Boissaudran.—The equivalent of gadolinia has been determined by M. de Marignac as about 120.5 ($\text{SO}_3 = 80$); that is, 156.75 for the atomic weight of Gd, and 361.5 for the molecular weight of Gd_2O_3 . The result of the author's approximate analysis of the gadolinia of M. de Marignac does not greatly modify these values, as the two chief impurities (Sm_2O_3 and Zr_2O_3) of the gadolinia in question exist

in it in almost equal proportions (about $\text{Sm}_2\text{O}_3 \frac{4.4}{100}$ and $\text{Zr}_2\text{O}_3 \frac{4.7}{100}$), and have molecular weights situate the one above and the other below the molecular weight of the total mass ($\text{Sm}_2\text{O}_3 = 348.0$; Gd_2O_3 (of Marignac) = 361.5 , $\text{Zr}_2\text{O}_3 = 367.0$ approximately), yielding a partial compensation of the effects of these impurities. On applying the result of the author's analysis, and setting out with the mean equivalent 120.5 , we obtain for the true gadolinia contained in the earth of M. de Marignac, equiv. = 120.79 , and $\text{Gd} = 157.19$, but these values seem a little too high. In spite of the small quantity of material available, the author attempted to take the equivalent of the gadolinias of his fractionations Nos. 6 and 9. A known weight of the earth was converted into sulphate and weighed, after exposing the salt to a dull red heat. On operating upon small masses (0.2 grm.) such as the author was obliged to use, the errors in weight, due to the absorption of air and moisture by the crucibles and their contents, are sometimes very important, unless special precautions are taken. It is useful to study the progress of the weights of the crucible, first empty and then full, and to deduce from the curve of these observations the value of the absorption exerted by the material from the extinction of the fire until the weighing. He thus obtains:—

No. 6. First Experiment.

	Equiv.	At. weight.
1. By weighing Gd sulphate	119.69	155.53
2. By BaOSO_3 obtained from such sulphate	120.04	156.06
Mean of first experiment ..	119.86	155.80

No. 6. Second Experiment (better than first experiment).

By weighing Gd sulphate	119.84	155.76
Meant for earth No 6	119.85	155.78

No. 9. (Good Experiment).

By weighing sulphate	120.08	156.12
Mean for Nos. 6 and 9	119.96	155.95

The slight impurities still contained in Nos. 6 and 9 should slightly reduce the equivalent, and, consequently, the mean experimental atomic weight, = 155.95 , would be a little increased if the earth were absolutely purified. According to estimations which are probably exaggerated, this additional value would scarcely raise the atomic weight of true Gd by 0.39 . The author thinks that the atomic weight of gadolinium will differ little from 156.15 , unless the experimental value of 155.95 involves some notable error. Prof. Clève has determined the equivalents of several successive portions obtained by fractionation with ammonia, but as his object was to know if gadolinia could or could not be split up into various earths having decidedly different equivalents, he had no inducement to take exceptional precautions to obtain a degree of accuracy higher than that which sufficed for his purpose. The following are the numbers found by Prof. Clève for some of his fractions:—

	Atomic weight.
First fraction, deeply coloured	154.15
Fourth „ pale yellow	155.28
Fifth „ nearly white	155.1
Sixth „ white	154.77

The observations of Prof. Clève thus agree fairly with those of M. de Marignac.

The Acetic Ether of Diacetyl-carbinol.—A. Combes.—The author has obtained a compound, $\text{C}_5\text{H}_8\text{O}_3$, of an acid odour, of powerfully reducing properties. It reduces Fehling's liquid and ammoniacal silver nitrate in the cold, and does not furnish metallic derivatives.

Vol. i., No. 13, August 15, 1890.

Gay-Lussac.—A biography of this illustrious chemist which appears in connection with the inauguration of a statue to his memory, at Limoges, on August 11th.

MISCELLANEOUS.

Appointments.—Sir Charles Cameron, Professor of Chemistry and Hygiene, Royal College of Surgeons, Ireland, has been appointed a member of the Army Sanitary Committee by the Secretary of War. The members of the Committee now number seven. They have to consider the sites, &c., of barracks, upon which £4,000,000 are to be expended.—Mr. J. Morrow Campbell, B.Sc., F.C.S., Assistant to Professor Sexton at the Glasgow and West of Scotland Technical College, has been appointed Assistant Engineer and Analyst to an expedition proceeding immediately to Persia, under the Persian Bank Mining Rights Corporation, Limited. Mr. Campbell is succeeded at the College by Mr. T. S. Goodwin, formerly Chief Assistant to Prof. Watson at the Anderson's College Medical School.

PATENTS.

Provisional Protection, from £2 2s.

Lowest cost of complete English and Foreign on application. Also, Designs and Trade Marks. Inventions financed.

WALLACE, WEATHERDON, & CO.,

REGISTERED PATENT AGENTS,

THE ACTION OF PHOSPHORUS TRICHLORIDE ON ORGANIC ACIDS AND ON WATER.*

By C. H. BOTHAMLEY and G. R. THOMPSON.

THE interaction of phosphorus trichloride is given in almost all the text-books on organic chemistry as a general method for the preparation of the acid chlorides, and is represented by the equation—

Some years ago Thorpe showed (*J. Chem. Soc.*, 1880, p. 186) that the action of phosphorus trichloride on acetic acid is accurately represented by the equation—

but this work, being contained in his memoir on specific volumes, and not separately indexed, seems to have escaped attention, and the old erroneous equation is given in the most recent books. The authors confirm Thorpe's result, but find that the equation only holds good within certain narrow limits. In presence of excess of acid or of phosphorus trichloride secondary reactions take place, and in almost all cases a small quantity of Leverrier's yellow oxide, P_4O_6 , is obtained. Propionic acid and butyric acid gave a precisely similar result, but the quantity of P_4O_6 formed and the general tendency of the reaction to be complicated by secondary changes increases with the molecular weight of the acid.

Benzoic acid and phosphorus trichloride yield hydrochloric acid and benzoyl chloride, but the quantities are lower than those calculated from the equation, and the character of the residue shows that secondary reactions have taken place to a considerable extent. It is not improbable that in this case some phosphorous acid is formed. Direct experiment showed that phosphorous acid and benzoyl chloride interact, with formation of benzoic acid and hydrochloric acid, and there can be little doubt that several reactions take place simultaneously.

The action of phosphorus trichloride on water takes place in accordance with the ordinary equation—

so long as the water is in considerable excess; but if the chloride is in excess it reacts with the phosphorous acid with formation of hydrochloric acid and yellow phosphorus oxide mixed with other oxides, and in some cases with free phosphorus. It is probable that phosphorous oxide, P_4O_6 , is first formed, but afterwards decomposes. In the interaction of water and excess of phosphorus trichloride the authors obtained the soluble form of P_4O_6 or P_4OH in the cooler parts of the vessel, but if exposed to a temperature above 70° it became insoluble, a result which agrees with an early statement of Gautier.

The authors consider that their results prove that in the interaction of phosphorus trichloride and monobasic organic acids the fundamental change is represented by the equation—

As soon, however, as any acid chloride and phosphorous oxide are formed they may interact with the still unchanged acid and phosphorus trichloride, especially if one of the latter is in excess. They may also interact with one another. In the acetic series the tendency to produce secondary changes increases with the molecular

weight of the acid, probably because of the more ready interaction of the acid and the phosphorous oxide. In the case of benzoic acid the secondary changes take place to a very considerable extent. Where, as in the action of phosphorus trichloride on acetic acid, the products are very volatile, and are rapidly removed from the sphere of action, there is very little opportunity for secondary changes to occur, but in other cases equilibrium is established between the many possible reactions, and the extent to which any given change takes place is determined by the conditions, and especially by the temperature.

The action of phosphorus trichloride on organic acids cannot be regarded as a good general method for the preparation of acid chlorides. It gives satisfactory results only in the case of the lowest members of the acetic series.

This investigation is being continued.

THE SULPHUR WATERS OF YORKSHIRE.*

By C. H. BOTHAMLEY.

THE sulphur waters of Yorkshire divide themselves geologically and chemically into two groups. The springs of one group come to the surface at intervals along a great anticlinal in the Yoredale beds, which stretches from near Clitheroe in Lancashire to beyond Harrogate; but they occur in greatest number and volume at Harrogate, which is built on the summit of the anticlinal. The springs of the other group are found at different points in an alluvial formation, which lies at the foot of magnesian limestone between the river Don and its tributary the Went, and which is in many places covered with a thick layer of peat. They occur in greatest number and volume at Askern.

The Harrogate waters rise from a considerable depth and are free from organic matter. In some cases they contain more than 14 parts of dissolved saline matter per 1000, about 12 parts being sodium chloride. The remainder of the solid matter is chiefly calcium carbonate and calcium and magnesium chlorides. It follows, therefore, that the Harrogate sulphur waters are of a highly chlorinated character. Sulphates are absent; bromides, iodides, and lithium are present in minute quantities. One of the most remarkable constituents is barium, the quantity of barium chloride in some cases being twice as great as the total quantity of solid matter in the best potable waters supplied to our largest towns. The volume of dissolved hydrogen sulphide amounts in the Montpellier Strong Sulphur Well to nearly 80 c.c. per litre.

The Askern waters rise from no great depth, and may almost be regarded as surface waters. They contain only about 2 parts of dissolved solid matter per 1000, the greater part being calcium carbonate and calcium and magnesium sulphates. Chlorides are present in very small quantities. Traces of iodides are present, but potassium, lithium, barium, and bromine could not be detected in 5 litres of the water. The whole of the hydrogen sulphide present is in the free state, and amounts in the strongest waters to about 50 c.c. per litre. There can be little doubt that the hydrogen sulphide results from the reduction of the sulphates; but exactly how this reduction is brought about has not yet been determined.

The latest complete analyses of the Old Sulphur Well and the strong Montpellier Sulphur Well at Harrogate will be found in *J. Chem. Soc.*, 1881. The Askern waters have not been examined for nearly fifty years. The investigation of these waters is still in progress, and

* Abstract of a Paper read before the British Association, Leeds Meeting, 1890, Section B.

* Abstract of a Paper read before the British Association, Leeds Meeting, 1890, Section B.

it is hoped that the results will be published in detail before the end of the year.

The Yorkshire College, Leeds.

NOTES ON THE VULCANISATION AND DECAY OF INDIA-RUBBER.*

By WILLIAM THOMSON, F.R.S.Ed., F.C.S.

UNDER ordinary conditions india-rubber for vulcanising is usually mixed with sulphur and heated to a high temperature, when chemical combination takes place between the sulphur and the rubber, producing a much more valuable compound for ordinary purposes than unvulcanised rubber; the former remaining soft at very low temperature and firm at high temperatures, whilst the latter becomes hard and quite plastic respectively at those temperatures.

In making cloth for waterproof garments another method is employed for vulcanising the rubber—viz., by wetting its surface with a mixture of somewhere about 5 to 10 parts of chloride of sulphur dissolved in 100 parts of bisulphide of carbon, and then heating the fabric gently to evaporate away the excess of these substances. The rubber-covered cloth cannot be heated to a high temperature like the rubber alone, because the heat would be liable to injure the cotton, silk, or wool of the fabric, or destroy or injure the colours.

The bisulphide of carbon softens and penetrates the fine layer of rubber, carrying with it the chloride of sulphur dissolved in it, and it is generally supposed that the chloride of sulphur breaks up the sulphur combining with the rubber, producing vulcanisation, and the chlorine combining with the hydrogen producing hydrochloric acid, which is liberated. This reaction is clearly not the correct one, and it is probable that the reverse is more in accordance with the facts—viz., that the chlorine of the sulphur chloride combines with the rubber, producing vulcanisation, leaving the sulphur in the free state or only partially in combination with the rubber, because in rubber vulcanised by the cold process I have found free sulphur to be present.

From a piece of rubber-covered cloth I separated the rubber and submitted it to analysis by mixing it thoroughly in small pieces with pure sodium carbonate and igniting, then dissolving the whole in water, and adding to it peroxide of hydrogen previously treated with excess of barium chloride (to separate sulphuric acid or sulphates.) The peroxide ensures the conversion of the lower oxides of sulphur into sulphuric acid, whilst the excess of barium chlorides precipitates the sulphuric acid in the solution, which is then weighed as barium sulphate.

Another portion of the made-up solution was neutralised and the chlorine present titrated. The rubber previous to ignition, as above described, had been well boiled in water and dried to separate any hydrochloric acid which might be present, but only a faint trace of chlorine compound could be thus separated from the rubber.

The total sulphur present in the rubber amounted to 2.60, and the total chlorine to 6.31 per cent.

The yellow-coloured sulphur protochloride is best adapted for vulcanising because it does not act too strongly upon the rubber, whilst the dark coloured chloride of sulphur, containing as it does a large quantity of the higher chlorides of sulphur, is liable to render the rubber quite hard by vulcanising it too much. The theory generally adopted to explain this is, that these higher chlorides break up easily, liberating their sulphur, which thus combines in greater quantity with the rubber; but my experiments and analyses prove that it is chiefly the

chlorine and not the sulphur of the chloride of sulphur which produces the vulcanisation.

A rubber substitute much used at present is produced by acting on vegetable oils, such as rape, linseed, &c., with a mixture of chloride of sulphur and bisulphide of carbon. The oil becomes converted into a solid substance resembling india-rubber to some extent, but being much more brittle. This body is now used in large quantity for mixing with india-rubber for the purpose of cheapening its production. On analysis of some samples of this material I have invariably found that it contained a much greater proportion of chlorine than of sulphur, and this process, therefore, is a vulcanisation by chlorine rather than by sulphur.

Recently I analysed three samples of rubber substitute, the one termed "special," another "spongy" india-rubber substitute, the third being similar to the first in appearance. The first contained of sulphur 3.4 and of chlorine 7.6 per cent; the second contained of sulphur 4.56 and of chlorine 8.22, and the third 2.67 of sulphur and 7.90 of chlorine per cent.

These rubber substitutes contain considerable quantities of oily matters soluble in ether, which I have also found to be chlorine and sulphur compounds of the oils. The first yielded 20.0 per cent, the second 14.3, and the third 11.5 per cent of these thick oily matters soluble in ether. This oily substance from the first sample contained 2.6 per cent of sulphur and 6.1 per cent of chlorine, whilst that from the second contained 2.97 and 6.87 per cent of sulphur and chlorine respectively.

Some rubber manufacturers regard this oily matter as injurious to the rubber and reject any substitute which contains any considerable proportion of it. I have found, however, by experiment that this oily compound instead of acting injuriously on india-rubber, actually acts as a preservative of it; some rubber threads were smeared with this oily extract, some with ordinary (unvulcanised) rape oil, and some left untreated: these were put into an incubator at 150° Fahrenheit for a few days, when it was found that the oil-treated rubber was quite soft and rotten, whilst the other two had remained sound; after a few days more, the original rubber threads had become quite rotten, whilst the threads smeared with the oily part of the vulcanised oil remained quite sound.

The first and second samples of rubber substitute were examined for soluble chlorides or hydrochloric acid, by boiling in water; the first gave 0.18 per cent of chlorine soluble in water and the second 0.05 per cent.

It has been known for some time that copper salts exert a most injurious influence on india-rubber; copper salts are sometimes used in dyeing cloths which are afterwards employed for water-proofing with india-rubber, and it seems quite astonishing what a small amount of copper is required to harden and destroy the rubber, and the destructive effect of copper is further enhanced if the cloth contains oily matters in which the copper has dissolved.

As an example, here is a piece of cloth alleged to have damaged the thin coating of india-rubber on it: I found it to contain copper, and with a view of demonstrating this point, I took one piece in its original condition; to the end of this I pasted a similar piece of the cloth from which the oily and greasy matters had been removed by ether, and to the end of this again I pasted another piece of the same cloth from which I had removed both oily and greasy matters and copper; these three pieces joined end to end into one were then coated in the usual way with india-rubber, and then hung in an incubator at 150° F.; in the course of a few days the rubber on the original cloth had become soft, and it then hardened and became rotten and useless; the second piece from which the greasy matters had been removed then became quite hard and rotten, whilst the part from which both greasy matters and copper had been removed has remained in a perfectly elastic and good condition.

Professor Dewar observed accidentally that metallic

* Read before the British Association, Leeds Meeting, 1889, Section B.

copper when heated to the temperature of boiling water in contact with the rubber exerted a destructive effect upon it. With a view of finding whether this was due to the copper *per se* or to its power of conducting heat more rapidly to the rubber, I laid a sheet of rubber on a plate of glass and on it placed four clean discs, one of copper, one of platinum, one of zinc, and one of silver; after a few days in an incubator at 150° F., the rubber under the copper had become quite hard, that under the platinum had become slightly affected and hardened at different parts, whilst the rubber under the silver and under the zinc remained quite sound and elastic. This would infer that the pure metallic copper had exerted a great oxidising effect on the rubber, the platinum had exerted a slight effect, whilst the zinc and silver respectively had had no injurious influence on it. A still more curious result was this, that the rubber thus hardened by the copper contained no appreciable trace of copper; the copper, therefore, presumably sets up the oxidising action in the rubber without itself permeating it.

I have pleasure in acknowledging the assistance rendered to me in this investigation by my assistant, Mr Frederick Lewis.

ON THE UNBURNED GASES CONTAINED IN THE FLUE GASES FROM GAS STOVES AND DIFFERENT BURNERS.*

By WILLIAM THOMSON, F.R.S.Ed., F.C.S.

I HAVE been working for some time with a view of determining whether the gases escaping as flue gases from gas stoves and different burners were really free from gas capable of combustion, such as carbon monoxide, or unburned hydrocarbons or hydrogen. I spent some time in trying to separate and determine the quantity of carbon monoxide present, if any; but this problem was beset with so many difficulties that for the moment I abandoned it, and contented myself for the present with determining the quantity of unburned carbon and hydrogen in whatever forms these might exist.

For this purpose I arranged an apparatus consisting of two carefully weighed U-tubes filled with strong sulphuric acid and two weighed U-tubes filled with soda-lime, through which the flue gases were first passed; these absorbed the water and carbon dioxide contained in the flue gases, leaving the hydrocarbons (not absorbed by vitriol), hydrogen, and carbon monoxide to pass through a red-hot glass tube filled closely to the extent of 15 inches with oxide of copper prepared *in situ* from copper wire gauze. The gases were then passed through strong sulphuric acid and soda-lime contained in previously weighed U-tubes, and the results were calculated on the gas, measured at 60° F. and 30 inches barometric pressure, from the measure of gas drawn into the aspirator (treated as water-saturated gas); the carbon dioxide and water vapour absorbed in the tubes being then added on, making up the measure of flue gas originally employed, and which was taken for the determination.

The coal-gas employed was previously passed through large cylinders filled with calcium chloride to dry it before combustion, and at the same time as the experiment was going on, and side by side with it, was estimated the carbon dioxide and water vapour present in the air itself by passing it by means of another aspirator through strong sulphuric acid and soda-lime in U-tubes previously weighed.

The carbon dioxide in the air itself ranged from 0.41 to 0.66 grain per cubic foot of air, and the water from 3.51 to 7.23 grains in the same volume.

The amounts of carbon dioxide and water collected from the flue gases, after deducting the quantities actually present in the air, were taken as those due to the combustion of the coal-gas.

The standard I employed was the one used by Professor Roberts-Austen in his analysis of the flue gases from the burning of coal, and the apparatus employed was generally similar to that also employed by him.

The carbon and hydrogen left unburned were measured in terms of 1000 parts of carbon actually derived from the combustion of the gas in the stove or burner.

The total quantities of carbon dioxide and of water in the flue gases amounted to from 6.6 to 10.8 grains per cubic foot for the former and from 5.6 to 10.5 grains of the latter in the same volume.

The amount of flue gas passed in each experiment was about one cubic foot, and although the variations were considerable, the general results were conclusive in showing that the combustion of gas when burned in gas stoves for heating purposes is much more incomplete than one might be led to suppose.

The only burner in which the weight of the tubes remained constant after passing the burned gas, and in which the combustion was presumably complete, was in a paraffin-oil lamp in which the flame was not turned to its highest point. In another experiment with the flame turned full on, 12.04 and 3.09 respectively of carbon and hydrogen escaped combustion per 1000 of carbon completely burned.

The next nearest approach to complete combustion was in an Argand burner, in which all the carbon was completely burned; but an amount representing 0.2575 part of hydrogen escaped combustion per 1000 parts of carbon completely burned, whilst in a second experiment 0.113 of carbon and 2.5414 of hydrogen escaping combustion were registered per 1000 parts of carbon completely burned.

Then came one of Bray's ordinary flat flame burners, burning 4 cubic feet per hour, which gave 11.12 of carbon and 0.95 hydrogen unburned per 1000 of carbon completely burned.

Following in order these results, came the Welsbach light, in which the gas heats to whiteness a tube or mantle composed of a filmy thickness of the oxides of zirconium and titanium, the mantle being surrounded by a glass tube similar to that used in some paraffin-oil lamps. In this case the unburned carbon exceeded in amount the unburned hydrogen, there being 15.486 of the former and 3.794 of the latter per 1000 of completely burned carbon.

Three experiments were made with a Marsh-Greenall's heating stove, in which three Bray's luminous burners were employed. The first was made with a consumption of 5.62 cubic feet of gas per hour, when 12.6 and 3.0 parts of carbon and hydrogen respectively were registered per 1000 parts of carbon completely burned. The second experiment, with a consumption of 5.74 cubic feet per hour, gave 37.6 and 11.8 respectively of carbon and hydrogen unburned. The third experiment, with an increased consumption of gas (7.1 cubic feet per hour), gave 97.4 and 12.1 of carbon and hydrogen respectively unburned.

Two experiments were made with one of T. Fletcher's heating stoves, in which eight Bunsen burners play upon some fancy metal work (iron coated with magnetic oxide). The one experiment, in which the amount of gas passing was not measured, gave 43.3 of carbon and 24.6 of hydrogen unburned per 1000 of carbon completely burned. In the second experiment, where 6.81 cubic feet of gas were burned per hour, 66.3 and 20.0 respectively of carbon and hydrogen unburned were registered.

One experiment was made with one of T. Fletcher's stoves, in which twenty Bunsen burners play on asbestos projecting from a fireclay back, with a consumption of 8.14 cubic feet of gas, 138.9 and 11.7 parts respectively of carbon and hydrogen per 1000 parts of completely burned carbon were found.

In a stove in which the hot gases rise to the top of a cylinder filled with pipes (through which cold air passes

* Read before the British Association Leeds Meeting, 1890, Section B.

to be heated), and from the bottom of which the burned gases escape, after having cooled to a considerable extent, upwards of 200 parts of carbon escaped combustion per 1000 parts of carbon completely burned.

I have to thank my assistant, Mr. Harry Bowes, for the careful manner in which he performed the delicate and difficult experiments from which the above results were obtained.

THE PRESENT POSITION OF THE HYDRATE THEORY OF SOLUTION.*

By SPENCER UMFREVILLE PICKERING, M.A., F.R.S.

(Concluded from p. 188).

If Raoult's views as to the constancy of the molecular depression can be maintained, the data themselves are conclusive against making this exception in the case of water; for, since the substances which give the lower values are supposed to act normally, it is evident that, if the values given are in any way abnormal, this abnormality must be due to the solvent. Now the values certainly are abnormal; they are about 1.03° , whereas the normal value for one molecule dissolved in 100 molecules of other solvents is 0.63° , and the excess can, therefore, only be explained by assuming that the molecules of water are more complex than those of other solvents in the proportion of 1.03 to 0.63 , or $1\frac{1}{4}$ to 1 ; in other words, the water molecules must be $1\frac{1}{4}\text{H}_2\text{O}$. This view cannot be reconciled with the atomic theory.

Indeed the theory of dissociation into ions is altogether unintelligible to the majority of chemists. It seems to be quite irreconcilable with our ideas of the relative stability of various bodies, and with the principle of the conservation of energy. Of course we know that each ion when dissociated is not supposed to be permanently dissociated, but to be continually combining with its neighbours and separating again from them as in every other case of dissociation; but at any particular moment a very large proportion of them is supposed to be free; a proportion which, according to the very results under discussion, must be very nearly, if not quite, 100 per cent of the whole; and we have to settle whether it is probable or possible that a decomposition such as this could have been effected by introducing the compound into water. And how can we regard it probable that compounds of such stability and compounds formed with such a development of heat as sulphuric or hydrochloric acid should be thus entirely dissociated by water; still less that these, and all the most stable compounds which we know, should be thus demolished, while all the less stable ones—such as hydrocyanic, sulphurous, boric acids, &c.,—remain intact? How can we admit that the more stable a body is, the more prone it is to be dissociated?

And if such a dissociation has occurred it must have been without any absorption of heat, and, consequently, energy must actually have been created. Take one of the simplest instances, that of hydrochloric acid. If anything at all is certain about atoms, it is that the atoms in an elementary molecule are united very firmly together, and that therefore in separating them a very large absorption of heat would occur. To separate 2HCl into 2H and 2Cl would absorb far more than the 44,000 cal. which we know are absorbed in separating 2HCl into H_2 and Cl_2 . Yet the supporters of the dissociation theory would have us believe that this separation has actually taken place, not only without any absorption of heat, but actually with a development of 34,630 cal.; that is, that—

$$44000 + 34630 + x \text{ cal.}$$

have been created, and that, too, through the intervention of the water, which has *ex hypothesi* no action whatever.

* Read before the British Association for the Advancement of Science, Leeds Meeting, 1890, Section B.

This difficulty is realised by the supporters of the physical theory, but the way in which they meet it does not appear to me in any way to overcome it. To explain the non-absorption of heat in the dissociation of the salt, they suppose that a charge of electricity combines with the liberated atoms, and, in doing so, evolves an amount of heat exactly equivalent to that absorbed in the separation of the atoms from each other. And a later development of the theory is, I believe, that the atoms, though separated, are still held together by means of these charges, so that the net result is the supplanting of the chemical bond by an electrical bond of a precisely similar value. It appears to me that nothing substantial is gained by such a substitution, and that its occurrence is not merely hypothetical, but impossible. Whence come these electric charges, and by what agency are they brought into play? On what grounds can it be maintained that a charge can combine with matter so as to evolve heat, and that the heat so liberated is always exactly equal to that absorbed in the decomposition of the compound? If this quality exists, how can we account for the force which develops one overcoming the equal force which develops the other? And how, again, can we account for the heat developed in the act of dissolving? If, on the other hand, the heat of the combination of these charges is supposed to be equivalent to the heat of combination of the atoms, plus that of the heat of dissolution, we are met by the objection that the latter is often negative, and that, therefore, the heat of the combination of the charges must often be less than that of the combination of the atoms, so that the lesser force must be regarded as overcoming the greater.*

That free ions exist in solution is supposed to have been proved by a recent observation of Ostwald's to the effect that these ions may be separated and brought into different parts of the liquid by the proximity of a charged body. The separation of the ions is, of course, recognised by the subsequent liberation of hydrogen, oxygen, acid, alkali, &c., and it is certain that on allowing these to mix and combine heat will be developed and the salt solution re-formed; and thus, by replacing and removing the charged body, it would evidently be possible to produce an unlimited amount of heat. Now, if the charged body has lost none of its charge, and if mechanical energy has not been expended, this heat must have been created, and the whole groundwork of physical science must be false; whereas, if energy in any form has been expended on the solution, the experiment proves nothing, for there is nothing to show that this energy has not been utilised in bringing about the very dissociation the previous existence of which was in question.

I have already shown that the experimental data prove the absence of that constancy and regularity which ought to exist according to the physical theory, and to place the hydrate theory on unassailable grounds it is only necessary to show that the deviations from constancy and regularity are of a magnitude such as might reasonably be assigned to deviations due to the presence of hydrates. That variations of 260 and 36,000 per cent in the value of the depression—such as are observed by altering the dissolved substance or the solvent respectively—are amply sufficient to satisfy the most exalted views of the influence of chemical attraction, requires, I think, no demonstration, and we may therefore content ourselves with examining the deviations observed when the proportions of the solvent are altered—such deviations as are illustrated in Fig. 1.

It cannot be maintained that the energy of the chemical combination of, say, water with sulphuric acid, is the only reason why the temperature of the mixture of these two must be cooled below 0° before any of the latter will crystallise out; some lowering of the freezing-point will be

* On the view that hydrates exist in solution, there is no difficulty, as I have shown elsewhere, in explaining the absorption of heat during dissolution without violating the principle of the conservation of energy.

* The actual total has been increased by 10.4 per cent of its value to give the figures quoted in these five cases, for reasons which will be given elsewhere. Some of the numbers in this table may be subject to slight corrections, as they have been quoted in the absence of the original calculations.

caused by the mere interposition of the foreign molecules of sulphuric acid between those of the water, and on certain grounds, which I have explained elsewhere,* I estimate the mechanical lowering, as I term it, at 0.56° for each dissolved molecule to 100 of the solvent (a molecule of solvent water being $3H_2O$), a value which, it may be noted, is not far removed from Raoult's experimental value of 0.63°. There is also another source of lowering depending mainly on the heat capacities of the substances concerned, which I term, for convenience, the physical lowering; but its value, in the case of weak solutions, is very small, and I need, therefore, say no more about it here. Both these lowering causes would exist whether there were hydrates present or not; but if these were present we should get a further depression due to their existence. Any given hydrate would have to be decomposed into the next lower one before it could give up any water for crystallisation, and a certain amount of resistance would thus be offered to this crystallisation, to overcome which the solution would have to be further cooled. The necessary cooling may be estimated in the following way:—Supposing the solution to be a mixture and to be cooled below its normal freezing-point; then, on solidification, the temperature would rise to this point; but if this solidification involved a chemical decomposition which absorbed x cal. the rise of temperature would be thereby reduced, the reduction thus caused amounting to $x \div$ the heat capacity of the solution. As the heat absorbed in the decomposition of the various hydrates of sulphuric acid is known, we can calculate the lowering produced by their presence.

In Cols. II., III., and IV., Table II., I have given the depression due to the three above-mentioned causes in the case of certain solutions, Col. V. containing their sum; and it will be seen what a small proportion of this total lowering can be attributed to purely chemical causes. With most solutions it does not exceed 10 per cent of the total, and with weak solutions, such as are generally used in freezing-point determinations—say 5 per cent—it amounts to considerably less than 0.1°; this, too, in the case of sulphuric acid, where the heat of formation of the higher hydrates is greater than with any other known substance.

The reason, therefore, why the deviations from constancy are so small as to have escaped detection hitherto, and the reason why solutions behave almost as if their chemical nature was non-existent, becomes apparent; but this near approach to constancy and regularity, instead of proving the correctness of the physical theory, and giving a death-blow to the chemical theory, is really one of the strongest arguments which can be adduced in favour of the latter. If the hydrate theory is right, the influence of hydrates must often be nearly inappreciable.

But it is not only a general concordance between the found and calculated magnitude of their regularities which the hydrate theory is capable of affording, but a concordance so exact that the precise value of the deviation at

any point may be calculated. In Col. VI. of Table II. are given the observed freezing-points of the solutions, and these show an average difference of but 0.004° for the three weaker solutions, and 0.06° for the four stronger solutions, from those calculated (Col. V.). The last two columns exhibit this concordance in a different manner; from the observed freezing-point we can calculate the composition of the hydrates which must exist in the solution (Col. VII.), and these are found to agree so fully with those indicated by the examination of the curved figures representing various properties of the solution (Col. VIII.) that the maximum difference between the two is only 0.48 in the percentage of acid present.

When we can by simple calculations, based on one series of determinations, prove that the hydrates in solution must be the same as those which totally independent experiments have led us to suppose, we have, I think, arrived at a proof as nearly absolute as it is possible to conceive; and, if I have succeeded in showing that this proof may be accepted without in any way rejecting the facts on which the advocates of the osmotic pressure theory rely—approximate constancy, approximate regularity, and approximate similarity between dissolved and gaseous matter—I shall feel that I have done far better work than the mere establishment of the hydrate theory, by pointing out a possible *modus vivendi* for both theories almost in their entirety, and by helping to break down that wall of separation between physicists and chemists which is fast crumbling into dust.

THE MANUFACTURE OF COLOURLESS TANNINS.

By A. VILLON.

THE author employs the following method for obtaining colourless tannins from tanning drugs, such as chestnut wood, quebracho, sumac, valonia, dividivi, oak-wood, &c.

It comprises three chief operations: lixiviation of the tanning matters, precipitation of the tannin in the state of an insoluble tannate, and the separation of the tannin.

The lixiviation of the tannin wares presents nothing particular; it is the methodic system with six becks acting in a current of carbonic acid at the temperature of 80°–90°. In this manner liquids are obtained at from 5½ to 11° Tw., according to the nature of the ware employed. The liquor is passed on into settling vats, where it is allowed to cool. When it has arrived at the temperature of the atmosphere it is allowed to flow into a refrigerating apparatus, similar to those employed in breweries, i.e., a vat fitted with a worm in which there circulates the uncongealable liquid of a freezing-machine.

The temperature is thus lowered to + 2°, at which point it is kept for half an hour. The extractive matter and the tannin which are insoluble in the cold are precipitated, and are separated by passing the liquors through a filter-press. To render this clarification more complete there

is added 0.5 per cent. zinc sulphate. The tannin contained in the liquid is then titrated and its weight in the mass submitted to one operation is calculated.

Per kilo. of tannin thus found the author adds to the liquid 2½ kilos. pure crystalline zinc sulphate previously dissolved in five times its weight of hot water. The liquid is transferred into a vat fitted with an agitator, into which is then passed a current of gaseous ammonia, derived from the decomposition of 2½ kilos. ammonium sulphate (by means of lime) to each kilo. of tannin existing in the liquid. The vat is entirely closed and the excess of ammoniacal gas passes into another vat.

The ammonia displaces the zinc oxide which combines with the tannin to form a zinc tannate insoluble in a neutral or an ammoniacal solution. During the passage of the ammoniacal gas the liquid is raised to ebullition by means of a steam worm. Hence, merely zinc tannate is precipitated. The liquid is passed into a filter-press and washed first with hot ammonia water, then with cold, and lastly with cold water. On leaving the filter-press the clear liquid is passed into cast-iron pans, where it is saturated with milk of lime so as to give off ammonia, which serves in a following operation.

The zinc tannate is stirred up in five times its volume of water and decomposed with dilute sulphuric acid, when zinc sulphate is formed and tannin is set free. Then separate the zinc sulphate from the liquid, a solution of barium sulphide is gradually added until no further precipitation takes place. A double decomposition takes place between the two salts, with the formation of insoluble zinc sulphide and barium sulphate. The precipitate is filtered off and the tanning liquid is ready for use.

The precipitate is treated with dilute sulphuric acid when the zinc sulphide is dissolved, yielding zinc sulphate which serves for succeeding operations, and sulphuretted hydrogen which is given off and which is utilised. There remains barium sulphate, which is separated from the zinc sulphate by filtration. The barium sulphate may be reconverted into barium sulphide by ignition with carbon. Calcium sulphide may be used in place of barium sulphide. Copper sulphate may be substituted for the zinc salt, but the process is more costly if any loss occurs in the treatment. In this manner we may obtain directly extracts of tannin at 14°–22° Tw., containing 20 to 30 per cent of tannin free from extractive matter and almost colourless. —*Bulletin de la Société Chimique de Paris.*

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING SEPTEMBER 30TH, 1890.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;

and C. MEYMOTT TIDY, M.B., F.C.S., Barrister-at-Law,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, Metropolis Water Act, 1871.

London, October 6th, 1890.

SIR,—We submit herewith the results of our analyses of the 182 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from September 1st to September 30th inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 182 samples examined, the whole were found to be clear, bright, and well filtered.

The improvement manifest in London water supply on or about the middle of August, and to which we have already directed attention, has been more than fully maintained during September. The colour-tint of the Thames-derived water during the first half of August was as brown to blue 20:20; during the latter half of August as 14:1:20; whilst during September the average colour-tint was 11.5:20. The same fact is clearly indicated by a comparison of the results furnished by the oxygen test. Thus, whilst during the month of August an average of 0.065 grain of oxygen was required per gallon, during September only 0.044 grain of oxygen was needed. These results show an unbroken purity of supply, even under the severe conditions consequent on flood, and an almost unprecedented rainfall.

The marked uniformity in the composition of the various waters during the past month is specially noteworthy. Further, the complete freedom of the numerous samples examined from any trace of suspended matter is to be remarked.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES.

WILLIAM ODLING.

C. MEYMOTT TIDY.

ON AN APPARATUS APPLICABLE FOR GAS ANALYSIS AND OTHER PURPOSES.*

By W. E. ADENEY, F.I.C., Assoc.R.C.Sc.I.,

Curator and Examiner in Chemistry in the Royal University, Dublin.

THE apparatus which forms the subject of this paper was originally designed to serve the double purpose of collecting and determining the gases incident to water analysis. In practice, however, it has been found applicable for a number of other purposes, including gas analysis by absorption and combustion, the analysis of carbonates, of nitrates, and of organic matter by the permanganate method; it may also be employed as an air-pump, and for distillation *in vacuo* or under reduced pressure.

The form of the apparatus is shown in the figure. It consists of a gas burette, A, enclosed in a glass cylinder, B, 75 m.m. in diameter, a barometer tube, C, which may also be employed as an open pressure tube, and a laboratory vessel, D. The whole apparatus is supported on a wooden stand.

The lower portion of the burette is contracted and passed through a hole cut in the centre of the india-rubber bung, E, which closes the lower end of the glass cylinder. It is then bent at right angles and joined to the pressure tube at A by a piece of india-rubber tubing, lined with canvas, and firmly wired to the tubes; and the joint is protected from the air in the ordinary way by fitting round it a piece of wide glass tubing, and filling the annular space formed with glycerin.

The way in which the glass cylinder, burette, and pressure tube are supported and held in upright positions will be understood from the drawing; it need only be mentioned that the wooden block which carries the cylinder, or rather on which the bung E rests, is cut away at the centre and side to allow the cylinder and burette to be placed in position, and that the upper portion of the

* Read before the Royal Dublin Society, June 18, 1890.

burette is held in its place by the brass plate *b*, one end of which is bent at right angles and screwed to the stand, and the other end is bent and cut to fit and clamp the upper part of the stop-cock as indicated in the drawing. By this means the burette is clamped firmly, but sufficient play is afforded for contraction or expansion of the glass by alteration of temperature.

The supply of mercury to the burette and pressure tube is regulated by means of a reservoir which can be raised or lowered by a pulley and small windlass, *c*, fixed to the back of the stand. The flexible tube from the reservoir passes through a hole in the back of the stand at *d*, and is attached to the pressure tube by means of the small side tube *e*. The necessity of attaching the connecting tube from the reservoir to the pressure tube, and not directly to the burette, will be explained later on.

The height of mercury in the pressure tube is read off by means of a millimetre scale etched on the unsilvered surface of the narrow slip of looking-glass, *f*, which is fixed close to the back of the pressure tube and inclined to the vertical plane, as shown in the drawing, so as to reflect the image of the tube from the portion of the glass bearing the scale. To read the height of the mercury in the tube the eye is held a little to the right of the scale, and moved about a little until the scale lines in the immediate vicinity of the reflected image of the mercury meniscus coincide with their images reflected from the silvered surface of the glass. When the eye is in this position the height of the mercury can be accurately read to 0.5 m.m., and with aid of a lens to about 0.25 m.m.

The burette and pressure tube are each provided with a Friedrich's patent glass stop-cock of the pattern shown in the drawing. Two branch tubes, *g*, *h*, spring from the stop-cock of the burette; the former is a capillary tube, and serves to connect the burette with the laboratory vessel and other purposes, while the latter is of wider bore (2 to 3 m.m.) and is intended to connect the vessel containing the substance to be examined with the burette. The two tubes are firmly held against the wooden block *k*, which is grooved to receive them, by a brass plate lined with cork and screwed to the said block. It is necessary to support the two tubes thus to obviate the danger of their being broken off from their junction with the stop-cock by a sudden blow or undue pressure. When firmly held in the manner described, the tubes will bear even considerable pressure without any danger of being broken, and, as will be explained afterwards, when the laboratory vessel is fixed in position for working, a decided pressure is exerted against the tube *g*.

The contracted portion of the burette immediately below the stop-cock is about 225 m.m. long, and has a capacity of 15 c.c.; the wider portion is about 410 m.m. long, with a capacity of about 250 c.c. Both portions are graduated, the former at intervals c.c., of 1 and the latter at intervals of 25 c.c.

The pressure tube is 1000 m.m. long; and since it can be employed both as an open and closed tube, a volume of a gas may be measured under a pressure equal to 1500 m.m. of mercury, or, on the other hand, under as low a pressure as 1 m.m. Thus the apparatus is more sensitive than Thomas's (*Chem. Soc. Journ.*, xxxv., 217).

The laboratory vessel differs in principle and shape from the one employed in Frankland's or Macleod's apparatus. The cylindrical portion, *n*, is 25 m.m. internal diameter and 55 m.m. long, and is furnished with the side tube, *o*, for connecting the vessel with an independent mercury reservoir; the portion *p* is 45 m.m. in diameter and 100 or 190 m.m. long, according to the character of the analysis to be made; this portion of the vessel, which is shown in the drawing, has a length of 100 m.m., the most useful size for water analysis. The upper part, *q*, which has an inverted conical shape, is 55 m.m. long, the diameter decreasing from 20 m.m. at the mouth to 4 m.m. at its narrowest part. Two platinum wires are sealed into the vessel in the positions shown in the drawing.

The particular shape given to the portion *q* allows the laboratory vessel to be easily connected or disconnected with the tube *g*. When the laboratory vessel is placed in position, as represented in the drawing, the tube *g*, the end of which is fitted in an india-rubber collar, tightly closes the narrow part of *q*, while the lower shoulder of the vessel rests upon the shelf *r*, which, in plan, has somewhat the shape of an inverted U. If the space above the collar be filled with water of mercury, a perfectly air-tight joint is obtained. The joint, in fact, may be made so staunch that, when the vessel is arranged in the manner described below, a torricellian vacuum may be maintained in it. When it is desired to disconnect the laboratory vessel, its lower portion is drawn forward sufficiently to clear the shelf, and is then lowered to detach it from the tube *g*. By reversing these movements the laboratory vessel may be again attached to the apparatus. The shape of the india-rubber collar is of importance; its lower end must be rounded off. It may be conveniently made in the laboratory from the core obtained by cutting a hole in an ordinary cork, by means of a cork-borer of suitable diameter; one end of the core will generally be found sufficiently rounded to suit the required purpose.

For some problems in gas analysis the laboratory vessel may be employed in the ordinary way. The lower and open end is immersed in a mercury trough, and may be filled from the trough in the following manner. The stop-cock is opened to the tube *h*, and the reservoir raised until the burette is full of mercury; the stop-cock is then turned to open to the tube *g*, and consequently to the laboratory vessel. The reservoir is now lowered slowly, and as the level of the mercury in the burette sinks, it rises in the laboratory vessel. The reservoir is lowered until the laboratory vessel is full. The air that is drawn into the burette during the operation is driven out into the atmosphere by opening the cock to the tube *h*, and again raising the reservoir. When the burette is full of mercury, the glass cylinder filled with water, and the pressure tube in proper order, the apparatus may be used in a similar manner to that of Frankland or Macleod.

Since the apparatus, however, can be employed as an air-pump similar in principle to Friedrich's new pump, as well as for measuring and analysing gases, its applicability to a great variety of purposes becomes possible, if the laboratory vessel be furnished with the means of filling it with mercury, as well as of adjusting the level of mercury in it, independently of the burette. This may easily be effected by closing the lower end of the vessel with an india-rubber cork, and connecting it by means of the side tube *o* to an independent adjustable reservoir which is raised and lowered by means of a pulley and windlass, *m*, fixed to the back of the stand, just as in the case of the reservoir furnished for the burette and pressure tube.

To provide the means for introducing reagents into the laboratory vessel, when it is modified as here described, the cork which closes the lower end of the vessel is fitted with a glass tube (which for the purpose of reference may be called the reagent) about 10 c.m. long, and 2 m.m. bore, one end of which is drawn out to a fine point, and the other end is bent at right angles, and has attached to it a piece of stout india-rubber tube about 15 c.m. long, and 1 m.m. bore. When the cork is fixed in its place, the fine point of the reagent tube projects into the interior of the vessel for about 2 c.m. A small Bunsen screw clamp is also provided with which to close the india-rubber tube when necessary.

The apparatus and stand should be permanently set on a small table of such a height that the mercury reservoirs may be lowered some 36 inches below the level of the lowest scale mark on the burette.

The heights of the mercurial columns corresponding to the different divisions of the burette are determined in the ordinary way with the aid of a kathetometer.

To calibrate the burette, it is filled with water in the following way:—The burette and glass tube *g* are first filled with mercury by raising the reservoir; a beaker con-

taining water is then held under the open end of *g*, and the reservoir lowered until the burette is filled with water down to the lowest division line. The beaker is now replaced by a small tared flask, and the reservoir slowly raised until the next division on the burette is reached by the mercury; the water displaced is received into the tared flask, and weighed; a similar operation is repeated for each division on the scale of the burette. Finally, the

capacity of the tube *g* is measured. During the process of calibration the wide glass cylinder which surrounds the burette is filled with water in order to maintain the water in the burette at a constant and known temperature.

During the analysis of a mixture of gases, all measurements are carried on with the level of the mercury in the burette adjusted to the same division line. The selection

of the division line must naturally depend on the volume of the gas to be analysed, and the object of the analysis.

An arrangement for accurately adjusting the level of the mercury in the burette at the division line selected for making measurements may be made thus:—A piece of white paper having a horizontal black line drawn upon it, is gummed to the stand behind the glass cylinder, and at the same level as the division line, an exact adjustment being made with the aid of a kathetometer. A similar arrangement may be made for each division line on the burette, but, generally speaking, it will only be found necessary for the 10, 15, 50, and 100 c.c. lines. With this arrangement the mercury may be adjusted to the level of a division line by the operator, with the naked eye, even more accurately than with the kathetometer, the operator being very much aided by the magnifying effect that the water in the cylinder has upon the burette, and upon the line gummed to the back of the stand.

The method of working the apparatus will be understood from the following description of the analysis of a water residue:—The residue is mixed with copper oxide, and packed in a combustion tube with oxide of copper and metallic copper; and the open end of the combustion tube is drawn out and shaped according to the directions given by Frankland and Armstrong in their method for the determination of the organic carbon and nitrogen in waters. The combustion tube may be directly attached to the tube *h* of the apparatus, but it is more convenient to interpose between them a U-shaped connecting tube, in the bend of which a bulb is blown for collecting the water formed during the combustion of a residue. The connections are made with pieces of india-rubber tubing protected with water jackets in the ordinary way, to prevent diffusion of air through them.

The burette and pressure tube, let it be supposed, are full of mercury, the stop-cock of the latter closed, and the laboratory vessel detached from the apparatus. If now the cock of the burette is opened to the combustion tube, and the reservoir lowered, air will pass from the combustion tube into the burette as the mercury flows out of the latter; when the mercury has reached the lowest level practicable in the burette, the stop-cock is turned to close connection with the combustion tube, and to open to the tube *g*, and the reservoir is raised to re-fill the burette with mercury and expel the air that has been drawn into it into the atmosphere. If, when the burette is again full of mercury, connection with the combustion tube be for a second time opened, and the cycle of operations described be repeated, a further quantity of air will be drawn from the combustion tube, and will be expelled from the apparatus. After several such repetitions the quantity of air remaining in the combustion tube will be inappreciable.

The degree to which the exhaustion has been pushed may be accurately determined by first filling the burette with mercury, and then, the stop-cock being closed, lowering the reservoir sufficiently to sink the mercury in the burette to the level of the 100 c.c. division line; a torricellian vacuum will consequently be obtained in the burette. Connection with the combustion tube is now opened, and the tube is gently warmed. After a few minutes the stop-cock is again closed, and the reservoir raised; if any air has been drawn from the combustion tube, its presence will be indicated as the mercury rises to fill the burette, and its volume may be accurately determined. With a little care it is quite possible to exhaust so completely the combustion tube, that no residuum of air can be detected in it by the method here described. The time required to exhaust a combustion tube, with the apparatus of the size described in this paper, is about ten minutes. The time, however, will vary somewhat with the dimensions of the combustion tube.

The combustion tube, after being exhausted, is heated to ignite the water residue, the stop-cock being closed during the process of heating.

During the combustion the laboratory vessel should be

carefully and completely filled with mercury, and attached to the apparatus in the following manner:—The laboratory vessel is held in a slanting position, with its lower shoulder just resting on the front edge of the shelf, *r*, and its upper part, *q*, loosely fitting round the collar at the end of the tube, *g*. The reservoir is then adjusted so that the mercury in it, when the laboratory vessel is full, shall be just above the level of the collar. The mercury slowly fills the laboratory vessel, and when it *has risen* a little above the collar, the lower shoulder of the vessel may be pushed into its place. After the laboratory vessel has been properly attached, the reagent tube must be freed from air. This may be done by unscrewing the Bunsen clamp, and allowing a little mercury to flow out of the tube. When the air has been completely driven out, the reagent tube is again closed by screwing up the clamp. If, after first attaching the laboratory vessel, any traces of air are detected in it (and small bubbles are especially liable to collect under the india-rubber collar attached to the tube *g*), the operator will be able to expel them by drawing the lower part of the vessel forward, and then lowering the vessel slightly to loosen its connection with the tube *g*. If the reservoir has been previously adjusted to the level of the end of the tube *g*, immediately on loosening its connection with the vessel in the manner described, the bubbles of air will escape into the atmosphere. After the laboratory vessel has been finally placed in position, a mercury trough filled with water, and supported on an ordinary table support, is placed under the vessel, and fixed at such a height that the lower end of the vessel is immersed in the water. This arrangement prevents leakage or diffusion of air through the india-rubber cork which closes the end of the vessel.

When the combustion of the water residue has been completed, the combustion tube is again exhausted, and gases resulting from the combustion are transferred to the laboratory vessel; this operation being completed, the gases are next passed into the burette to be measured.

The method of adjusting the level of the mercury in the burette, after the gases have been passed into it, will require some explanation. The simple plan of closing the stop-cock, and then raising and lowering the reservoir, in order to bring the mercury to the level of the division line selected for measurement, cannot be followed, since after transferring the gas, a small bubble of it remains in the laboratory vessel under the india-rubber collar attached to the tube *g*, and cannot be expelled. When, therefore, the level of the mercury in the burette is being adjusted, the connection between the burette and laboratory vessel must be left open, and the adjustment be made by working the two reservoirs conjointly. To transfer in the first instance the gases into the burette from the laboratory vessel, the reservoir of the former is lowered, and that of the latter raised, until nearly all the gas has passed over, a little, however, still remaining in the laboratory vessel. The operator at this point must observe whether the gases will require to be compressed or expanded, in order that the mercury in the burette shall stand after final adjustment, at the level of the division line selected for measurement, and in order that, at the same time, the laboratory vessel shall be completely filled with mercury, with the exception, of course, of the space occupied by the small bubble above referred to. With a little practice, the final adjustment may be effected in a few seconds. An indication that the laboratory vessel has been completely filled may always be obtained by causing the mercury or water, if the vessel be moist, to rise to a definite height in the capillary tube *g*.

When the necessary adjustments have been made, the height of the mercury in the pressure tube is read off; the difference between the reading and the number corresponding to the height of the division at which the measurement is made, gives the pressure exerted on the gas in millimetres. The temperature of the water in the cylinder, *c*, is at the same time observed.

The analysis of the gases is conducted in a manner that

is now commonly adopted with this class of apparatus. To absorb the carbon dioxide, a few drops of a strong solution of potash are introduced into the laboratory vessel thus:—The stop-cock of the burette is closed, the reservoir of the laboratory vessel is fixed above the level of the reagent tube, and a small pipette containing the solution of potash is connected with the india-rubber tube attached to the reagent tube. As the reservoir is above the level of the reagent tube, on unscrewing the Bunsen clamp, there will be a tendency for the mercury to flow into the small pipette; and this may be taken advantage of in order to expel the air that collects in the open end of the india-rubber tube to which the pipette is attached. The air having been completely expelled, the reservoir is dropped to a level slightly below that of the reagent tube, and after a few drops of potash solution have been drawn into the laboratory vessel, the Bunsen clamp is screwed up again. The stop-cock may now be opened, and the gas passed from the burette into the vessel. After about ten minutes the carbon dioxide may be considered to have been completely absorbed, and the remaining gases may be transferred to the burette, and again measured, after the mercury has been again adjusted to the levels as before. The remainder of the analysis needs no further description.

When commencing to experiment with the apparatus, it was anticipated that a correction for the error introduced by the bubble of gas being retained in the laboratory vessel, as above described, would be necessary when calculating the volume of the gas. In order to determine the amount of this error, my friend Mr. James Carson very kindly made a number of experiments with the apparatus for me. About 175 c.c. of air were drawn into the burette through the tube *h*, the stop-cock was closed, and the air was compressed until the level of the mercury in the burette reached the 100 c.c. division. The pressure exerted by the air was then found to be equal to 410 m.m. of mercury plus that of the atmosphere, viz., 759.51, that is a total pressure of 1169.51 m.m. of mercury. The air was then passed into the laboratory vessel and back again, the mercury being returned to the same level in the burette; the pressure was read, and found to be exactly the same as before, viz., 1169.51 m.m. The experiment was repeated, and a like result obtained. It was then decided to try a similar experiment with a small volume of air under reduced pressure. About 3 c.c. of air was drawn into the burette, as before, the stop-cock closed, and the volume expanded until the mercury reached the level of the 14 c.c. division line. The pressure of mercury then indicated by the pressure tube was equal to 161 m.m. of mercury; on passing the air into the laboratory vessel, and back again, and adjusting the mercury to the same level as before, the difference of pressure indicated by the pressure tube was found to be less than 0.1 m.m. It is hence evident that the bubble of gas retained in the laboratory vessel is too small to introduce any appreciable error when the adjustments of the levels of the mercury in the burette and laboratory vessel are made, before making measurements, in the manner above described.

(To be continued).

NOTICES OF BOOKS.

Air Analysis: A Practical Treatise on the Examination of Air. With an Appendix on Illuminating Gas. By J. ALFRED WANKLYN and W. J. COOPER. London: Kegan Paul, Trench, Trübner, and Co., Limited.

The manual before us is not, as it will at once appear, a treatise on gas analysis from a technical point of view, but a guide to the sanitary examination of atmospheric air. Of course the processes here taught have their due place in technical gas analysis. The apparatus recommended by Mr. Wanklyn is that of Hempel, which is shown in use

in nine plates. For the determination of oxygen in gaseous mixtures nitric oxide, as used by Priestley and Cavendish, is recommended in preference to the pyrogallic acid process and to combustion with an excess of hydrogen. A reason given is that the two latter methods are inapplicable in presence of carbonic acid. The author distinguishes two methods for the investigation of gases. In the former, to which the name eudiometry is here restricted, a change in the volume of the gas is directly observed. In the second method, which is here named "complementary eudiometry," the analyst notes the action of the gas in question on substances with which it is brought in contact.

This work is calculated to render more general the understanding and the practice of gas analysis, a department which, until lately, has been much neglected.

Electro-Chemical Analysis. By EDGAR F. SMITH, Professor of Analytical Chemistry, University of Pennsylvania. Philadelphia: Blakiston, Son, and Co.

A MANUAL of electrolytic analysis is becoming more and more necessary, as most analytical manuals, from whatever reason, have ignored the subject. At the same time the great advantages of this method in inorganic determinations render a knowledge of its conditions and its resources of great importance to the student and to the practising analyst.

The author, in supplying the want of a systematic exposition of the electrolytic method of analysis is, therefore, conferring a decided benefit upon chemists. He does not exaggerate when he tells us that the electrolytic method of analysis is especially inviting, since it permits of clean, accurate, and rapid determinations where ordinary methods yield unsatisfactory results. He first considers the action of the electric current upon acids and salts. Next he proceeds to a definition of the terms ohm, volt, and ampère, followed by instructions on the sources of the electric current. Here he describes the bichromate cell, the Leclanché, the Daniell with its modifications, the Meidinger, and the "crowfoot," with the Bunsen and the Grove for cases where a current of greater electromotive force is required. Both these cells, he remarks, require constant attention. To thermopiles he objects on the score of their fragility and of the frequent insufficiency of their currents.

As the best source of electric energy for analytical purposes the author recommends secondary batteries of the Julien type. We find next an account of resistances for the reduction of the current down to any required strength, and of the voltmeters and ammeters for measuring currents.

In a survey of the history of the electric method of analysis we find it mentioned that Gaultier de Claubry (1850) was probably the first who applied the current to the detection of metals in solution.

The author then proceeds to the electrolytic determination of the different metals, copper, cadmium, mercury, bismuth, lead, silver, zinc, manganese, iron, uranium, thallium, platinum, palladium, molybdenum, gold, tin, and antimony. The processes for the electrolytic determination of vanadium, tungsten, and osmium are not inserted, as they require further elaboration. A successful method for the electro-deposition of arsenic is not known.

Next we come to the separation of the metals. As regards iron, manganese, zinc, nickel, cobalt, aluminium, chrome and phosphoric acid the methods to be adopted require further elaboration.

Finally come some instructions for oxidations by means of the electric current.

The greatest advantage of the electrolytic method of analysis is its simplicity. We do not require to introduce materials, the purity of which often leaves something to be desired, and which have to be again removed, frequently at the cost of much time and trouble. Hence, where avail-

able, the electrolytic methods of analysis possess an indisputable advantage. We hope that Prof. E. Smith's little work will call increased attention to this branch of mineral analysis.

Sap: Does it Rise from the Roots? Experiments and Observations on Trees and other Plants. By J. A. REEVES. London: G. Kenning.

THE author of this work propounds a novel theory in vegetable physiology. He holds that the sap of plants does not ascend from the roots, but "is obtained by the foliage from the moisture in the air, and from the rain, and more especially from the dews at night, the latter being more frequent and lasting than rain." He tells us that the gas evolved from stable yard manure is found to be superior to that from artificial manures, and is more lasting in its action. Now ammonia is, or may be, given off both from farm-yard manure and from some kinds of artificial manures. But from other very efficient artificial manures, e.g., phosphates and potassium salts, no gases are known to be given off. If Mr. Reeves can demonstrate the existence of a gas given off, e.g., by basic slag, or by "precipitated phosphate" capable of supplying growing crops with their necessary supply of phosphoric acid, he will have done chemists a service which they will appreciate. If, meantime, he wishes it to be understood that farm yard manure, or stable dung, is superior to artificial manures, he is running in the teeth of facts. We should advise him to study experimentally the work of M. Georges Ville.

Wattles and Wattle Barks: Being Hints on the Conservation and Cultivation of Wattles, together with Particulars of Their Value. By J. H. MAIDEN, F.L.S., F.C.S., &c., Curator of the Technological Museum, Sydney. Sydney: Potter.

"WATTLES" is the colonial name for certain species of *Acacia*, rich in tannin and becoming of increasing value in the tanning and, we presume, in the dyeing industries. Contrary to what is now very generally the case in commerce, the demand for these barks, as, indeed, for every drug containing available tannin, is gaining ground on the supply. These trees are able to grow in the poorest soils, and require but little rainfall. Hence they are capable of yielding good returns in districts which would otherwise be deserts. Their systematic cultivation has been already undertaken with success in the Colonies of Victoria and South Australia, and it is now recommended for New South Wales.

Of the 312 (*sic*!) Australian species of *Acacia* not all are equally valuable. One of the finest is the *Acacia mollissima*, called indiscriminately by the colonists "black wattle," "green wattle," and "silver wattle." The bark, according to Baron Mueller (*Extra-Tropical Plants*), yields in the dry state from 30 to 54 per cent of tannin. 1½ lbs. of black wattle bark give 1 lb. of leather, whereas 5 lbs. of English oak-bark are required for the same quantity. A quarter and even half a ton of bark is sometimes obtained from a single tree. The bark of *Acacia pycnantha*, the "broad-leaved wattle," yields up to 46.47 per cent of tannin in South Australia.

The preparation of extracts of these naturally arises, and it has, in fact, been successfully attempted at Echunga, in South Australia. It was, however, complained that the extracts were undesirably rich in gum, and that a part of the tannin was destroyed during the process of concentration. These difficulties, however, could doubtless be overcome.

Would it be possible to use these barks as a source of tannic acid?

Concerning the adaptability of the wattle barks for the purposes of the dyer and the tissue-printer we find no data.

CORRESPONDENCE.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—As you have opened your columns to correspondence on this subject, I should like to take this opportunity of observing that in the main I cordially agree with the views propounded in your last issue by Mr. Arnold Philip.

It appears to me that the Chemical Society is intended to be an association or club, as it were, formed by persons interested in the progress of chemical science, and that any one who is thus interested has a reasonable claim to membership, whether he be a professional consultant or analyst, a scientific investigator, a manufacturer, a teacher, or simply an educated individual with scientific proclivities. No qualification of any kind beyond the possession of such an interest appears to me to be indispensable for membership; and by insisting on qualifications based on having conducted researches, or holding teaching appointments, &c., &c., a grave injustice would be done to many who have sufficient knowledge of chemical science to wish to belong to an association formed to further the pursuit of that branch of knowledge, but have not pushed their studies sufficiently far to entitle them to put forward such qualifications.

Further, the notion of endeavouring to some extent to imitate the Royal Society by making critical selections of candidates would, I imagine, be in the long run extremely prejudicial to the interests of the Society. The number of persons annually admitted would materially diminish, and in consequence the maintenance of the excellent *Journal of the Society* would be jeopardised if not rendered impracticable, at least in its present form.

On the other hand, it is unfortunately the fact that certain persons have obtained admission to the Society who use the letters F.C.S. in an objectionable way for advertising purposes; also that the bulk of the general public are still so densely ignorant of almost everything pertaining to science, that the employment of these initials is often taken to be a sort of guarantee that the person using them is necessarily skilled in all sorts of professional matters.

The proper remedy for the first of these evils is, I conceive, that the Society should acquire powers to prevent anyone from using the letters F.C.S. unless he actually at the time belongs thereto, and to expel and deprive of membership anyone misusing his privileges as a Fellow. Probably this is impracticable under the present charter; if so, it is worth considering whether it would not be well to resign it and obtain another conferring the requisite powers.

As regards enlightening the general public in reference to the wide difference subsisting between societies instituted for the advancement of abstract science (such as the Chemical, Linnean, &c.), and qualifying bodies dealing with the professional applications of science (such as the Royal Colleges of Physicians and Surgeons, the Institute of Chemistry, &c.), it is to be hoped that in time the general progress of education will enable such distinctions to be more widely appreciated than is the case at present. It seems to me, however, that the qualifying bodies, rather than the purely scientific ones, are the proper agents to take active steps in the direction of instructing the public in such matters; and that as regards the particular points raised by Drs. Teed and Lloyd, what is chiefly wanted is that the Institute of Chemistry should

be roused up from the lethargy to which it has apparently fallen a prey of late years.—I am, &c.,

C. R. ALDER WRIGHT.

RAPID DETERMINATION OF TIN IN MINERALS.

To the Editor of the Chemical News.

SIR,—In the *CHEMICAL NEWS*, vol. lx., p. 271, there is an article entitled "A New, Easy, Rapid, and Correct Method of Detecting Tin in Minerals," by Alexander Johnstone, F.G.S. The method therein described for obtaining the beads of metallic tin is substantially that known as "Gahn's method." But to prove that the beads so obtained are tin, Mr. Johnstone recommends that "two or three drops of boiling concentrated hydrochloric acid be poured over them in the mortar; and then, by means of a glass tube, one drop of a fairly strong solution of gold chloride be mixed with the hydrochloric acid solution." "Then," he adds, "if the white metallic scales originally observed were composed wholly or partly of tin . . . the bottom of the mortar will receive a distinct purple stain by the formation of the well-known characteristic purple of cassius; also further confirm the presence of tin by allowing a current of SH_2 gas to impinge for a short time on the moist stained bottom of the mortar, &c."

Now, as several other metals besides tin may be obtained by "Gahn's method," and as some of these would give substantially the same reactions as tin, when treated as directed by Mr. Johnstone, it may be well to caution the unwary chemist or mineralogist not to place implicit confidence in what might seem a positive indication of the presence of tin from the use of the above tests.

As a matter of fact, the blowpipe tests for tin are very unsatisfactory, save in such minerals as contain a high percentage of the metal unmixed with other easily reducible metals. I was forcibly reminded recently of the danger of depending too much upon what seemed to be a positive indication of tin in a certain complex ore. I had followed the directions of Mr. Johnstone carefully in the above-referred to test, and obtained what seemed to be positive indications of the presence of tin, when, upon reflection, it occurred to me that some other metal or metals might be present instead, and upon further examination I found that tin was entirely absent, and that the only metal present, in appreciable quantity, were lead and copper. The action of HCl on Cu in the presence of air had produced cuprous chloride, and the following reaction took place on the addition of AuCl_3 :—

but in consequence of the resemblance between thin laminæ of iron and tin (this metal with spangles of lead mixed) would be more liable to mislead than Cu , by the formation of ferrous chloride, which would reduce the AuCl_3 , as follows :—

To adopt this otherwise convenient method for the detection of tin in minerals to such cases as it now evidently is unsuited, I would suggest the removal of the interfering metals (previous to fusion) by means of (NO_2HO) nitric acid.—I am, &c.,

THOMAS CHARLTON.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 12, September 22, 1890.

Account of a Scientific Ascent of Mont Blanc.—J. Janssen.—The author's object was to solve the controversial question of the presence of oxygen in the solar atmosphere. At the end of October, 1888, he had ascended Mont Blanc up to the hut of the Grand Mulets, situate at the altitude of 3000 metres, above the junction of two of the glaciers which descend from the north slope of the mountain into the valley of Chamounix, *i.e.*, those of Bossons and of Tacconoz. The observations then made showed, in the rays due to the action of the atmospheric oxygen, a decrease proportionate to the height of the station, and which indicated that at the limits of our atmosphere these groups would disappear entirely, and that, consequently, the solar atmosphere did not intervene in the production of the phenomena. The decrease of intensity of the group B between the Grand Mulets and the station of the Bosson, near the summit, was surprising, being greater than seemed to result from the height and the density of the atmospheric column between the two stations. The totality of the author's observations compel us to recognise the absence of oxygen in the gaseous solar coatings which surmount the photosphere; at least, oxygen with the constitution which enables it to exert upon light the phenomena of absorption which it produces in our atmosphere, and which are manifest in the solar spectrum by the system of rays and bands which we know. It is certain that if oxygen exists simultaneously with hydrogen in the exterior envelopes of the sun, and accompanies the latter element to the coronal atmosphere, the ultimate refrigeration at a period of time which we cannot yet fix would have the effect of provoking the combination of oxygen and hydrogen if jointly present. Watery vapour would then be formed in these gaseous envelopes, and the presence of such vapour, according to what we know of its properties, would oppose a considerable obstacle to the solar radiations, especially those which produce heat.

Bulletin de la Société Chimique de Paris.
Series 3, Vol. iii., No. 11.

Action of Oxygenated Water upon the Oxygen Compounds of Manganese.—A. Gorgeu.—In this second memoir the author examines, at considerable length, the action of oxygenated water upon permanganic acid and the permanganates.

Action of Oxygenated Water upon Hydrated Manganese Oxide.—A. Gorgeu.—The author, in opposition to M. Carnot, maintains that this reaction, in the varied conditions under which he operated, always obtained a compound bordering on the sesquioxide and containing 10·10 per cent of oxygen.

On the Selenium Chlorides.—W. Ramsay, F.R.S.—The author upholds the accuracy of his former communication as against M. Chabré. He submits that a body which, even in presence of an excess of selenium, distils with dissociation between 130° and 170° cannot boil about 300° without decomposition.

On the Dissociation of Selenium Chloride.—W. Ramsay, F.R.S.—A supplement to the last communication. The author considers that M. Chabré was in error in submitting the sub-chloride to distillation. The boiling-point does not exceed 190°, even when the temperature of

Manufacture of Colourless Tannins.—A. Villon.—See p. 195.

the oil-bath is 300°. The conditions are very different when its vapour is exposed to a temperature of 300°. He believes that it is then completely dissociated.

On the Oxidising and Decolourising Properties of Carbons.—P. Cazeneuve.—It results that if the decolourising properties of charcoal are due to a mechanical fixation of the colours upon the carbonised matter, we must not neglect the part played by the oxygen condensed in the pores in a state comparable to ozone, and exerting an evident destructive action upon certain colours, and, on the contrary, occasioning the production of certain other colours, which are oxidation products.

On the Conditions of Equilibrium of Saturated Carbon Compounds.—J. A. Le Bel.—This paper does not admit of useful abstraction.

A Characteristic Reaction of Hydrogen Peroxide.—G. Denigès.—If a solution of 10 per cent of ammonium molybdate in water is mixed with an equal volume of concentrated sulphuric acid (say 1 c.c. of each) it gives, with a few drops of oxygenated water, a decided yellow colour, equal in intensity to the solutions of the alkaline chromates and di-chromates.

On Paranitro-ortho-toluene sulphonic Acid.—J. Hauser.—The sulpho-conjugated acid of paranitro-toluene displaces sulphuric acid in soluble sulphates. Metasulphonated nitrotoluene seems to possess the same properties as its isomers.

Revue Générale des Sciences Pures et Appliquées.
Vol. i., No. 16, August 30, 1890.

The Chlorides of the Bibasic Acids.—Victor Anger.—The only acids which can form dyssymmetric chlorides are those in which the carboxyls are in the position 7, or, as it is otherwise called, in the position 1·4. Here there is a manifest approximation to the production of the lactones and the lactames.

Vol. i., No. 17.

Researches on the Absorption of the Ultra-violet Rays of Various Substances.—J. Soret and A. Rillet.—The authors commenced investigations on this subject about ten years ago, and have latterly been chiefly engaged with bodies of the fatty series. They have encountered considerable difficulty in obtaining these bodies in a state of purity, which interferes with the accuracy of the results. The alcohols present a high transparency. Rectification and especially complete desiccation occasion a decomposition or an oxidation of the alcohols, which often diminishes their transparency. It would be premature to affirm that there exists a determined difference of transparency among the various alcohols if perfectly pure. The authors cannot, therefore, confirm the conclusion of Hartley and Huntington, that the transparency of alcohols diminishes progressively as their chemical formula becomes more complicated. The measure of absorption of the ultra-violet rays constitutes a very delicate means for appreciating the purity of alcohols. Aldehyd, if undiluted, intercepts the ultra violet rays almost completely. The acetones are very absorbent. The energetic absorption of aldehyd and the acetones is probably due to the group carbonyl, CO, for if this group is replaced by O we obtain very transparent bodies. The authors have finally made summary researches on the absorption of the ultra-violet rays by the vapours of different organic substances, and have been able to demonstrate that very opaque liquids, if sufficiently volatile, give vapours which exert a sensible absorption.

FOR SALE.—THE CHEMICAL GAZETTE.
Complete Set (unbound and uncut), 17 volumes; from November, 1842, to December, 1859.—Address, "Publisher," Chemical News Office, Boy Court, Ludgate Hill, London, E.C.

THE CHEMICAL NEWS.

VOL. LXII. No. 1613.

ON THE INFLUENCE OF HEAT ON COPPER-POTASSIUM CHLORIDE AND ITS SATURATED SOLUTION.*

By Prof. VAN 'T HOFF.

THE blue crystals of copper-potassium chloride,—

when heated upwards to 100° change their colour, and more close investigation proves such is due to the formation of a new brown salt, $\text{CuCl}_2 \cdot \text{KCl}$, according to the equation $\text{CuCl}_2 \cdot 2\text{KCl} \cdot 2\text{H}_2\text{O} = \text{CuCl}_2 \cdot \text{KCl} + \text{KCl} + 2\text{H}_2\text{O}$.

This same new substance can be obtained at low temperatures, on heating the blue double salt in presence of copper chloride; it then results from a reaction, given by the following symbols:—

Both these transformations are reversible, *i.e.*, the primitive substances are obtained anew on cooling, and both take place at definite temperatures, 93° and 56° respectively, which temperatures can be accurately determined in studying the abrupt change of volume which accompanies that of chemical composition.

The temperatures of 56° and 93° are, moreover, characterised by an interaction of three curves of solubility, in each case, *viz.*:—

1. At 56° the following three will meet:—

- That of the system $\text{CuCl}_2 \cdot 2\text{KCl} \cdot 2\text{H}_2\text{O}, \text{CuCl}_2 \cdot 2\text{H}_2\text{O}$.
- That of the system $\text{CuCl}_2 \cdot 2\text{KCl} \cdot 2\text{H}_2\text{O}, \text{CuCl}_2 \cdot \text{KCl}$.
- That of the system $\text{CuCl}_2 \cdot \text{KCl}, \text{CuCl}_2 \cdot 2\text{H}_2\text{O}$.

2. At 93°:—

- That of the system $\text{CuCl}_2 \cdot 2\text{KCl} \cdot 2\text{H}_2\text{O}, \text{CuCl}_2 \cdot \text{KCl}$.
- That of the system $\text{CuCl}_2 \cdot 2\text{KCl} \cdot 2\text{H}_2\text{O}, \text{CuCl}_2 \cdot \text{KCl}$.
- That of the system $\text{CuCl}_2 \cdot \text{KCl}, \text{KCl}$.

Lastly, those same temperatures are characterised also by an intersection of four vapour pressure curves at each, *viz.*:—

1. At 56° those of the above-mentioned three saturated solutions and that of the dry blue salt, mixed with copper chloride, meet.

2. At 93° those of the other three mentioned above and that of the dry blue salt mixed with potassium chloride.

Amsterdam, Sept. 14, 1890.

THE ESTIMATION OF NITRITES IN POTABLE WATERS.†

By JOHN C. THRESH, M.B., D.S.C.,
Medical Officer of Health.

PROBABLY no analyst feels that he has made a complete examination of a water unless he has at least made a qualitative test for nitrites, and if he finds indications of their presence he justly regards the water with suspicion, but, uncertain what further inference to draw, a quantitative examination is rarely made. Though this quantitative analysis, therefore, does not seem to be a matter of much importance in the present state of our knowledge, a series

of experiments I am now making on the changes in composition of certain waters, by keeping under varied conditions, lead me to believe that ere long the study of these changes will be of great aid in enabling us to judge of the quality of a water, and especially of those waters which at the present time the chemist or medical officer can only state to be suspicious. One of these changes, and one of the most easily followed, is the variation in amount of nitrous nitrogen. As an example I will quote that of the most extreme case I have yet met with. A water which from a mere chemical analysis would have been passed as "usable" when examined soon after drawing from the pump showed no trace of nitrites. Three days after it contained no less than 3·5 parts of nitrous nitrogen per litre, and on the sixth day after, it was again free from nitrites. Other changes proceeded *pari passu*, and these together with a bacteriological examination proved the water to be seriously contaminated.

It was when commencing this investigation that the want of a simple and reliable quantitative test for nitrites made itself felt. The metaphenylene-diamine and the naphthylamine tests were fairly tried, but did not answer my purpose, neither did titration with potassium permanganate. In working out the process for determining the amount of dissolved oxygen in water which I described early this year in a paper read before the Chemical Society, the action of nitrous acid on potassium iodide in the presence of a varying proportion of free oxygen was determined, and the results led me to believe that after all the old potassium iodide and starch test for nitrites could be made a reliable colorimetric quantitative one for water analysis. The results of my experiments having this for their object may be summarised as follows:—

1. With the same proportions of acid, starch, and potassium iodide, the rapidity with which the blue tint is developed, and the depth of tint varies with the degree of oxygenation of the water.

2. The depth of tint increases with the time which elapses between the addition of the reagents and the observation. This is due to the fact that the NO liberated is acting continuously as a carrying agent between the oxygen dissolved in the water, and of the air in contact with the surface of the fluid and the hydric iodide, liberating an equivalent of iodine corresponding to the oxygen carried.

3. The effect of temperature is such that comparisons cannot be made unless the fluids are within 2° or 3° of the same temperature. Thus, *e.g.*, at 65° F., in very weak solutions, the colour is not developed so rapidly as at 60° F., *ceteris paribus*.

4. With the same proportions of starch and iodide and in samples fully oxygenated, &c., the colouration varies with the amount and nature of the acid used.

5. The amount of potassium iodide added affects the result considerably. The larger the proportion of iodide, within certain limits, the greater the rapidity of the reaction.

6. The quantity and nature of the starch solution are also factors requiring recognition. If too large a proportion of starch be added, a marked reddish tint is first developed instead of the blue tint, and this reaction is still more marked if the starch solution has begun to change by keeping.

7. When all the above factors are constant, then the rapidity with which the blue tint is developed and the depth of tint varies directly with the amount of nitrite present in the water.

I need not trouble you with the account of the numerous experiments upon which these conclusions are based, nor of the further investigation conducted to ascertain how the information so obtained could be made available for rendering the iodine and starch reaction reliable as a quantitative test. I will merely give you now an account of the reagents required and the mode of conducting the analysis which I have found to give the most satisfactory results.

* Abstract of a Paper read before the British Association, Leeds Meeting, 1890, Section B.

† From the *Pharmaceutical Journal*, September 20, 1890.

Reagents:—

1. *Solution of Starch and Potassium Iodide.*

Starch in powder	0.2 grm.
Caustic potash	1.0 "
Potassium iodide	2.0 grms.
Water	200 c.c.

Add the starch to 10 c.c. of water, and when uniformly diffused add the caustic potash. Dissolve without the aid of heat and add the remainder of the water and the potassium iodide. Strain or filter. This solution keeps for months without appreciable change. One c.c. is required for each determination.

2. *Dilute Sulphuric Acid.*

Pure sulphuric acid	1 vol.
Distilled water	3 vols.

This is the same strength as used for the permanganate test, and I always employ it for both purposes.

3. *Solution of Sodium Nitrite.*

Sodium nitrite	0.493 grm.
Water	1 litre.

Dissolve:—

1 c.c. = 0.1 m.gr. nitrogen.

Apparatus.—Two or more 50 c.c. Nesslerising cylinders. **Process.**—Shake the sample of water vigorously in a bottle only partially filled, to saturate with air; pour 50 c.c. into the cylinder, and add 1 c.c. of the starch and iodide solution, and afterwards 1 c.c. of the dilute acid. Stir. Assuming the temperature to be about 60° F., if a dark blue tint develops instantaneously the water contains more than 1 per million of nitrous nitrogen. If it becomes blue in a few seconds it contains about 0.1 per million. If it requires more than 10 seconds to develop it contains less than this amount.

If the blue colour appears instantly the water must be diluted with known proportions of nitrite free water (saturated with air) until it is found by experiment that the colour takes a few seconds to develop.

With a very little experience the approximate amount of nitrite present can be ascertained with considerable precision by these simple preliminary experiments. Now prepare a standard solution of sodium nitrite by diluting 1 c.c. of the strong nitrite solution with 200 c.c. of water. One cubic centimetre of this weaker solution diluted to 50 c.c. corresponds to 0.01 m.gr. nitrous nitrogen per litre.

Measure into the Nessler glasses varying quantities of this dilute nitrite solution and fill up with water. Now take 50 c.c. of the water to be examined, or of the diluted water, if dilution were found necessary, and to each add successively 1 c.c. of the starch and iodide solution and dilute acid and note how the blue tint develops. If none of the solutions correspond with the water a fresh series must be prepared. In this way, in a very few minutes the amount of nitrite in any sample of potable water can be easily obtained with a very considerable approach to accuracy.

Since I commenced employing this test I have analysed over 180 samples of water, 51 of which contained nitrites, varying from 0.005 to 3.4 parts nitrogen per million, and I have had no reason to suspect inaccuracy from the interference of other constituents in any single case.

To render the process more intelligible I will give details of two determinations. Two solutions were prepared for me by an assistant and marked "a" and "b" respectively.

a. Fifty c.c. + reagents gave a blue tint in about ten seconds. It was therefore about the proper strength for estimation.

Ten c.c. of the dilute nitrite solution was diluted to 50 c.c. and compared with the sample. The colour seemed to develop a little more rapidly, but the difference was not very marked. Three solutions were prepared by diluting

5, 7, and 9 c.c. respectively of dilute nitrite solution to 50 c.c.

5 c.c. = 0.05 N per million	too weak.
7 c.c. = 0.07 "	"
9 c.c. = 0.09 "	too strong.

Another solution containing 0.08 N per million was then made and compared with the sample; the blue tint developed a little more rapidly. The strength was certified to be 0.075 N per litre. The actual strength was 0.07 per litre.

b. Original water gave a dark blue instantly.

Diluted to 1-10th a pale blue	"
" 1-25th colour developed in a few seconds.	"
Compared 1-25th with 0.05	too weak.
and 0.10	little too strong.

Now compared with:—

0.08	too weak.
0.09	about right.
0.10	too strong.

0.09 + 25 = 2.25 N per litre. The actual strength was said to be 2.5 N per litre.

The following results may also be quoted as fair examples of the accuracy obtainable:—

Nitrous Nitrogen per litre.		
	Present.	Found.
1	0.1 per million	0.10 per million.
2	0.625 "	0.65 "
3	0.625 "	0.625 "
4	0.093 "	0.095 "
5	0.01 "	0.01 "
6	0.05 "	0.05 "
7	0.125 "	0.13 "

The time occupied by a determination is usually about 5 minutes, the reagents are easily made and preserved, and the necessary conditions easily observed. I can, therefore, recommend the process to such as may desire at any time to estimate the nitrites in potable waters.

ON AN APPARATUS APPLICABLE FOR GAS ANALYSIS AND OTHER PURPOSES.*

By W. E. ADENEY, F.I.C., Assoc. R.C.Sc.I.,
Curator and Examiner in Chemistry in the Royal University, Dublin.

(Concluded from p. 199).

THE following results, taken at random, of analyses of sewage and of air will serve to indicate the degree of accuracy which is ordinarily attainable with the apparatus:—

(I.) Analyses of the gases resulting from the combustion of the residue obtained by evaporating 50 c.c. of the sample of sewage with metaphosphoric acid to dryness.

All measurements made at the 14 c.c. division line on the burette. Closed pressure tube employed.

	I. M.m.	II. M.m.
Height of mercury in pressure tube (moist)	776.5	786.0
" " " burette	351.0	351.0
Pressure of the gas	425.5	435.0
Temperature	20° C.	20° C.

After absorption with potassium hydrate:—

Height of mercury in pressure tube	514	512
" " " burette	351	351
Pressure of gas after absorption of CO ₂	163	161
Tension of CO ₂	262.5	274.0

* Read before the Royal Dublin Society, Jun: 18, 1890.

After absorption with pyrogallic acid :—

Height of mercury in pressure tube	509.5	511.0
" " " burette	351.0	351.0
Pressure of nitrogen	158.5	160.0
Capacity of burette at 14 c.c. division line = 14.2267 c.c.		

The parts per 100,000 of organic carbon and total nitrogen contained in sewage are calculated from the above determinations in the ordinary way.

Analysis No. I. gives :—

4.9 parts carbon per 100,000
6.96 parts nitrogen per 100,000

Analysis No. II. gives :—

5.1 parts carbon per 100,000
7.02 parts nitrogen per 100,000

(II.) Analyses of air. About 175 c.c. air at ordinary pressure taken.

All measurements made at the 100 c.c. line on burette. Open pressure tube employed.

	I. M.m.	II. M.m.
Height of mercury in pressure tube	628.50	628.5
Atmospheric pressure	755.75	759.1
Total pressure	= 1384.25	1387.6
Height of mercury in burette	210.00	210.0
Pressure of the gas	= 1174.25	1177.6

After absorption with potassium hydrate :—

Total pressure	1173.45	1176.80
Tension of CO ₂	0.80	0.80

After absorption with pyrogallic acid :—

Total pressure	933.25	936.30
Tension of oxygen	240.20	240.50
Temperature	16.5° C.	18.4° C.
Tension of nitrogen	919.286	920.911
Tension of aqueous vapour at 16.5 = 13.964 m.m.		
" " " " 18.4 = 15.389 m.m.		

	I. M.m.	II. M.m.
Percentage of nitrogen	= 79.2299	79.2379
" oxygen	= 20.7001	20.6933
" carbon dioxide	= 0.0689	0.0683

When explosions are to be made in the apparatus, the gas is first measured as above described; the oxygen or hydrogen is then passed into the laboratory vessel through the reagent tube, and after the mixed gases have been measured, they are returned to the laboratory vessel and exploded therein under reduced pressure according to the directions given by Thomas (*Chem. Soc. Journ.*, xxxv., 213).

The hydrogen or oxygen may be passed into the laboratory vessel with great facility. The gas is first collected in a test-tube or other suitable vessel over mercury; the india-rubber tube attached to the reagent tube is then carefully freed from air and filled with mercury in the manner above described, and cautiously inserted into the test-tube; then, on lowering the reservoir, the gas will pass from the test-tube into the laboratory vessel.

The method of employing the apparatus for the analysis of nitrates or carbonates, and for other similar purposes, will be understood from the foregoing descriptions. It need only be mentioned that a known quantity of the substance to be analysed is placed in a small flask in the solid form or in solution, and the flask is attached to the tube *h* of the apparatus. The flask is exhausted and the necessary reagent added through the cup and stop-cock *g*.

I trust in a future communication to the Society to give the results of a research on certain methods of water analysis upon which I have been engaged for some time past, and to show how the apparatus may be conveniently

employed for determining the dissolved gases, organic carbon, and the nitrogen in waters.

In the early part of this paper it was pointed out that the reservoir supplying mercury to the burette and pressure tube was connected with the latter and not with the former. With this class of apparatus such an arrangement is essential, because, when the reservoir is kept for any length of time at a lower level than that of the bottom of the burette, and this is constantly necessary when working in vacuo or under reduced pressure, air diffuses through the india-rubber connecting tube, and passes into the pressure tube immediately the reservoir is raised again. It would, of course, pass into the burette, and the experiment would be vitiated if the connecting tube were directly attached to the burette. The air may be expelled from the pressure tube when necessary by opening its stop-cock and raising the reservoir sufficiently high to fill the tube with mercury.

It will be noticed that the pressure tube is not provided, as in the case of Thomas's or Macleod's apparatus, with a water jacket for keeping its contents, when employed as a closed and "wet" pressure tube, at the same temperature as the contents of the burette, nor are means furnished for continually renewing the water in the cylinder *c* during an analysis. I have found that neither additions are necessary to this class of apparatus for all ordinary purposes. Since the burette is of a considerable length, viz., 640 m.m., the measurements may in nearly all cases be made with advantage with an open pressure tube; and if the cylinder *c* be filled with water that has been kept exposed for some time to the temperature of the laboratory in which the apparatus is kept, the water will not, if ordinary care be observed, alter sufficiently to appreciably affect the results of an analysis. When it is necessary to use a closed pressure tube, and it is at the same time necessary to work with the utmost degree of accuracy, then it is preferable to employ a "dry" closed tube; but even if it be employed "wet" very good results will be obtained. The additions above referred to have the great disadvantage of rendering the apparatus much more complicated and liable to fracture. I have endeavoured to make the apparatus here described as simple as proper regard for accuracy of result will allow, in the hope that it will supply the want of an effective and simple apparatus, which I have, in common with other chemists, experienced in teaching methods of analysis involving the evolution, collection, and measurement of gases, and that it will be consequently found useful in a laboratory in which advanced students are taught, as well as for the purposes of research work.

With reference to the possibility of maintaining the apparatus in good working order, I may say that I have employed it for a large number of experiments of various kinds during the past six months, and have found no difficulty in maintaining the stop-cocks in such good order that a vacuum can be maintained in the burette and pressure tube unimpaired for several days. Some difficulty was at first experienced when attempting to subject a gas in the burette to high pressure, owing to the stopper of the burette being loosened and pressed out. The difficulty was overcome by lubricating the stopper with a mixture of beeswax and vaseline.

Other advantages of the apparatus besides simplicity and wide range of applicability are its comparative freedom from the risk of breakage, and its cheapness. The glass parts,* with the exception of the scale at the back of the pressure tube, were obtained at a cost of 45s.; the cost of putting the parts together, including time and fittings, was about 40s.; and it may be taken that the apparatus cost in all not more than £5.

In conclusion, I desire to express my sincere thanks to my old pupil and friend, Mr. James Carson, C.E., Assoc.

* My acknowledgments are due to Messrs. Baird and Tatlock, of Glasgow, through whom I obtained the glass parts of the apparatus, for the care and accuracy with which all the directions given to them were carried out.

R.C.Sc.I., for the aid he has unsparingly given me in making a large number of laborious experiments with which to test the apparatus. My thanks are also due to John Connolly, the laboratory assistant in the Royal University, for the skilful assistance he has rendered me in fitting the apparatus together.

THE OXIDATION OF SULPHIDES BY MEANS OF THE ELECTRIC CURRENT.*

By EDGAR F. SMITH.

IN the *Proceedings* of the Chemical Section of the Franklin Institute, i., 52, and the *Berichte*, xxii., 1019, a preliminary report was published, describing a rapid method for the conversion of sulphur into sulphuric acid through the agency of the electric current. It was there demonstrated that the sulphur in the mineral chalcopyrite, for example, was completely oxidised to sulphuric acid in ten minutes, and that the oxides Fe_2O_3 , CuO , &c., were eliminated from the analysis, so that the barium sulphate finally weighed was perfectly white in appearance, and not contaminated with the impurities usually accompanying it when precipitated from solutions containing much iron, &c.

To give a better idea of the mode of carrying out an oxidation of this description, the apparatus used for this purpose will be first outlined.

T represents a table upon which stands *A*, an ordinary filter-stand, in the base of which is fixed a binding screw holding in position a heavy copper wire bent as seen in the sketch, and intended to carry the nickel crucible in which the oxidation occurs. The arm of the filter-stand has attached to it a binding screw holding a heavy platinum wire, as well as the copper wire generally in connection with the anode of the battery. *E* is a Kohlrausch ampere-meter, registering amperes and half amperes; this is in connection with *C*, a block of wood screwed or nailed to the table. There are four depressions (*x*) in *C* containing a few drops of mercury, in contact with the binding screws (*a*). *D* is the movable top of *C*; the wires crossing it project on the under side and rest in the mercury cups (*x*). When *D* is so arranged that the wires on its upper face run in the direction of the dart, the crucible becomes the anode of the battery, whereas if they have a horizontal position, —→ the crucible is the cathode.

F is a resistance frame, consisting of about 500 feet of common iron wire arranged upon a light wooden parallelogram. It should always be in the circuit.

The movable cap *D* is necessary and important. It enables the operator to change the poles quickly—to reverse the current at a moment's notice. In the oxidations to be described later on, this was frequently necessary, chiefly because when the crucible served as cathode in many of the decompositions there often occurred a considerable deposition of metal upon its sides, and in the act of separating this metal enclosed undecomposed material and withdrew it from the field of oxidation. In such cases, by making the crucible the anode, as above indicated, the mineral matter will be liberated, and, upon coming in contact with a large oxidising surface, all the sulphur contained in it will be converted into sulphuric acid. The crucible should always be covered during the oxidation.

Oxidation of the Sulphur in Sulphides.

In the oxidations given later, nickel crucibles $1\frac{1}{2}$ inches high and $1\frac{1}{2}$ inches wide were used; but a more advantageous form, one which should always be employed when more than 0.15 gram of material is used, would measure

2 inches in length and $1\frac{1}{2}$ inches in width. In such a vessel place 25–30 grms. of pure potassium hydroxide (not sodium hydroxide), and warm the same until the excess of moisture is expelled. Bring the weighed sulphide into the crucible, connect the latter with the copper wire shown in the sketch, and lower the platinum wire so that it extends a short distance below the surface of the molten mass. The current is then made to pass by bringing a metallic cup, connected with one pole of the battery, in contact with one of the wires of the resistance frame, *F*. The sulphur will be completely oxidised in from ten to twenty minutes. Interrupt the current, allow the crucible and contents to cool, then place the same in water. In a few minutes all but the insoluble oxides will have dissolved. Filter, acidulate the warm filtrate with hydrochloric acid, and precipitate the sulphuric acid in the usual manner. If, upon adding acid to the alkaline solution the latter becomes turbid, from separated sulphur, it is an indication that the oxidation was incomplete. Observe closely whether sulphur dioxide is liberated even when the liquid remains clear. Never omit the examination of the residue remaining on the filter, after the alkaline solution has been filtered. The caustic alkali must always be tested for sulphur before using it in this work. It is well to estimate the impurities in the alkali and deduct them, in each determination, from the barium sulphate found.

To ascertain to what extent this method could be applied in oxidising sulphur, the following minerals, representing all the various classes of natural sulphides, were subjected to experiment:

Sphalerite (ZnS).

No difficulty was experienced in oxidising the sulphur of this mineral. A current of one ampère (=10.45 c.c. electrolytic gas per minute) was amply sufficient for the purpose. When the mineral was added to the melted caustic potash and the current applied, the mass assumed a muddy appearance, which it retained for ten minutes, when it became white and froth-like. It was discovered, by experiment, that this appearance indicated the complete oxidation of the sulphur.

(I.) 0.1195 gram. mineral, 20 grms. alkali, 1 ampère (time, 20 minutes), gave 32.97 per cent S.

(II.) 0.1025 gram. mineral, 20 grms. alkali, 1 ampère (time, 20 minutes), gave 32.96 per cent S.

(III.) 0.1180 gram. mineral, 20 grms. alkali, 1 ampère (time, 10 minutes), gave 32.80 per cent S.

By oxidising the sulphur in a fourth portion with nitric acid and potassium chlorate, 32.90 per cent sulphur was obtained.

A specimen of Joplin (Mo.) blende gave 32.60 per cent and 32.80 per cent S by the nitric acid method, while by the electrolytic method 32.90 per cent S was found.

* Read at the Chemical Section of the Franklin Institute, June 17, 1890.

An impure sphalerite, locality unknown, in which there was considerable gangue and other admixtures, gave 29·8 per cent S when oxidised with nitric acid, and when acted upon in alkaline solution by a current giving one ampère of electrolytic gas per minute, the sulphur found was :

(I.)	29·23	per cent S.
(II.)	29·45	" "
(III.)	29·68	" "
(IV.)	29·67	" "
(V.)	29·90	" "
(VI.)	29·58	" "

Cinnabar (HgS).

Very pure material was employed in this oxidation. Several trials were required, in order to learn the proper conditions for successful working. The tendency of this mineral, when finely divided, was to collect in lumps, which appeared to rise and fall in the alkaline solution; in order to bring every particle of material within the field of oxidation, the current was reversed every few minutes. By doing this the sulphur was completely oxidised in twenty minutes or even in less time. If the precaution just mentioned with reference to the reversal of the current be not heeded more time will be required for complete oxidation, and even then it will be doubtful whether the sulphur is fully converted into sulphuric acid. Twenty-five grms. of caustic alkali were used in each experiment with this mineral.

0·1089 grm. cinnabar gave 13·82 per cent S, while the required percentage is 13·79.

A current of two ampères per minute was used.

Galenite (PbS).

There is no difficulty in oxidising this mineral. The same quantity of alkali and the same current strength were employed here as in the mineral immediately preceding :

(I.)	0·1093	grm. galenite	gave	14·30	per cent S.
(II.)	0·1092	" "	" "	14·60	" "

Another portion in which the sulphur was oxidised by heating the mineral in a current of chlorine gave 14·30 per cent S.

Argentite (Ag₂S).

No difficulty was encountered in oxidising this mineral. The decomposition was made with conditions analogous to those already described. Silver did not pass into the alkaline solution, so that when the sulphuric acid was precipitated, barium chloride was employed as usual. The specimen analysed being exceedingly pure, it was not thought necessary to determine the sulphur by any other method. None of it remained unoxidised :

0·1032 grm. argentite gave 13·04 per cent S; required 12·90 per cent S.

Chalcocite (Cu₂S).

Thus far this mineral has resisted all efforts to convert its sulphur into sulphuric acid. Repeated attempts have been made, but not more than half of the sulphur contained in the mineral was oxidised, notwithstanding the current was very much increased in each trial. Since some time may elapse before another opportunity offers itself to continue experimentation with this mineral, it need only be stated that a modification of the usual method will be tried upon it. The copper and sulphur are evidently in very intimate union.

Molybdenite (MoS₂).

The sulphur in this mineral is given up readily to the oxidising influence of the current. One annoying feature is that the fine mineral particles are so very light that they are apt to be carried up and adhere to the cover crystal. In this oxidation the poles should be repeatedly reversed. The result given below is from a sample that contained much quartz, &c. The residue, however, gave not a trace of sulphur when tested for it.

0·1045 grm. mineral gave 0·2785 BaSO₄ = 36·60 per cent S.

Stibnite (Sb₂S₃).

While a current of two ampères was employed in this oxidation, the sulphur can be completely changed to sulphuric acid with one ampère. Three trials proved this conclusively.

0·1095 grm. mineral gave 0·2230 BaSO₄ = 27·91 per cent S; required sulphur, 28·5 per cent.

Orpiment (As₂S₃).

Pure material could not be obtained, so that the experiments were made with inferior mineral, and the greatest care was given the oxidation, so that sulphur was not afterwards discovered in the insoluble residue.

0·1150	grm. sub.	gave	0·2922	gr. BaSO ₄	=	34·90	p.c. S.
0·1044	" "	" "	0·2721	" "	=	35·79	" "

The arsenic was also oxidised to arsenic acid. Several tests proved the conversion to be quantitative. Results obtained in this direction will be published later.

Jamesonite (Sb₂S₅Pb₂).

The sulphides of lead and antimony offer no difficulty in the oxidation of their sulphur. This sulpho-salt is decomposed with equal facility. A current of two ampères per minute was employed. The crucible was the anode for ten minutes, and the cathode for an equal period.

(I.) 0·1078 grm. mineral gave 0·1426 gr. BaSO₄ = 18·16 per cent S.

(II.) 0·1093 " " 0·1447 " = 18·18 per cent S.

Required S = 18·30 per cent.

Enargite (As₄S₃Cu₃).

The oxidation was made in the same manner as in jamesonite :

0·1102 grm. mineral gave 0·2449 gr. BaSO₄ = 30·52 per cent S.

A second sample, oxidised with nitric acid, gave 31·00 per cent S.

Stephanite (Ag₅SbS₄).

This mineral was oxidised without difficulty. The conditions under which it was worked were similar to those of the preceding minerals :

(I.) 0·1044 grm. substance gave 16·69 per cent S.

(II.) 0·1109 " " 16·55 " "

Theory requires 16·20 per cent S.

Kobellite [(BiSb)₂S₅Pb₂].

The sulphur in this mineral was oxidised with ease :

(I.)	0·1136	grm. sub.	gave	0·1562	gr. BaSO ₄	=	18·38	p.c. S.
(II.)	0·1157	" "	" "	0·1594	" "	=	18·41	" "

The sample here oxidised was of the same material as that analysed by Dr. Keller (*Proc. Chem. Soc. Franklin Inst.*, 1, 127). On comparing the mean of his four sulphur determinations with the results obtained by the electrolytic method, it will be seen that the latter does not lack in completeness :

Current Oxidation.	Nitric Acid Oxidation.
Sulphur percentage.	18·37, 18·33, 18·46, 18·39
18·38—18·41	Mean, 18·39 per cent S.

Tetrahedrite (Sb,As)₂S₇(Cu₂Hg₂Fe,Zn)₄.

Quite a number of sulphur determinations and complete analyses of tetrahedrite of the above composition were made in this laboratory during the college year just closed. In all of these the chlorine method was employed for decomposition purposes. The percentage of sulphur found was 24·48 per cent. Samples of the same were then exposed to the action of a current of two ampères for

twenty minutes, and the sulphuric acid determined in the usual manner with these results:

- (I.) 0.1073 gr. mineral gave 23.81 per cent S.
(II.) 0.1096 " " 24.38 "
(III.) 0.1086 " " 24.23 "
(IV.) 0.1095 " " 24.37 "

Tetrahedrite seemed to require the full time (twenty minutes) for oxidation, for in several instances, where the current was interrupted after acting fifteen minutes, the alkaline solution became quite turbid upon acidulation.

Stannite ($\text{SnS}_4\text{Cu}_2\text{Fe}$).

The conditions here were the same as those already mentioned for the other sulpho-salts:

- (I.) 0.1087 grm. mineral gave 28.61 per cent S.
(II.) 0.1091 " " 28.02 "

Pyrrhotite ($\text{Fe}_{11}\text{S}_{12}$), Marcasite (FeS_2), and Pyrite (FeS_2).

The sulphur in the first of these three minerals is very readily changed to sulphuric acid. None of its iron passes into solution, so that the barium sulphate, after ignition, was perfectly white in colour. The residue, not soluble in water, showed no unoxidised sulphur:

- (I.) 0.1087 grm. mineral gave 0.3049 gr. BaSO_4 = 38.51 per cent S.
(II.) 0.1067 " " 0.3014 " = 38.79 per cent S.

By oxidation with nitric acid the sulphur found was 38.78 per cent S.

An exceedingly pure specimen of marcasite was exposed to the action of the current. Its sulphur was rapidly and completely oxidised:

0.1043 grm. substance gave 0.4056 gr. BaSO_4 = 53.40 per cent S. Required S = 53.33 per cent.

While these sulphides of iron parted with their sulphur with great ease, pyrite held half of its sulphur content quite tenaciously, notwithstanding it was exposed to the influence of much more powerful currents than the other two minerals.

(I.) 0.1667 grm. pyrite and 20 grms. KOH were exposed for ten minutes to the action of a current giving one ampere per minute. The crucible served as anode for half the time. The sulphur that was oxidised equalled 24.53 per cent.

ILLUSTRATIONS OF SEWAGE DECOMPOSITION IN STREAMS.*

By J. H. LONG.

DURING the last four years I have had occasion to carry out a lengthy investigation on the question of pollution of streams in Illinois, and in the progress of the work have observed certain points which I consider of interest to chemists dealing with analytical problems of similar nature.

This work was undertaken by authority of the State Board of Health, and since its beginning I have examined nearly 1000 samples. The results reached in a preliminary examination were presented to the Board in 1887. A few of them were explained in a paper in the *American Chemical Journal*, vol. x., No. 1, while the methods employed and tabulated results of the whole will appear in a future annual report of the Board.

The largest part of the work consisted in a study of the Illinois river from its sources to its mouth, and it is only with this part of the subject that I have to deal here.

At all seasons of the year the upper Illinois river receives a good part of its water from Lake Michigan through a canal flowing south-west from Chicago to

Joliet, when a union with a small stream known as the Des Plaines river is made. A few miles further toward the south-west these waters are joined by those from the Kankakee and Du Page, thus forming the Illinois proper. The watershed separating the basin of Lake Michigan from that of the Mississippi is very low, and is but a few miles from the lake. The canal referred to is fed by pumps, the water being drawn through the city and discharged by these pumps toward the west at the rate of 50,000 cubic feet per minute. The water in going through the city receives about three-fourths of its sewage, and in the canal flows undiluted to Joliet, a distance of 33 miles.

It will be seen, therefore, that we have here a most interesting problem. We have given a stream, highly contaminated at its source, and are able to follow and measure changes in the amount of contamination for many miles. In my first series of experiments, completed during the summer of 1886, very curious and important results were obtained. That season was unusually warm and dry, the rainfall in the part of the state under consideration being the lowest recorded in 15 years, and it was therefore possible to measure changes in the flowing river water, undisturbed by dilution of rain.

In the tests of that season, the determinations made were free and albumenoid ammonia and oxygen consumption by the Kubel method. The following mean results were obtained, expressed in parts per 1,000,000:

	Free Ammonia.	Albumenoid Ammonia.	Oxygen consumed.
Bridgeport	17.44	1.195	20.58
Lockport, 29 miles..	10.23	0.669	11.30
Joliet, 33 "	6.93	0.408	7.79
Ottawa, 81 "	0.382	0.237	5.57
Peoria, 159 "	0.035	0.187	4.85

Between Bridgeport and Joliet the dilution was practically zero during the whole season. Between Joliet and Ottawa the Illinois receives the water of the Kankakee, Du Page, and Fox, so that at the last named place it was estimated that the canal water was reduced to 43 per cent of the whole. But as a part of the diluting water came from a marshy region, it was by no means free from organic matter. Besides, some town drainage entered the stream between the two places. It is, therefore, probable that a reduction in organic matter took place between these points. The proportion of canal water, in the whole, was but slightly changed between Ottawa and Peoria, while some drainage entered at the town of LaSalle. We can trace, therefore, a very remarkable decrease in organic matter between the contaminated source at Bridgeport and the city of Peoria. From a study of all the facts bearing on the case, I have held that this change was due chiefly to oxidation (using this term in the broad sense to include changes brought about by micro organisms) rather than to sedimentation.

During the following winter these mean results were obtained, expressed in parts per 1,000,000:

	Free Ammonia.	Albumenoid Ammonia.	Oxygen consumed.
Bridgeport	9.7	3.7	22.4
Joliet	6.5	2.2	11.3
Ottawa	4.7	0.75	9.0
Peoria	1.7	0.43	6.45

In this table the increased amount of albumenoid ammonia with smaller amount of free ammonia at Bridgeport is apparent, and is, of course, due to the fact that decomposition is slower at a low temperature, and hence the sewage reached the pumps in a less advanced stage of oxidation. The large amount of albumenoid ammonia at Joliet is worthy of note at a time when sedimentation could accomplish the best results. The very slow decrease in free ammonia must also be noticed.

As intimated above, these tests may be considered as preliminary to a more complete investigation begun May

* From the *Journal of Analytical Chemistry*, Vol. iv., Part I.

1st, 1888, and concluded in March, 1889. In this investigation water was collected once a week at the following places between the source of supply at Chicago and the Mississippi river: Bridgeport, Lockport, Joliet, Morris, Ottawa, LaSalle, Henry, Peoria, Pekin, Copperas Creek, Havana, Pearl, Beardstown, and Grafton, the last being at the mouth of the Illinois river. Parallel tests were also made of the water supplied by the various tributaries of the Illinois to determine the nature of the dilution. In this investigation, in addition to free and albumenoid ammonia and oxygen consumption, total solids, suspended matter, nitrates, chlorides, and hardness were determined. In the following table only those data important for the present purpose are given and for places where water was regularly collected. During the early part of the season the rainfall throughout Illinois was heavy, in consequence of which the streams were full at times, adding much to the dilution of the main river.

The amount of this dilution can be roughly estimated from the chlorine determinations along the main stream and in the tributaries.

Mean Results of Analyses. May to October, 1888, inclusive.
(In Parts per Million.)

Grafton	0.087	7.523	0.875	0.722	9.818

In explanation of some of the peculiarities of the above tables, it must be stated that while the rainfall during 1888 was much heavier than during 1886, the mean temperature was in a marked degree lower. The winter of 1888-89 was, however, much milder than that of 1886-1887. In comparing the summer tests of 1886 with those of 1888, we notice that at Bridgeport in the first-named year the free ammonia was much higher and the albumenoid ammonia much lower than during the second season. It is also clear that the rate of change in these products between Bridgeport and Joliet is different for the two seasons. I think this can be largely looked upon as an effect of temperature, as dilution, contamination, and agitation of water were practically the same within these limits through the two seasons. During the hot summer of 1886 much greater decomposition must have taken place in the Chicago sewers themselves than during the cooler one of 1888, so that in the first case the diluted sewage reached the pumps in a more advanced stage of oxidation than in the latter.

One would expect to find, under these circumstances, less free ammonia and more albumenoid than in a season when the oxidation conditions had been more favourable.

To follow the change in the sewage after it leaves Chicago in its flow toward the Mississippi, we must consider the character of the diluting water from the tributaries. The mean results obtained by analysis of these waters are given (see next page), in parts per million, as before.

The flow from the DuPage is very small during the summer and its effect on the Illinois can be left out of consideration.

The Kankakee, draining a marshy country, has a steady flow throughout the summer, and forms about 20 per cent of the Illinois water at Morris. Its character is shown by low chlorine and nitrates and high albumenoid ammonia and oxygen consumption. Between Morris and LaSalle the Fox enters and dilutes the Illinois largely, as indicated by the decrease in chlorine. The dilution by the Big Vermillion is not large. The high nitrates here are worthy of interest. The city of Streator and several coal mines drain into the stream. Below Peoria the tributaries of importance are the Sangamon and Spoon. I have no data for the latter, but the results for the Sangamon are given above. Perhaps 30 per cent of the flow at Beardstown comes from these two streams.

Aided by these data, we can now consider the main river. Between Bridgeport and Lockport, a distance of 29 miles, there is during the summer an evident disappearance of organic matter, as shown by change in the free and albumenoid ammonia and oxygen consumption. But during the winter the change is in a marked degree less. This is especially apparent if we notice that the chlorine tests during the winter show some dilution between the two places. From Lockport to Joliet the distance is four miles, but on its way the water passes through four locks and over two dams to point of collection. It is thus thoroughly agitated and aerated. During the summer the tests show a decrease in organic matter, but the winter examinations indicate, apparently, an increase, as shown by albumenoid ammonia. A slight increase in free ammonia is also found. These observations are of practical importance. They show, first, that at Lockport the decomposing matter was not yet in condition to respond most perfectly to the albumenoid ammonia test, and also that the free ammonia gradually produced had accumulated rather than decreased by fermentation. Dilute solutions of white of egg undergoing putrefaction yields its largest amount of albumenoid ammonia at the start, as shown by experiments carried out in my laboratory by Mr. Powers. (See *Journal of Analytical Chemistry*, Oct., 1889.) But it is conceivable that solids in suspension, or other nitrogenous matters more stable than white of egg, would yield their largest amount of albumenoid only after preliminary disintegration.

Between Joliet and Morris the distance is 22 miles, and on the way there is a dilution of about 20 per cent by water in which the numbers for albumenoid ammonia and oxygen consumption are high. A part of the drainage of Joliet enters here besides. Giving these points due weight, it will be seen that there is a large reduction of organic matter in this part of the stream during the summer. This is not chiefly due to sedimentation. It has been shown by engineers in charge of surveys along the Illinois river, that owing to sufficiently high velocity of the water, sedimentation does not take place here. During the winter the relative dilution from the Kankakee was much greater, about half the water at Morris coming from the last-named stream. When the character of the diluting water is remembered, it is plain that the nitrogenous matter has suffered no change between the two places. In the 37 miles between Morris and LaSalle there is a great decrease in free ammonia with increase of nitrates, but when the dilution of the Fox river is considered, it is plain that the change in albumenoid ammonia is not important. During the winter season the Fox

	Nitrogen in Nitrates and Nitrites.	Chlorine.	Free Ammonia.	Albumenoid Ammonia.	Oxygen consumed.
DuPage river, enters above Morris	0.307	5.786	0.417	0.346	4.743
Kankakee river, enters above Morris.. ..	0.094	1.015	0.114	0.585	12.661
Fox river, at Ottawa, above LaSalle.. ..	0.027	4.974	0.278	0.463	7.066
Big Vermillion river, at LaSalle, ab. Henry ..	3.348	5.461	0.129	0.341	6.914
Sangamon river, above Beardstown	0.755	3.609	0.053	0.285	5.480

river dilution was relatively greater, which lessens somewhat the apparent decrease in albumenoid ammonia at this time. It is true, however, that changes take place in this part of the river which in the warmer season took place above.

In the 28 miles between LaSalle and Henry no important changes have taken place.

At Peoria the river widens into a lake, which receives a portion of the drainage of the city. The point where the samples were taken for analysis was evidently not beyond the influence of this contamination. During the winter this was increased by the drainage from sheds at the distilleries at which 25,000 head of cattle were fed. The effect of this is shown in the Peoria water, but most clearly in that from Pekin, ten miles below. Especially interesting is the great increase in nitrates observed at this point, and after the addition of fresh contamination.

Between Pekin and Beardstown there is a gradual improvement in the river, as shown by both summer and winter tests. Below Beardstown the Illinois was often diluted by back water from the Mississippi, which made the result of analysis irregular and obscure.

From the above it is apparent that while a gradual loss in organic matter occurs all the way between Bridgeport and Peoria, the rate of change was far less rapid in the summer of 1888 than in that of 1886. This difference, I believe, is chiefly due to differences in temperature and rainfall, which act directly and indirectly to modify the rapidity of bacterial oxidation.

In a wet summer the contents of the Chicago sewers, besides being cooled by rainfall, are rapidly washed out into the canal leading to the pumps. In a season of little rainfall much matter remains long enough in the sewers to become greatly modified by decomposition, and consequently disappears rapidly when thrown into the main channel. These opposite conditions were illustrated in the summer seasons in which tests were carried out, and they doubtless can be duplicated in all large cities in which the sewers are built with but slight incline. Sedimentation cannot play a more important part in the apparent purification of these waters in summer than in winter. In fact, after the navigation of the canal closes in the early winter, precipitation can take place which was impossible during the warmer months. Yet the winter tests show practically no decrease in the organic matter between Bridgeport and Morris. It would appear, therefore, that the self-purification of a very cold water is a slow process, even when aided by sedimentation.

On the other hand, the very remarkable results obtained between Bridgeport and Joliet in our first season's work show that with a sufficiently high temperature the disappearance of organic matter may be very rapid, unaided to any great extent by sedimentation.

It is known that temperature differences of a few degrees make very important differences in the rates of bacterial multiplication in many cases, and consequently in their efficiency as filth destroyers, and giving proper weight to this fact, I think many of the discrepancies observed between different examinations of the same polluted water, made at different times, may be explained.

The appearance and increase in nitrates and nitrites in the Illinois river affords us an instructive illustration. Frankland and others have shown that they are not formed in fresh sewage, and we see here that they appear only after a flow of many miles.

With the slower disappearance of albumenoid ammonia and less abundant formation of free ammonia in the cold season, we notice the later appearance of nitrates and

nitrites. Investigation may show that the appearance of these compounds marks an important stage in the purification of a polluted stream.

It is probable that they are produced only after practically all the readily fermentable bodies have been more or less changed, as in presence of such matter denitrification can take place with destruction of nitrites, and evolution of nitrogen even. The greatly increased nitrates below Peoria after pollution by fresh drainage from the cattle sheds, would seem to disprove this view. But such drainage is rich in hippuric acid, and this body, as well as its derivative, glycocholic, is readily broken up. Besides, because of the comparatively simple nature of the cattle feed (distillery slops and hay), the other matters present here must be less complex than what we have in ordinary city sewage, and therefore sooner converted into ammoniacal and other simple compounds.

Investigations, such as I have given an outline of above, are very difficult because of the practical impossibility of controlling all the conditions of experiments. Irregularities creep in where least expected, and in consequence the results of single observations have but little value when taken alone.

The results of investigations extended through a season have a different value, and I believe we can draw conclusions from these experiments on the Illinois which can be applied to the study of polluted river waters in general.

NOTICES OF BOOKS.

The River Irwell and its Tributaries. A Monograph on River Pollution. By G. E. DAVIS and A. R. DAVIS. Manchester and London: J. Heywood.

WE have here a contribution to the question of river-pollution worked out upon one of the filthiest streams or stream-systems in the world. Perhaps in no other locality is such a dense population, and such an amount of manufacturing chemistry collected along rivers of such insignificant dimensions. Hence, the concentration of the foul waters is unquestionable.

The immediate occasion for the appearance of this work is the prospect that at no distant date the total liquid—it might be hazardous to say *water*—now flowing in the channel of the Irwell must find its way into the Manchester Ship Canal. The authors hold out the prospect that the canal and its docks will become pestiferous in summer, and that the first reach of 2½ miles in length will become one "vast settling tank."

The authors consider that the suspended matters are the *crux* of the question, and that their removal, even if we disregard the soluble impurities, would be a great improvement.

The chlorine they regard—in our opinion rightly—as not in a manufacturing district a measure of sewage contamination. Nine-tenths of all the chlorine present in the bleaching agents used in the water-shed of the Irwell reappears in the stream at Throstle Nest Weir. Upon the determination of nitrates in polluted waters they lay no high emphasis.

The tables giving a view of the composition of the Irwell at different points and of its tributaries will be very useful for reference. We find here the statement that the water of the rivers Irk and Medlock in time of drought is more polluted than the normal sewage of Leeds or of Salford. We are glad to find that Messrs. Davis protest

against the current notion that river waters in time of flood are exceptionally pure, and may be safely let "slip by" down stream.

We regret, however, to find the opinion expressed that "the authorities should require a certain standard of purity to be attained before a liquid of any kind is allowed to flow into a water course." The authors approach here unpleasantly near to the "standards" of the Rivers' Pollution Commissioners, the objections to which have been fully explained in the *CHEMICAL NEWS*.

The methods used at the "Manchester Technical Laboratory"—which is throughout kept well in view—are given in full, and are in the main those of Mr. Wanklyn.

The Heating and Lighting of London by Pipe Lines. An Open Letter to Walter Wren, Esq., L.C.C., on the Abolition of London Fog. By T. HOWELL WILLIAMS, F.C.S., L.C.C.

THAT London fogs are a great and a growing evil is very generally admitted, though their harmful results are probably exaggerated. For their abolition a variety of means have been proposed, and if the public hesitate it is because, on the one hand, they are nearly powerless in the matter, and on the other because they justly fear that every scheme suggested must lead to an increase of the intolerable burden of local taxation. We have been truthfully told that if we would give up our "cheerful" fire-places and adopt the Dutch earthenware stove, our consumption of coal could—speaking within the limit—be reduced to one-fourth of its present amount. This would, of course, involve a corresponding decrease in the products of combustion and would besides bring the Coal Exchange to its knees. The author estimates the present cost of the transit of coal together with the profits of the middleman and the dealer amount to at least £6,000,000 annually.

Another proposal, due to our late friend Peter Spence, of the Manchester Alum Works, was to erect centrally a tower of Babel, into which all the products of combustion should be drawn through the sewers, the gases of which would at the same time be disinfected by the sulphur fumes. W. A. Gibbs, of Gillwell Park, would likewise draw the smoke downwards into the sewers, by means of gigantic tidal fans, discharging it near the mouth of the river. Here, also, there would be simultaneous ventilation and disinfection of the sewer-system.

Whether the engineering difficulties involved would prove fatal to either of these two projects we are not in a position to decide. We fear that they have both been condemned without a fair trial.

It is here mentioned that "Dr. Carpenter and others have proposed a tax in the nature of a hearth tax." If it were needful to make manifest the absurdity and the injustice of this proposal we might show that the number of hearths in a house gives no clue to the yearly consumption of fuel in such house, and that the tenant-occupier, though he may, perhaps, not use half the hearths in his dwelling cannot close them up at his pleasure.

Mr. Howell Williams proposes "that gas should be made at the coal fields, as close to the pit's mouth as convenient, that it should be conveyed from the gas-works situate in the country up to the metropolis in suitable mains, that it should be stored in gas-holders as at present, and that it should be solely utilised for heating and lighting the metropolis, together with providing all the motive power required for driving engines and machinery."

It will be seen that the author proposes to introduce two kinds of gas—one for illumination and another for heating. Hence, two pipe lines would be necessary. There is the question as to the locality for the giant gas-works which would have to be erected in the country. Other things being equal, they would have to be erected as near to London as possible. They would have to be

situate where the supply of coal would be in no danger of early exhaustion or of temporary interruption by "strikes."

It will be necessary that the gas, whether for heating or lighting, should be purified from sulphur quite as thoroughly as the gas now supplied in London. Otherwise, if sulphur be a cause—say the main cause—of the "London particular" we should still have the same quantity of the sulphur oxides in our atmosphere as at present.

We must call attention to the following passage, premising that the italics are the author's own:—"Gas pipes laid through arable land, *if it is found desirable to lay them underground*, are not harmful to the land itself, but rather do a certain amount of good, as they assist in draining the country. If the joints are made perfect and well covered round with clay, they will effectually prevent any possible escape of gas." Suppose the sole supply of light and warmth to London dependent upon the integrity of a couple of pipes-lines extending for 100 miles: would not an army be required to guard them against intentional mischief? If placed underground the operation would have to be conducted with much greater care than in laying down our street mains, in which leakage is never absolutely excluded. The only safe method would be to bury them very deeply along the sides of roads.

As to the matter of expense, the question is not so much how the capital is to be obtained as how the interest on such a large sum is to be paid. Sanitary reformers—like reformers in general—are apt to forget that, however desirable some project may seem, communities, as well as individuals, may have to forego it if they cannot afford the outlay. Would not the existing gas companies consider themselves entitled to compensation if this scheme were carried out?

Inorganic Chemistry: Theoretical and Practical. A Manual for Students in Advanced Classes. By WILLIAM JAGO, F.C.S., F.I.C. London: Longmans, Green, and Co.

CONCERNING this work we must say substantially what we have remarked concerning not a few of its predecessors; chemical phenomena and laws are here, in the main, accurately described and laid down, but not more accurately than they may be found in other manuals. Hence we are compelled to ask, as we have asked in the case of not a few earlier manuals, *cui bono*?

A few oversights have slipped in. Thus we read that "the impure commercial hydrochloric acid is largely used for the formation of chloride of tin, SnCl_2 , a salt employed by the dyer and calico-printer." But impure acid invariably contains iron, which even in infinitesimal traces spoils certain colours, such as alizarin reds and pinks. Hence the makers of such preparations of tin are very careful to use the purest hydrochloric acid attainable.

On p. 361 the author, after mentioning the use of aluminium hydrate (better, soluble aluminium salts) for precipitating the impurities of sewage, goes on to say: "As a converse of this certain pigments called lakes are prepared by precipitating aluminium hydrate in the coloured solutions, when the colouring matter is carried down by the precipitates." Now these two applications of alumina are not one the converse of the other, but identical. The hydroxide, or more probably the basic salt, forms in either case an unstable combination in sewage with the impurities and in dye liquors with the tinctorial principles.

We feel a difficulty in harmonising the two following consecutive sentences:—"Glass, if well-made, is practically insoluble in water and acids, except hydrofluoric acid. Nevertheless, water dissolves glass in appreciable quantities."

The account of the production of ferrous sulphate in § 441 is not in accordance with general practice. The author writes:—"On heating alum schists containing

pyrites sulphates of alumina and iron are formed. On lixiviation and crystallisation ferrous sulphate separates as greenish crystals." The material used for the manufacture of ferrous sulphate is the soft pyrites of the coal formations, which are not heated but oxidised by prolonged exposure to air and rain.

The account of spectroscopic research here given is more complete than that contained in many elementary works, but we do not find any notice of the absorption spectra of solutions.

The only serious defect in this work, in our humble opinion, is the author's evident faith in the Science and Art Department, and, as a corollary, in the examination *regimé*. For the teachers and students of a nation to "model their work on lines of general treatment adopted by any "Department" seems to us a great misfortune, tending to stereotype, or we might say to ossify, the national intellect. The constitution of the Department does not escape foreign criticism. The Continent says that Britain places her army and navy under the rule of civilians, and in return places higher education in the hands of half-pay officers.

CORRESPONDENCE.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—As you have opened your columns to a discussion on a circular respecting the Fellowship of the Chemical Society, signed and issued on behalf of our committee by Mr. Lloyd and myself, I am requested to write and ask you to be so good as to publish the circular *in extenso*.

The letter of Mr. A. Philip is of the nature of an *ex parte* statement, and the committee feel that in fairness the circular should also appear in your valuable paper.—I am, &c.,

FRANK L. TEED.

"THE CHEMICAL SOCIETY.

"Those who have watched the elections to the Chemical Society during the past few years, cannot fail to have observed that persons are obtaining admission as Fellows who are in no way interested in the promotion of Chemistry, or who take advantage of the Fellowship for trade purposes, or whose admission is for other obvious reasons injurious to the Society and the Chemical profession.

"The Chemical Society having been in existence for fifty years, its Fellowship is known and appreciated as a qualification, while that of the Institute of Chemistry is as yet inadequately recognised. Hence, since the formation of the Institute of Chemistry, and largely owing to the greater difficulty in obtaining its Fellowship, the number of undesirable candidates for the Fellowship of the Chemical Society has increased.

"Injudicious admissions to the Chemical Society counteract to a great extent the beneficial effects of any steps taken by the Institute of Chemistry to raise the *status* of professional chemists. The attention of Fellows is therefore drawn to the necessity of maintaining the dignity of the Fellowship of the Chemical Society, and of preventing its prostitution to trade purposes, whilst retaining its legitimate professional use.

"It has been stated that the simplest method is to blackball unsuitable candidates. This practice has not recently been properly and judiciously utilised by the Fellows of the Society. It can, moreover, only be carried out by those Chemists who are resident in London, and while throwing upon them an unpleasant duty, which should be unnecessary, it does not provide adequate means for the exclusion of undesirable persons.

"Careful attention to the two following courses of action, and unanimity in carrying them out, are in the first instance urged upon the Fellows:

"(1)—The exercise of greater care in recommending candidates, and the refusal to sign any certificate unless the candidate and his object in wishing to join the Society are well known to the Fellows applied to.

"(2)—That Fellows should vote against those whose scientific claims are obviously insufficient to entitle them to the Fellowship, or who from any other cause known to them, ought not to be elected.

"While these steps are open to the Fellows, the Council should be requested to consider the matter fully, and to frame such by-laws as may be required to place the method of admission upon a sound and satisfactory basis.

"It should be noted that under the present system of election, no opportunity is afforded for making known to the Fellows any information which might assist their judgment while balloting.

"The following recommendations are suggested to the Fellows for consideration, with the view of calling the especial attention of the Officers and Council to them, as worthy of incorporation in the by-laws:

"(a) Exact definitions of the qualifications requisite in candidates for the Fellowship.

"(b) The Council to consider every application for admission to the Fellowship: to be empowered to inquire into the suitability of candidates, and to invite and receive strictly confidential communications from Fellows who may know anything against any proposed candidate.

"(c) The Council to submit to the Fellows, at stated times, a list of those candidates whom they consider suitable for election, and also a list of those with regard to whom they make no recommendation. Full particulars as to the candidates to be supplied with each list.

"The final election of candidates must remain in the hands of the General Body of Fellows, and be carried out by a properly organised system of balloting after three 'Readings' before the Society.

"Steps are being taken to ensure the carrying out of the recommendations made herein during the ensuing Session.

"Fellows are requested to sign the annexed form, striking out any recommendations with which they do not agree, and adding any remarks that they may consider desirable; and to return it to either of the Honorary Secretaries to the Committee,

"FREDERICK J. LLOYD, 4, Lombard Court, E.C.

"FRANK L. TEED, 15, Victoria Street, S.W.

"October 1st, 1890.

"I have received your communication, dated 1st Oct., 1890, relating to the present method of electing Fellows of the Chemical Society. My views on the subject are understated. I am of opinion:—

"1. That the taking of immediate steps to maintain the dignity of the Fellowship of the Chemical Society is necessary.

"2. That Fellows should refuse to sign any Certificate unless the Candidate, and his object in wishing to join the Society, are well known to them.

"3. That Fellows should not recommend, and should vote against, those whose scientific claims are obviously insufficient to entitle them to Fellowship, or who, from any other cause known to them, ought not to be elected.

"4. That the Council should be requested to consider the matter, and to frame such by-laws as may be required to place the method of admission upon a sound and satisfactory basis.

"5. That such by-laws should contain exact definitions of the qualifications requisite in candidates for the Fellowship.

"6. That such by-laws should provide that the Council shall consider every application for admission to the Fellowship, and shall be empowered to inquire into the

suitability of Candidates, and to invite and receive confidential communications from Fellows who may know anything against any proposed Candidate.

"7. That the Council should submit to the Fellows, at stated times, a list of those Candidates whom they consider suitable for election, and also a list of those with regard to whom they make no recommendation, and that full particulars as to the Candidates should be supplied with each list.

"8. That the final Election of Candidates should remain in the hands of the General Body of Fellows, to be carried out by a properly organised system of balloting after three 'readings' before the Society."

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 13, September 29, 1890.

Absorption of Carbon Monoxide by Earth.—M. Berthelot.—The author refers to the well-known fact that it is dangerous to enter the galleries of a mine immediately after an explosion, or to even go into the cavities hollowed out by the explosion of large bombs, especially if gun-cotton or melinite has been used. Carbon monoxide is the cause of most of these accidents which have been observed in gaseous mixtures so rich in oxygen that a candle will burn in them readily. This result has been attributed to some specific property in consequence of which the soil retains carbon monoxide more persistently than other gases. The carbon monoxide thus occluded is gradually given off, and there is no reagent capable of absorbing it under these conditions. The only remedy is a sufficient and prolonged ventilation.

On the Acetylene Condensed by the Effluve.—M. Berthelot.—The condensation of acetylene effected by the effluve is quite different in character from that which takes place under the influence of heat (at about 400° to 500°). The pyrogenous polymerisation of acetylene produces especially benzene, but it takes place with a considerable loss of energy (+171 cal.), which explains the great stability of the product. On the contrary, the product condenses in the cold under the influence of the effluve, retaining a much stronger proportion of energy, as is shown by the explosive (exothermic) character of their decomposition.

Electric Spectrum of Gadolinium Chloride.—Lecoq de Boisbaudran.—The author, on causing the spark of his induction-coil with a long wire to strike over the hydrochloric solution of gadolinium, obtains a beautiful spectrum, consisting chiefly of bands having numerous rays, many of which are strongly degraded towards the red. With Demarcay's short-wire coil and a very small interpolar space the bands disappear, and there is developed a new spectrum composed of definite rays, numerous and very brilliant. With the same short-wire bobbin, but with the poles placed at the greatest possible distance from each other, the band-spectrum is developed with extraordinary splendour. The spectral reaction of Gd is therefore very decisive. The author gives a long description of the spectrum furnished by the spark of the long-wire coil. Besides these bands, there are also seen traces of some of the principal narrow rays of the high-temperature spectrum which is developed when the short-wire coil is used without elongating the spark.

On the Equivalent of the Terbias.—Lecoq de Boisbaudran.—In a former investigation (*Comptes Rendus*,

Feb., 1886, p. 395) the author determined the equivalent of his best earth, Z β (a very deep brown terbia) by weighing the sulphate obtained from a given weight of the earth. The minimum value obtained was eq.=124.7; atomic weight of the metal =163.1: but the corrections of the weights subsequently mentioned (C. R., September, 1888, p. 492; and September, 1890, p. 410) were not employed, and the earth was simply weighed, after ignition to full redness, which leaves the proportion of the oxygen of superoxidation somewhat uncertain. The author has repeated this determination, weighing the sulphate obtained from a known weight of Z β O₃, but after igniting it to whiteness and studying the absorptions excited by the substance after the extinction of the fire. The oxygen of superoxidation (much less than after mere ignition to redness) was determined, and its weight deducted from that of the earth. He thus obtains lower values.

	Equiv.	Atomic weight.
First experiment	122.63	159.95
Second "	122.01	159.01
Mean	122.32	159.48

Further determinations could not be effected from the want of sufficient material. The earth Z β , ignited to whiteness in a covered crucible, but over the oxidising flame of a gas blowpipe, dissolves slowly in dilute hydrochloric acid with the aid of heat. It still retains $\frac{0.16}{100}$ of oxygen of superoxidation; its colour is much lighter, but still very yellow.

A New Safety Lamp for Mines.—Charles Pollak.—A rectangular box of ebonite contains accumulators of the Pollak system; it rests upon a metal plate. An ebonite lid serves as support for a glow-lamp enclosed in a cylinder of thick glass. The whole is covered with a metal top, fixed closely by means of pins. A leaf of soft caoutchouc, introduced between the top and the box renders the junction hermetic. Into the lid are inserted rods of an inoxidisable metal, which pass through it and support at their bases contacts of platinum, which meet the platinum contacts of the accumulators, and which have at their summits springs, one of which is in metallic connection with a foot of the lamp. The other foot of the lamp is insulated, and can be brought in contact with a pole of the accumulator by means of a needle introduced into a horizontal channel made in the lid. As the contacts are in the interior of the box and the lid, neither the opening nor the closing of the current can cause an explosion; hence the lamp can be either ignited or extinguished in an inflammable atmosphere. If the system is dismounted, or if the glass globe of the glow-lamp is broken, the lamp is extinguished. The model exhibited weighed 1800 grms., and gives a perfectly constant light of 0.7 to 0.8 candle-power for twelve hours.

The Properties of the Natural Colouring Principles of Yellow Silk, and on their Analogy with Vegetable Carotene.—Raphael Dubois.—According to the researches of Roard and Mulder, the colour of yellow silk is due to a resinoid matter containing a red pigment, insoluble in water, though soluble in alcohol, ether, and the volatile and fatty oils. In fact, yellow silk contains several colouring-matters, some of which the author has extracted. 1. A golden-yellow pigment, soluble in solutions of potassium carbonate, and precipitated by acetic acid in excess. 2. Crystals of a reddish yellow by transmitted, and of a brownish red by reflected light. 3. An amorphous lemon-yellow matter. 4. Lemon-yellow octahedral crystals, like those of sulphur. 5. A deep greenish blue pigment present in very small quantity. The mixture of the colouring-principles 2, 3, and 4, which the author has not yet been able to separate, on account of the small quantity of material at his disposal, agrees in its characters with carotene.

MISCELLANEOUS.

Robbery of Platinum at Messrs. Dunn and Co., Stirling Chemical Works, West Ham.—The following circular has been sent out by Messrs. Dunn and Co.:—"Six Platinum Dishes were stolen from our premises on Sunday, October 12th. 3 Dishes, 10½ inches diameter by 8½ inches deep, weighing about 80 ounces each; 3 Dishes, 8½ inches diameter by 6½ inches deep, weighing about 50 ounces each. If you should hear of any attempt to dispose of such platinum (in scrap or otherwise), we would thank you to acquaint the Police and advise us by telegraph. By so doing you would confer a great favour."

Literary Announcements.—A very important new work, entitled *The Mechanical Engineers' Office Book for Machine and Boiler Construction*, will shortly be issued by Messrs. Crosby Lockwood and Son, London. The work is written by Mr. Nelson Foley, and illustrated by fifty specially prepared plates, in large folio.—The same publishers also announce *The Colliery Managers' Handbook: a Guide to Practical Coal Mining*. By Caleb Pamey, M.E., with about 400 Plans and Diagrams. Medium 8vo.—*The Analysis and Valuation of Fuel*, Solid, Liquid, and Gaseous; a Manual for Chemists and Engineers. By H. J. Phillips, F.C.S. Crown 8vo.—*Asbestos: Its Properties, Occurrence, and Uses*. By R. H. Jones. Illustrated with Collotype Plates. Crown 8vo.—*Ventilation: a Practical Handbook for Sanitary Engineers, Architects, &c.* By W. P. Buchan. Fully Illustrated. Crown 8vo.—*The Number, Weight, and Fractional Calculator*, being the third edition of "The New Calculator." By William Chadwick. Thick 8vo.—*Electric Light: Its Production and Use*. By J. W. Urquhart. Fourth Edition. Revised and extended. Crown 8vo.—*A Handbook for Young Brewers*. By Herbert Edwards Wright, B.A. Entirely New Edition. Re-written and enlarged.—Also the following New Edition in Weale's Rudimentary Scientific Series: *Portland Cement for Users*. By Henry Faija, M.Inst.C.E. Third Edition. Corrected and enlarged.

PATENTS.

Provisional Protection, from £2 2s.

The Guardians are desirous of receiving
TENDERS

at the meeting of the Board, to be held on the 29th day of October, 1890, for the supply of the following articles for twenty-two weeks from the 26th day of October, 1890:—viz., Laudanum, Quinine, (sulphate and unbleached), Cod Liver Oil, Morphia Pills, Castor Oil, Double and Single Trusses, &c., and Disinfectants.

The Contractor will be required to enter into an Agreement for the due fulfilment of his contract.

Printed Forms of Tender may be had on application to the Master, and no Tender in any other form will be received.

The Price to be stated in words at length, and Tenders to be delivered at the Board Room on Tuesday, the 28th day of October inst., at, or before, six o'clock in the evening, after which hour Tenders cannot be received.

The Guardians reserve the power of rejecting any Tender or article on delivery.

By order of the Board,

A. C. COOLE, Clerk.

9, Carfax, Horsham,
October 6th, 1890.

Chemists, Druggists, Perfumers, Store Proprietors, and others.—By order of the Trustees, under Deed of Assignment.—Estate of G. F. Fuller, Sun Street, Hitchin.

JOSEPH DAWE is instructed to offer for SALE by Tender the whole of the extensive stock herein of PATENT MEDICINES, Drugs, Perfumery, Chemist's Sundries, and Toilet Requisites, amounting at cost or stock-book prices to about £350. The Tenders will be opened on Thursday next, Oct. 30, 1890, at twelve o'clock, at the offices of Messrs Oscar Berry and Carr, Chartered Accountants, Monument House, Monument Yard, E.C. The goods can be inspected on the premises, and full details ascertained on application to Oscar Berry, Esq., C.A., Monument House, E.C.; Geo. White, Esq., C.A., 14, Old Jewry Chambers, E.C.; and to Joseph Dawe, Auctioneer, 7, Eastcheap, E.C.

Wanted, a Situation as Assistant Analyst in an Analytical or Manufacturing Laboratory. Has been three years studying General and Organic Analysis, and Assaying, and has some knowledge of Gas Analysis and Practical Physics. Certificates for Chemistry from the Science and Art Department, London; good references.—Address, G. H. B., 48, Broadmead, Bristol.

THE CHEMICAL NEWS.

VOL. LXII. No. 1614.

EXAMINATION OF OILS, FATS, AND ALLIED SUBSTANCES.

By THOMAS T. P. BRUCE WARREN.

In dealing with a mixture of two oils, the following equation will be found very useful. The mixture contains linseed oil and lard oil. The iodine absorption per cent of linseed oil is 170, and for lard oil is 52.5 per cent; x and y are the quantities respectively of each oil required to give an iodine absorption = 84.5 per cent—

$$\begin{aligned}(170 \times x) + (52.5 \times y) &= 84.5(x + y), \\ 170x - 84.5x &= 82.5y - 52.5y, \\ 85.5x &= 32y,\end{aligned}$$

i.e., 117.5 parts of the mixture contains $85.5 \times x$ and $32 \times y$ of the separate oils. We simplify by making $y = 1$. The problem now is:—How much lard oil, = 52.5 per cent, must be mixed with 1 part linseed oil, = 170 per cent, to yield a mixture = 84.5 per cent iodine absorption.

$$\frac{170 + 52.5x}{x + 1} = 84.5,$$

$$\begin{aligned}170 + 52.5x &= 84.5x + 84.5, \\ 32x &= 85.5 \therefore x = 2.67;\end{aligned}$$

hence, 1 part linseed oil and 2.67 lard oil is the mixture required for—

$$\begin{aligned}52.5 \times 2.67 &= 140.17 \text{ lard oil} \\ 170 \times 1.0 &= 170.0 \text{ linseed oil}\end{aligned}$$

$$3.67 \quad 310.17$$

adding $\frac{310.17}{3.67} = 84.5$, the iodine absorption required; then—

$$\frac{3.67 : 2.67 :: 100 : 72.8 \text{ per cent lard oil}}$$

and—

$$72.8 \times \frac{52.5}{100} = 38.22, \text{ iodine absorption for lard oil}$$

$$27.3 \times \frac{170}{100} = 46.41, \quad \text{,,} \quad \text{,,} \quad \text{linseed oil}$$

$$84.63 \quad \text{,,} \quad \text{,,} \quad \text{mixture.}$$

Supplementing the calculations given in the CHEMICAL NEWS, vol. lxii., p. 125, the following simple treatment gives direct results:—The numbers for the iodine absorption of each oil, if subtracted from the averages of the iodine absorption of a mixture, and 100, will give the percentage quantity of each oil.

Mean of 100 and 96.4 = 98.2.

$$\begin{aligned}98.2 - 42.8 &= 55.42 \text{ per cent sesame oil} \\ 98.2 - 53.6 &= 44.6 \quad \text{,,} \quad \text{olive ,,}\end{aligned}$$

Mean of 100 and 84.5 = 92.25.

$$\begin{aligned}92.25 - 19.95 &= 72.3 \text{ per cent lard oil} \\ 92.25 - 64.6 &= 27.65 \quad \text{,,} \quad \text{linseed oil.}\end{aligned}$$

The figures obtained in this way are confirmed by other methods. In dealing with a mixture of more than two oils, we must introduce other functional equations for exact results.

Let $M = 100$ be a mixture of olive, lard, and linseed oils, with iodine absorptions 84.5 per cent, 52.5 per cent, and 170 per cent respectively, and let 84.5 per cent be the iodine absorption of M .

Let 58.5° C. be the rise of temperature (Maumené's reaction) observed on M , and let 42°, 42°, and 133° C. be the rise of temperature noted on each oil respectively.

Now, as olive oil and lard oil each give a rise of 42°, and linseed oil 133°, a rise of temperature above 42° is due to linseed oil; knowing, then, the weight of linseed oil, we can eliminate from the iodine absorption of M the absorption due to linseed oil. The remaining iodine absorption is due to a mixture of olive and lard oils, and from which we can calculate the quantities of each.

Let x , y and z be the unknown quantities of each oil respectively, then—

$$x + y + z = M = 100 \quad \dots \dots \dots (1).$$

$$100 \times 84.5 = 84.5x + 52.5y + 170z \quad \dots \dots \dots (2).$$

and—

$$100 \times 58.5^\circ = 42^\circ x + 42^\circ y + 133^\circ z \quad \dots \dots \dots (3).$$

Combining equations (1) and (3)—

$$42(x + y) + 133z = 58.5 \{ (x + y) + z \}$$

$$x + y = 4.51z.$$

Substitute this for $x + y$ in equation (1)—

$$4.51z + z = 100.$$

$$\therefore z = 18.1 \text{ per cent linseed oil;}$$

whence—

$$x + y = 100 - 18.1 = 81.9 \text{ p.c. olive and lard oils.} \quad (4).$$

From equation (2)—

$$84.5x + 52.5y + (170 \times 18.1) = 8450,$$

subtracting 170×18.1 from each side of this equation, we get—

$$84.5x + 52.5y = 5373 \quad \dots \dots \dots (5).$$

From equation (4), $y = 81.9 - x$, substitute, in equation (5), this value of y :—

We have $32x = 1057.2 \therefore x = 33.0$ per cent olive oil, and $81.9 - 33.0 = 48.9$ per cent lard oil.

Collecting results :—

			Actual mixture.*
Olive oil ..	33.0	I. abs. = 27.88	Olive oil .. 33.3
Lard ,, ..	48.9	,, = 25.67	Lard ,, .. 48.5
Linseed oil ..	18.1	,, = 30.77	Linseed oil .. 18.1
	100.0		84.32
			100.0

My attention was directed to a mixture of these oils, some time ago, by a friend, who said it was used in soap-making, and was purchased as olive oil of a special grade. As such a mixture has an industrial application, this method of equating its composition may be useful.

A mixture of these oils may be complicated by adulterations of olive or lard oils, or perhaps both, by cotton-seed oil. In every case, we must first be sure that we have obtained most reliable evidence of the individual oils contained in a mixture.

THE ALCOHOL TEST FOR PURE CASTOR OIL.

By J. ARTHUR WILSON.

CASTOR oil differs in many respects from most fixed oils especially in consisting largely of the glyceride of ricinoleic acid, which is soluble in absolute alcohol. Hence this reagent can be used for the detection of impurities in castor oil. Like most other tests of a similar kind, it is not of much use for the detection of small quantities of foreign oil, owing to the solvent action of the dissolved castor oil on the small proportion of foreign oil that may be present.

The British Pharmacopoeia directs that pure castor oil shall be soluble in an equal measure of absolute alcohol and twice the measure of rectified spirit.

* Made by taking 1 part olive oil and 2 parts of the mixture of lard oil and linseed oil referred to (CHEMICAL NEWS, vol. lxii., p. 179).

According to Mr. Allen ("Commercial Organic Analysis, vol. ii., 128) this is correct at 30° C., providing spirit of exactly 0.838 gravity be used. I have examined a number of samples of both commercial and medicinal castor oil, strictly at 30° C., and by a spirit of exactly 0.838 specific gravity, and find that at exactly 30° C. the oil is not completely soluble, but that the temperature of solution varies between 38° and 43° C. I may say that the oils I used satisfied all other requirements as to purity.

In carrying out the alcohol test, it is best to operate as follows:—One measure of the castor oil under examination is mixed thoroughly with two volumes of spirit of exactly 0.838 specific gravity, and then heated, stirring well with a thermometer till complete solution. In the case of genuine castor oil this will be between 38° and 43° C., possibly lower than the former; whilst if any foreign oil be present, the temperature will be much higher; and in gross adulteration, some oil may not be dissolved even at the boiling-point of the mixture.

Tottington, Oct. 20, 1890.

THE SEPARATION OF TIN AND ANTIMONY.*

By H. N. WARREN, Research Analyst.

A CONVENIENT quantity of the sample, either an ore or slag, as the case may admit of, having been reduced to powder by the usual method, is introduced into a nickel crucible of convenient dimensions, and intimately mixed with about ten times its weight of a mixture of sodium carbonate and one of borax, the decomposition being brought about by the application for a few minutes of a full red heat from an ordinary foot blowpipe. When all necessary reaction has terminated, the contents may be advantageously poured on to the surface of an iron slab or other incombustible substance. The melt thus obtained is rapidly and completely dissolved by the aid of a small quantity of dilute HCl, introduced into a flask of known capacity, together with the small quantity which still adheres to the sides of the crucible, which is rapidly detached by pouring into the same a further quantity of dilute acid and gently warming. The contents of the flask are now diluted to the containing mark, and a known quantity withdrawn by the aid of a pipette, which is received into an accompanying flask and saturated with a stream of SH_2 gas. Tin, antimony, and similar metals of the same group, becoming consequently precipitated as sulphides. The mixed precipitates thus obtained are filtered and collected by means of a plug of cotton inserted in the neck of a glass funnel; the cotton, with its contents, after being once washed, is dislodged and received into a vessel containing a strong solution of NaHO, the same being raised and maintained for a few minutes at the boiling-point; the tin and antimony sulphide passing into solution as sulphostannate and sulphoantimoniate of soda. The soluble tin and antimony compounds thus obtained are separated by re-filtering, as in the previous case, and divided into two separate portions, being received, for convenience sake into two flasks, and labelled A and B portions. To the A portion is introduced a somewhat large excess of oxalic acid, and the solution allowed to boil until the small quantity of antimony sulphide that remains presents a pure orange-red colour, characteristic of that compound; the precipitate being collected in the usual manner, and decomposed in a porcelain crucible at a very low red heat, weighing as Sb_2O_3 and calculating to percentage of antimony. To the second, or B portion, is added an excess of dilute HCl, and the whole gently warmed; the re-precipitated sulphide thus obtained treated precisely the same as in the previous instance, weighing as oxides. The total amount of tin being obtained by

deducting the former weight of precipitated oxide obtained from the A portion, from that of the mixed oxides obtained from the second, or B, portion, and calculating by its respective formulæ.

The speed and accuracy obtained by the method foregoing largely depends upon the judicious use of the borax employed towards the commencement of the operation, whereby not only a most readily fusible compound is obtained, but, at the same time, being readily soluble in acid; inasmuch that the author has not unfrequently effected a complete assay of from twenty to thirty samples in a day; whereas, by any of the ordinary methods hitherto employed, one-tenth of that quantity would be attended by considerable labour accompanied by more or less inaccuracy.

Everton Research Laboratory,
18, Albion Street, Everton, Liverpool.

BIOPHENE.*

By LOUIS E. LEVI, Ph.D.

THE gap which now separates the fat from the aromatic series is being rapidly filled. The great researches upon pyridine, pyrrol, furfuran, thiophene, and other groups of bodies similarly derived from the fat series, have already shown to chemists that the words "fat" and "aromatic" must soon be changed to some more appropriate terms. All the reactions which the above groups possess, although they are derived from bodies in the fat series, show them to be closely related to the aromatic compounds.

The actions of acids, halogens, and all other reagents, upon these groups, are more marked, and progress more easily and rapidly, than upon the aromatic compounds. The thiophene discovered by Victor Meyer being the first body containing sulphur and possessing the properties of aromatic bodies, is of especial interest. During the time the writer had the pleasure of working under Victor Meyer, and later of working with him, the idea of a body similar to benzol, in which two "CH" groups are replaced by two sulphur atoms, was first suggested. The interest in the question, whether a body with the symbol—

would also possess the properties of an aromatic compound, was very great. Since the action of phosphorus trisulphide upon succinic acid,—

forms thiophene,—

so thiodiglycollic acid, $\text{COOH}-\text{CH}_2-\text{S}-\text{CH}_2-\text{COOH}$, should, under the same conditions, produce the body which we will call "biophene":—

The probability of the formation of biophene by this reaction is increased by the fact, that while succinic acid and phosphorus trisulphide yield thiophene, thiodiglycollic acid is composed of two half molecules of succinic acid

* The Chemical Trade Journal Prize Essay.

* From Technology Quarterly, vol. iii., No. 2.

joined together by an atom of sulphur. Biophene, is produced, as was expected, by the above reaction, but only under certain conditions.

The method of distilling the acid with the phosphorus trisulphide, the way in which thiophene is made, yields an impure product containing very little biophene, but yet sufficient to show the characteristic indophenin reaction. In order to obtain biophene in sufficient quantity and purity, the method of its preparation was modified.

Preparation of Biophene.

Five grms. of thiodiglycolic acid are mixed with ten grms. of phosphorus trisulphide, and placed in a tube, closed at one end, with 15 to 20 c.c. of ether. The tube is then closed with a fine capillary, placed in an oven, heated two hours at a temperature of 170° C. After cooling, the capillary is opened to allow the escape of the hydrogen sulphide formed. The contents of the tube, which has an odour not unlike the secretions of a skunk, is placed in a separating funnel, and washed with potassium hydrate. The alkali is then drawn off, and the remaining oil dissolved in ether and dried with chloride of calcium. After drying thoroughly, the ether is evaporated and the substance fractionated. The oil passes over in fractions between 140° and 170° C., accompanied by a slight decomposition. By re-fractionating, an oil having the constant boiling-point 165—170° is obtained. This product, when mixed with sulphuric acid, and a crystal of isatin added, gives a beautiful violet colour, the characteristic indophenin reaction of the thiophenes. The analysis showed that this oil was biophene.

0.180 gr. of the oil oxidised with HNO₃, yielded 0.7208 gr. BaSO₄.

	Found.	Theory for C ₆ H ₈ S.
Sulphur	55.00	55.17

Aceto-bienone, C₆H₄S₂COCH₃.

To a mixture of 1 grm. of biophene, 10 grms. of petroleum ether, and 1 grm. of acetyl chloride, aluminium chloride is slowly added. A reaction begins immediately, accompanied by the evolution of hydrochloric acid gas. If the flask is shaken every five minutes, the reaction will be quickly finished, and the aluminium compound of the ketone will settle to the bottom of the flask. When, on further addition of aluminium chloride, no more hydrochloric acid gas is given off, the product is warmed about fifteen minutes upon the water-bath, and the petroleum ether poured off. The thick oily mass is then decomposed with ice and water, and purified by distilling with steam. The distillate is extracted with ether, and dried over chloride of calcium. On evaporating the ether, there remains a heavy slightly coloured oil, whose odour is very aromatic and like that of aceto-thienone.

Aceto-bienone distils at a temperature above 300° C., at the same time decomposing. The action of light upon it turns it dark brown. In order to characterise aceto-bienone as a ketone, the phenylhydrazine compound was made.

Aceto-bienone and Phenylhydrazine.

Molecular weights of aceto-bienone, phenylhydrazine, and anhydrous sodium acetate are heated upon the water-bath, with a little water, about six hours. On cooling, beautiful red - coloured needles precipitate, which upon re-crystallising out of alcohol are obtained pure. The phenylhydrazide has a melting-point of 128°, and is soluble in alcohol and ether.

0.156 gr. of the salt, oxidised with HNO₃, yielded 0.2905 BaSO₄.

	Found.	Theory for C ₆ H ₄ S ₂ C $\begin{smallmatrix} \text{CH}_3 \\ \text{N}_2\text{HC}_6\text{H}_5 \end{smallmatrix}$
Sulphur	25.6	25.8

Oxidation of Aceto-bienone.

To 1 grm. of aceto-bienone take 2.55 gr. KMnO₄, and add 15 c.c. of a 14 per cent KOH solution for every 50

c.c. of a 2 per cent KMnO₄ solution. This mixture is placed in a flask with a return cooler attached, and agitated continually. The reaction begins immediately, and the liquid assumes a dark green colour. As soon as the green colour disappears, the substance is heated on the water-bath for thirty minutes, when the oxide of manganese which is formed will settle to the bottom, leaving a clear liquid. The oxide of manganese is removed by filtration, and the liquid acidified with sulphuric acid and extracted with ether. After the ether solution is evaporated, an oil remains, which, on standing, crystallises. The crystals are purified by crystallisation from alcohol or water. The water solution shows the characteristic acid tests with litmus-paper and sodium carbonate. The yield being small, an analysis could not be made.

Phenylbienylketone, C₆H₅>CO, C₄H₃S₃

is formed by the action of benzoyl chloride upon biophene in the presence of aluminium chloride, in the same way as the above-described aceto-bienone. Phenylbienylketone is a dark brown oil, having a boiling-point of 241° C., and is soluble in alcohol and ether.

0.2933 gr. oil yielded 0.6310 gr. BaSO₄.

	Found.	Theory for C ₆ H ₅ >CO, C ₄ H ₃ S ₃
Sulphur	29.18	29.09

Nitrophenylbienylketone.

Two grms. of phenylbienylketone are slowly mixed, drop by drop, with nitric acid (sp. gr. 1.62), cooled by a freezing mixture of Glauber's salt and hydrochloric acid. As soon as the two substances come in contact, a violent reaction takes place, and the oil is completely dissolved. On cooling, the product of the reaction is diluted with water, and a light yellow mass precipitates. The precipitate is then placed upon a filter, and washed with water until an acid reaction is no longer noticeable. The dried substance is then crystallised from acetic acid, and shows a melting-point of 112° C. Alcohol and ether can be used as crystallising agents, but are not so good, as the substance crystallised from them will still have a slight yellow colour. One would expect, from the analogy between this substance and the aromatic bodies, that a dinitro compound would be formed, yet such is not the case. The mononitrophenylbienylketone, in long needle-like crystals, is formed. The analysis of the substance is as follows:—

0.0893 gr. of the salt yielded 4.45 c.c. nitrogen, at a temperature of 21° C., and a pressure of 745 m.m.

	Found.	Theory for C ₁₁ H ₇ S ₂ O ₂ N.
Nitrogen	5.55	5.29

The results of this work show, once more, that compounds may be formed from the fat series which show decided characteristics of the aromatic series, and which may be regarded as belonging to it; also, the similarity between biophene, and thiophene, and benzol has been shown.

In conclusion, let me add that the action of phosphorus trisulphide upon thiodiglycolic acid has been tried, and a product obtained which shows the isatin reaction, proving that in all probability the dimethylbiophene or bioxene can also be obtained in the same manner as biophene.

On Muscarine and its Higher Homologues.—H. Lochert.—The author has obtained muscarine synthetically founded upon the total combination of trimethylamine and bromoacetal. He has also obtained compounds of bromoacetal with triethylamine, dimethylaniline, pyridine, and quinoline.—*Bull. de la Soc. Chim. de Paris*, Vol. iii., No. 12

INTERNATIONAL STANDARDS FOR THE
ANALYSIS OF IRON AND STEEL.*EXTRACTS FROM THE WORK OF THE AMERICAN COM-
MITTEE.

By JOHN W. LANGLEY.

In the summer of 1888 it was the fortune of the writer to present the subject of the desirability of establishing a set of samples of steel, which should be analysed with extreme care, in order that they might become standards to which scientific and commercial analyses of iron and steel could be subsequently referred. Also, that greater uniformity in the results of analyses might be brought about, since these standards would bear towards analytical methods somewhat the position which the original units of weight and length, the gramme and metre, or the pound and yard, preserved in Paris, London, and Washington, do to the mechanical arts.

The plan met with hearty co-operation, with the result that committees were appointed in Sweden, Germany, France, England, and America to receive the material and to see that the necessary analyses were executed.

In England the British Association for the Advancement of Science appointed a committee, who subsequently published a plan of operations for that country, reports of which will be found in the British Association Transactions for 1888 and 1889.

The writer of this paper was entrusted with the duty of preparing the material and distributing it to the five countries named. This has been done, and analytical work on the steel is now going forward.

In the United States a committee of seven chemists was appointed to make the analyses, consisting of:—Andrew A. Blair, Philadelphia, Pa.; Regis Chauvenet, Golden, Colorado; Thomas M. Drown, Boston, Mass.; Charles B. Dudley, Altoona, Pa.; John W. Langley, Pittsburgh, Pa.; Albert B. Prescott, Ann Arbor, Mich.; Porter W. Shimer, Easton, Pa.

This committee held a meeting at Washington, Feb. 19th, 1890, and came to the decision that the whole subject of the existing methods for the determination of carbon in iron and steel seemed to be affected by so many discrepancies and differences of opinion that, before beginning work on the International Standards, it would be desirable to make a preliminary study of methods. Accordingly, the writer was asked to prepare some additional material which could be used in somewhat large quantities for the above purpose only, and which should be known as the "Experimental Standards," to distinguish them from the "International" ones.

Method of Making the Exp. Standards.

An ingot of tool steel, $3\frac{1}{2}$ inches square, poured from a single crucible in which the metal had been thoroughly "dead melted," was heated and hammered barely enough to round off the corners. The ingot was then cut into two pieces, one of which was then re-heated and hammered down to a bar $1\frac{1}{2} \times \frac{1}{2}$ inches. The other half of the ingot was turned in a lathe with a blunt tool, exactly as in the manufacture of the International Standards, and the turnings, after sifting from fine dust, were thoroughly mixed and then sealed up in glass jars. The hammered bar was drilled and the drillings similarly treated. This material was given by the Crescent Steel Company, of Pittsburgh.

The object of this was to have two bodies of metal presumably identical in original composition, but one of which had received a large amount of mechanical work, the other approximately none. These samples are designated Exp. Standard, Ingot, and Exp. Standard, hammered, respectively.

Scope of the Proposed Work.

The committee decided to limit the investigation to the following points at first:—

a. The best method of conducting the igneous combustion of the carbon previously liberated from the metal by a solvent.

b. The best method of conducting the aqueous combustion of the carbonaceous residuum left by the solvent.

c. The influence of the solvent on the quantity and mode of release of the carbon.

For division a it was decided further to commence with a study of the method of burning the carbon in a stream of oxygen.

This work was assigned to Messrs. Blair, Dudley, and Shimer.

For b. The examination of oxidation methods by hot solutions of sulphuric and chromic acids. Work by Mr. Langley.

For c. The use of a double chloride of copper and ammonium, or of copper and potassium, either neutral or acid. Work by Messrs. Blair and Dudley.

A description of the apparatus for igneous combustions is as follows:—

The apparatus used by Dudley consisted of an ordinary Bunsen furnace with 15 burners, in which was a porcelain combustion tube five-eighths of an inch internal diameter, and eighteen inches long. Inside this tube, about three inches from the end towards the absorption apparatus, was granulated and porous oxide of copper, occupying about four inches of the length of the tube, and filling the bore. This was held in place by asbestos plugs at either end. Next to the oxide of copper, towards the boat, was placed a roll of metallic silver about 4 inches long, nearly filling the bore of the tube. Rubber corks were used at each end. The combustions were all made in oxygen gas, using air to finish the aspiration and clean out the tube. The oxygen gas used was obtained in the market in cylinders, the gas being compressed to 250 lbs. per square inch. Between the oxygen holder and the combustion tube was placed first a copper tube, about four feet long and $\frac{1}{2}$ inch in diameter, fitted with three coils at the middle; next a potash bulb, and after that a chloride of calcium tube. All the oxygen gas, and the air used in the combustions, was passed through these parts. The copper coils were kept red-hot by a Bunsen burner, during the passage of the gases, the idea being to burn any possible traces of combustible in the gas or air, and absorb the CO_2 formed before they should go into the combustion tube. Between the absorption end of the combustion tube and the potash bulbs were, first, a washing tube containing about 5 c.c. of sulphate of silver solution with perhaps $\frac{1}{2}$ gm. of silver sulphate, and next, a chloride of calcium tube. The potash bulbs were of the Geissler form, of small size made to order. These were fitted with a small chloride of calcium tube containing chloride of calcium simply, and commonly called the prolong. The whole absorption apparatus weighed, when charged, about 60 grms. The absorbing solution in the bulbs was the ordinary caustic potash solution recommended by Fresenius. The absorption apparatus was protected against the aspirator bottle by a full size chloride of calcium tube. The joints were made with ordinary rubber tubing. The carbon from the steel was caught on an asbestos filter in a platinum boat, and dried after very complete washing at about 90°C . The boat with its filter and carbon was put into the tubes without transfer. During combustions a slight pressure above the atmosphere was always maintained in the combustion tube. Careful experiments show that the sulphate of silver washing tube is a complete protection against hydrochloric acid, and the metallic silver in the tube was relied on for protection against free chlorine, or other chlorine compounds. The time of making a combustion was about an hour and a quarter; fifteen to twenty minutes being taken to heat the oxide of copper, about half an hour for the burning, and twenty-five to thirty minutes for the air aspira-

* Transactions of the American Institute of Mining Engineers, Pittsburgh International Session, October, 1890.

tion. Blair's apparatus is substantially the same as the above. His purifying train following the combustion tube contains a tube of anhydrous sulphate of copper on pumice stone. This tube is always freshly filled.

Shimer's apparatus is a porcelain tube containing oxide of copper. A stream of purified oxygen is used. An anhydrous copper sulphate absorbing tube is employed, and then the customary CaCl_2KHO and CaCl_2 absorbents.

Preliminary Results of Oxygen Combustion.

In the following analysis, a solution of double chloride of copper and ammonium, except where otherwise noted, was used as the solvent of the steel. The carbon sponge was washed with dilute HCl and water till the filtrate was free from chlorine, then the asbestos with adhering carbon was put into the combustion tube. These determinations were made before the elements of uncertainty attaching to the use of double chloride were discovered, and it will be seen in the latter part of this paper, that quite different numbers can be obtained.

Under date of April 22nd, 1890, Dudley reports: Exp. Standard, Ingot, contains:—

Carbon	1'058 per cent.
"	1'065 "
"	1'052 "
"	1'058 "

Average .. 1'058 per cent.

Ditto hammered standard:—

Carbon	1'050 per cent.
"	1'051 "
"	1'051 "
"	1'060 "
"	1'050 "
"	1'056 "
"	1'056 "

Average .. 1'053 per cent.

Under date of April 5th, 1890, Blair reports, that using double chloride of copper and ammonium, with enough ammonia added to produce a slight cloud, and re-dissolving the basic salts formed in acidulated double chloride, he obtains:—

	Ingot.	Hammered.
Carbon	1'016	1'022 per cent.
"	1'013	1'020 "
"	1'015	1'025 "
"	1'010	1'022 "

He then weighed out four portions of the "ingot" sample, and added to each 200 c.c. double chloride of copper and ammonium, after adding to each the following amounts of strong HCl :—

HCl .	Carbon.
10 c.c.	1'048 per cent.
20 "	1'048 "
30 "	1'048 "
40 "	1'051 "

He then took four portions of the "hammered" sample, and treated them each with 200 c.c. of double chloride and 20 c.c. HCl . Results:—

Carbon	1'046 per cent.
"	1'046 "
"	1'044 "
"	1'049 "

Showing that the addition of HCl in excess of five per cent does not sensibly vary the results.

A combustion of sugar at the same time showed:—

Carbon	42'05 per cent.
"	42'14 "
Theory	42'11 "

In answer to the suggestion that possibly oxides of nitrogen might be derived from the breaking up of am-

monia retained by the carbon sponge, Blair reports, under date of April 17th, that he has made four combustions on the "ingot" sample, using a four times re-crystallised double chloride of copper and potassium.

No. 1, Carbon	1'010 per cent.
" 2, "	1'044 "
" 3, "	1'012 "
" 4, "	1'022 "

No. 1 was dissolved in the filtered solution of the above double chloride.

No. 2 was dissolved in 200 c.c. double chloride, with 200 c.c. strong HCl .

Nos. 3 and 4 were dissolved in the filtered double chloride, to which enough potassic hydrate had been added to produce a slight permanent precipitate.

Blair offers the hypothesis that a strictly neutral or slightly alkaline double chloride dissolves a small portion of the carbonaceous matter, which is consequently lost so far as the combustion is concerned. Therefore, the addition of acid, by preventing this action of the liquid on the carbon sponge, will give higher and more nearly accurate results.

That the use of an acid double chloride solution gives higher results was promptly verified by Dudley and Langley. This subject is more fully discussed in the latter portion of this paper.

Shimer reports, April 25th, that by using 4 grms. of steel in a neutral solution of double chloride of copper and ammonium, he obtains:—

"Ingot," average of two combustions, 1'055 per cent.

"Hammered," average of two combustions, 1'052 per cent.

The Wet Method.

The chromic acid combustion was conducted in an apparatus originally designed by Dr. Hermann Wedding, although the method of absorption used by him has been radically modified. Wedding's design consists of a flask capable of holding 220 c.c., and provided with a glass cap of two tubulures; through one of these passes a funnel tube with stop-cock, and through the other the delivery tube surrounded by a water jacket. All the joints are of ground glass.

The merit of this apparatus is its compactness and its freedom from rubber or cork joints, at least in the parts liable to come in contact with chromic acid. The absorption train, which is wholly different from Wedding's, consists of:—

1st. A tube filled with pumice stone and anhydrous sulphate of copper.

2nd. A small washing bottle containing the "pyro" solution referred to later on.

3rd. A solution of sulphate of silver.

4th. A wash bottle of strong sulphuric acid.

5th. A chloride of calcium tube, having a small plug of moist cotton in its anterior end.

6th. A Liebig tube, containing potassic hydrate solution.

7th. A U-tube, having solid potassic hydrate in its anterior limb and granulated calcium chloride in the posterior one.

8th. A chloride of calcium guard tube.

9th. An aspirator filled with water.

The absorption portion for CO_2 is constituted by Nos. 6 and 7. The other parts, except Nos. 2 and 3, need no explanation, since they are well known adjuncts of the chromic acid method described in such treatises on analysis as those of Fresenius and of Blair.

The method of conducting a combustion is to place the carbon, which has been liberated from 3 grms. of steel by the action of 150 c.c. of solution of double chloride of copper and ammonium, to which 10 c.c. of HCl has been added, into the flask, and run in through the funnel tube 100 c.c. of a solution made by dissolving 10'5 grms. CO_2 , 66 c.c. H_2O in 210 c.c. strong H_2SO_4 . Purified air is drawn through at the end of the combustion.

The train at first used did not contain the "pyro" tube

No. 2; under these conditions the following numbers were obtained from the exp. ingot standard:—

Carbon	1'099
"	1'145
"	1'040
"	1'058
"	1'109

A search was instituted to find the cause of these discordant results. It is well known that the carbon sponge from the action of the double chloride retains chlorine or hydrochloric acid in a form not removable by washing; suspicion at once fell upon the HCl known to be evolved from the carbon sponge.

A series of blank combustions were made, and also mixtures of air and HCl were drawn through the absorption train. It was found that the anhydrous CuSO_4 would only stop HCl when it was perfectly fresh and in relatively large quantity, a quite small degree of hydration impairing its absorbing powers seriously. A tube containing an aqueous solution of sulphate of silver was then added to the CuSO_4 tube, with the result that vapours of HCl are perfectly and completely arrested. When this point was established blank combustions were made and small quantities of chlorides introduced into the chromic acid mixture; it was invariably found that the potash bulbs gained in weight. As one example out of many the following is quoted:—

One tenth grm. of NaCl in generating flask. CuSO_4 and Ag_2SO_4 absorbents were interposed. The silver solution showed not a trace of chloride, and yet the potash train gained 0'0055 grm.

This gain appears to be owing to chloro-chromic anhydride, or to oxides of chlorine, not absorbable by copper or silver sulphates.

This observation is not new, for it has previously been noted by other chemists that chloro-chromic anhydride was not arrested by copper sulphate.

After a long series of experiments an absorbent for these bodies has been found in the following solution:—

Pyrogalllic acid	0'2 grm.
Potassic oxalate	5'0 "
Sodic chloride	3'0 "
Sulphuric acid	0'2 "
Water to make up to	20'0 c.c.

The theory of the action of this mixture is as follows:—

The pyrogalllic and oxalic acids are deoxidants. The sulphuric acid will form potassic sulphate, liberating a very little free oxalic acid to guard against the solution becoming alkaline. The sodium chloride is not essential, but it is advantageous by diminishing the solubility of CO_2 in the liquid.

The action of this absorbent is very energetic. It will allow HCl to pass through it without change, but the smallest traces of free chlorine, or of oxides of chlorine, or of chloro-chromic anhydride, at once turn the solution brown, and are either arrested or changed into HCl. Indeed, as a qualitative reagent this liquid will approximate to iodised starch paper.

In using this in the absorbing train, the copper sulphate tube may be dispensed with, the pyrogalllic liquid being used in its place, and followed by a sulphate of silver tube, so that the train between the generating flask and the potash bulbs will contain:—(1) a cooling tube; (2) the "pyro"; (3) the sulphate of silver; (4) sulphuric acid; (5) chloride of calcium.

Blank "combustions" were made as before with NaCl, using the Pyro train till it was proved that there was no systematic gain in weight of the potash bulbs.

As examples of carbon oxidation in presence of chlorides—Taken 0'0712 grm. sugar with a crystal of NaCl. Found 0'1098 grm. CO_2 . Theory 0'110 grm. Taken 0'030 grm. Ceylon graphite, of about 3 per cent ash. Found 0'0292 carbon, equal to 97'3 per cent carbon.

The following analyses were then made, using the new train:—

Exp. standard, hammered, 1'075 per cent C.	
" " " 1'070 "	
" " ingot, 1'041 "	
" " " 1'034 "	

It seemed possible that the carbon sponge left on the asbestos, after filtering from the double chloride solution, might suffer a slight oxidation and loss of carbon while drying. A set of duplicate analyses were therefore made on a variety of steels. The terms wet and dry, below, refer to the state of the carbon sponge when introduced into the chromic acid flask. The drying was performed at a temperature not above 100°C .

	Wet.	Dry.
Steel A	0'981	0'936 per cent C.
" B	0'836	0'813 "
" C	0'904	0'891 "
" D	1'054	1'073 "
" E	1'145	1'154 "
" F	1'095	1'108 "
" G	1'027	0'968 "
Pig	3'695	3'722 "
Totals,	10'737	10'665 "
Average,	1'342	1'333 "

These determinations were made before the discovery of the variability of action of double chloride with age and manner of crystallising, to be pointed out hereafter. Moreover, they were distributed over a period of three months, so that some of the differences may be properly attributed to the chlorides used. Still, these would pretty well neutralise each other in sixteen determinations, so that the practical identity of the final averages would appear to show that the sponges do not lose appreciable amounts of carbon by drying.

On the other hand, the "hammered" standard, similarly treated, but having the sponge dried in an air-bath at a temperature not exceeding 120°C ., gave—

	Wet.	Dry.
Carbon	1'064	1'027
"	1'059	1'023
"	1'064	1'018
"	1'045	1'032
Average	1'058	1'025

Apparently, therefore, there is a loss of carbon by drying the sponge at temperatures above 100°C . The same double chloride, acidulated, was used in these eight determinations.

(To be continued).

PHOSPHORUS IN PIG-IRON, STEEL, AND IRON ORE.*

By CLEMENS JONES, Hokendauqua, Pa.

THE analytical history of phosphorus in its relation to the metallurgy of iron is an interesting study, the progress of which runs parallel with the development of the greatest industry in the world. Without the means of finding out how much phosphorus crude pig-iron contained, the Bessemer steel process would have been impossible. To do this was originally tedious and slow work; on the other hand, the "direct" process of to-day, as well as the various special processes for steel or iron, have demanded the utmost rapidity in the operations of analytical chemistry.

In general, any rapid process for the conversion of un-

* Transactions of the American Institute of Mining Engineers, Washington Meeting, February, 1890.

refined metal into a product of standard composition depends upon the rapidity of some accurate means employed to control it. Moreover, in our modern practice, it is not improbable that the differences in physical properties among the various makes of iron or steel are affected, if not produced, by the use of different methods of analysis.

Recourse is always had for correction to the "standard methods," but I incline to think that these methods are susceptible to error. It is very certain that the system of duplicates would not be resorted to if the fact were otherwise. Even when duplicated, under the most careful and skilful manipulation, these standard methods produce disagreements. In proof of statements like these, which may sound heretical, I hope, further on, to cite some evidence worthy of attention. I do not now mean to lay claim to the distinction of discovering the ultimate corrective. That result will come, no doubt, in time, as the product of the experience of many workers.

In the case of phosphorus, as of the other ingredients of iron or steel, a great deal has been done to accommodate the methods of analysis in vogue to the growing necessity for more rapid procedures. Much of this work has concerned what might be called the incidents of method. There is no better example of the accumulation of these incidental improvements than the work done on phosphorus; and I believe that the final successful outcome of such progressive changes will be properly considered the standard method.

The ideal analysis, both for refined conditions and delicate determinations, is to be found in nearly all instances in a volumetric method. But in the preparatory stages the treatment by this standard method must consist of *visible reactions*.

I have classified what appear to be the salient features already embodied separately in the different methods; and when so related, they apparently fulfil the conditions and the object that each has had in view.

The method of Mr. F. A. Emmerton (*Trans.*, xv., 93), is the real beginning of this progressive series. As recommended, certain objections were found to it. The first of these was in the use of dilute nitric acid as a wash for the yellow precipitate. Acid ammonic nitrate, as suggested by Dr. Drown, was then substituted with only partial success. The presence of nitric acid in the final solution reduced for titration seriously interfered with accurate work. I communicated this fact to Mr. A. L. Colby, chemist to the Bethlehem Iron Co., who at the time was also experimenting. His conclusion, reached by careful examination through it, pointed out the remedy. I quote from Mr. Colby's notes, kindly placed at my disposal:—

NOTES ON EMMERTON'S METHOD FOR PHOSPHORUS,
OCTOBER, 1887.

Blank Phosphorus Determination.—A clean dry 16 oz. Erlenmeyer flask was washed twice with am. nitrate wash (NH_4NO_3 , 200 grms.; HNO_3 conc., 30 c.c.; H_2O , 2000 c.c.), pouring it on a filter, and draining the flask as much as possible each time; the paper was then washed twice with the wash and sucked dry; the stem of the funnel was rinsed off on the outside with water, and the funnel placed in the flask; paper punctured with platinum rod, and washed with dilute NH_4OH (1:4), about 30 c.c. being used; 5 grms. granulated zinc was added to the contents of the flask, and 80 to 90 c.c. H_2SO_4 of the dilution, 150 H_2SO_4 : 420 H_2O . A small funnel was put in the top of the flask, which was then heated till nearly all the zinc was dissolved. The reduced solution was then filtered; flask, funnel, and paper were thoroughly washed with hot water, and the solution was titrated with KMnO_4 at once.

A permanent tint was not obtained until 12 c.c. of KMnO_4 had been used. (As 1 c.c. of KMnO_4 = 0.000106 grms. P., this is equivalent to an error, in analysing an ore where 8 grms. are taken, of 0.016 per cent., and for a

steel or iron where 4 grms. are taken, of 0.032 per cent P.).

Above blank test, using as a wash HNO_3 (1:25). Permanent tint at 8.5 c.c. of KMnO_4 .

Above blank test, using as a wash HNO_3 (1:50, which Emmerton recommends). Permanent tint at 3.2 c.c. of KMnO_4 .

Above blank test, using as a wash H_2SO_4 (1:50). Permanent tint at 0.45 c.c. KMnO_4 .

Above blank test, using as a wash $(\text{NH}_4)_2\text{SO}_4$, made up as follows: $(\text{NH}_4)_2\text{SO}_4$, crystals, 25 grms.; H_2SO_4 , conc., 50 c.c.; H_2O , 2500 c.c.

Permanent tint at 0.45 c.c. of KMnO_4 .

Zinc 5 grms. and H_2SO_4 (90 c.c.), placed directly in a dry, clean flask, reduced as usual, filtered, washed and titrated. Permanent tint at 0.45 c.c. of KMnO_4 .

To ascertain if yellow precipitate is soluble in H_2SO_4 , or in $(\text{NH}_4)_2\text{SO}_4$ wash, which would prevent its use as a substitute for NH_4NO_3 wash. Selected crystals of $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$, containing by theory 8.6572 per cent P, were dissolved, 1.5408 grms. in 500 c.c. distilled water, and the following tests were made:—(See Table, next page).

As the blanks run both with H_2SO_4 wash (1:50) and with $(\text{NH}_4)_2\text{SO}_4$ wash used up 0.45 c.c. KMnO_4 instead of 0.5 c.c., as subtracted above, analyses Nos. 4, 10, and 11 should show 8.685 per cent instead of 8.668 P.

The above analyses, using 10 c.c., were made on too small a quantity of Na_2HPO_4 . Small variations in KMnO_4 make too large differences in per cent of P, 0.5 c.c., or one drop of KMnO_4 , being equal to 0.007 per cent P.

But the set of analyses shows that even strong H_2SO_4 (1:5) exercises no appreciable solvent action on yellow precipitate, and that $(\text{NH}_4)_2\text{SO}_4$ wash is rather better in agreement than H_2SO_4 (1:50).

As an example of the possibilities of the method when using the $(\text{NH}_4)_2\text{SO}_4$ wash for determination of small amounts of P, a solution of C.P. Fe_2Cl_6 was tested. Of this solution, which had been prepared from the filtrate from P determinations in pig-iron, by precipitation with NH_4OH , thorough washing, and solution in HCl , 25 c.c., containing about 2.5 grms. Fe, were precipitated for P as usual; the cloud of yellow precipitate was filtered off, washed with H_2SO_4 (1:50), dissolved, reduced, &c., as usual, titration giving only 0.75 c.c. KMnO_4 , which after zinc correction of 0.5 c.c., equalled 0.001 per cent phosphorus—a result not obtainable when using NH_4NO_3 wash.

In addition the following test of ores were made, using $(\text{NH}_4)_2\text{SO}_4$ wash for the volumetric determinations, and washing four times on the paper (instead of twice, to test the solvent action, if any), and twice in flask.

Sept. 23.—*Filtration by suction*, taking the usual precaution of draining flasks and funnels, and washing stem of funnel.

interesting to note that nearly a year later Mr. Porter W. Shimer, in a paper before the Institute (*Trans.*, xvii., 100), observes: "Sulphuric acid and ammonium sulphate completely take the place of nitric acid and ammonium nitrate."

In the same paper Mr. Shimer describes the use of potassium permanganate as an oxidising agent. This appears to be the next important detail. By means of it the complete oxidation of the phosphorus to ortho-phosphoric acid, as Dr. Drown puts it, is accomplished. This is indispensable, and cannot be omitted in the solution of pig-iron, steel, or iron-ore.

Dr. Drown's method (*Trans.*, xvii.) of dissolving pig-iron or steel in nitric acid of 1.135 specific gravity, in which potassium permanganate, as suggested by Mr. Shimer, is used as an oxidising agent, is a most happy expedient. It opens the way to the most rapid method in use. There is no ground to doubt its efficacy, if applied to iron ore, by taking advantage of a simple device, namely, solution in dilute sulphuric acid of the fused residue from the ore. According to Dr. Drown, silicon exerts no influence on the determination of phosphorus in pig-iron or steel. As a soluble silicate there is good evidence of its non-interference in the treatment of iron ore. A determination in iron ore can thus be made in nearly the same time as in iron or steel.

Here, then, seem to be collected nearly all of the requisite conditions. There is but one remaining—the reduction of the molybdic acid. I believe that this is fully covered by using the method discovered by me for reducing ferric solutions (*Trans.*, xvii., 411). I have found that it applies in all respects equally well to the complete and instantaneous reduction of molybdic acid.

It is possible then to reconstruct a method, based on these incidents, which should be peculiarly adapted to every demand for the rapid and accurate determination of phosphorus.

Before advancing so far, however, I propose to show with what degree of accuracy these principles may be employed, by giving the following results. These were obtained by the Emmerton method, modified by the use of ammonic sulphate in washing the yellow precipitate, and by the use of the reductor.

No. 3588.—Pig-Iron.			
Weight. grm.	KMnO ₄ . c	Correction. c.c.	Phosphorus. Per cent.
0.5000	18.67	0.03	0.447
0.5000	18.52	0.03	0.443

1 c.c. KMnO₄ = 0.00012 P.

No. 3980

	Phosphorus. Per cent.
No. 1, gravimetric	0.717
No. 2, volumetric	0.720

The following comparison is between this method (called "Reductor") applied to iron ore, and the Emmerton method of adding the zinc directly.

No. 4260.			
Weight taken. grms.		KMnO ₄ . c.c.	Phosphorus. Per cent.

The conclusion to be drawn is not that the direct use of zinc always gives uniformly low results (by reason of the higher correction), but that the same errors are introduced, as I have pointed out in the case of the reduction of ferric solutions.

(To be continued)

ON THE
VARIATION OF THE DENSITY WITH
THE CONCENTRATION OF WEAK AQUEOUS
SOLUTIONS OF CERTAIN SALTS.*

By Prof. J. G. MacGREGOR, D.Sc.

In a paper on "The Density of Weak Aqueous Solutions of Certain Salts,"* which I had the honour of laying before the Royal Society of Canada in 1885, I pointed out, as an incidental result, that in the case of zinc and magnesium sulphates, the increase in density produced by adding the anhydrous salt to water was proportional, or very nearly proportional, to the amount of salt added, provided the solutions thus formed did not contain more than about 2 or 1 per cent respectively of salt. I have recently had occasion to make a number of determinations of the concentration and density of dilute solutions of the above salts and of several others, and to hunt out similar determinations by other observers; and the data thus obtained enable me to settle, in the case of a number of salts, the limits of concentration within which this simple proportionality holds.

The solutions which I examined myself were made by mixing weighed quantities of the crystallised salt with weighed quantities of water. The salts had been purchased as pure, and had been re-purified by crystallisation. The water had been carefully distilled. In the case of iron sulphate solutions it was boiled in order that the solutions employed might contain but little dissolved air.

In all cases at least two solutions of any one salt were prepared by mixing weighed quantities of the salt and of water. Usually the other solutions required were prepared by diluting one of these with water, or strengthening it by adding salt. In the case of iron sulphate, all the solutions used were prepared by mixing salt and water directly, this course being pursued in the case of this salt, because of the fact of its undergoing progressive decomposition after being dissolved in water, and of the consequent necessity of determining the density of a solution as soon as possible after the solution had been formed.

In preparing the solutions, all determinations of mass were made by the method of double weighing, and all weighings were made in stoppered bottles. The weighings were of course reduced to *vacuo*. The errors of the standards employed were neglected. The balance used was a delicate one made by Colliot, of Paris. In calculating the percentage of anhydrous salt in the various solutions, the values of the atomic weights given in Clarke's "Constants of Nature" were employed.

Densities were in all cases determined by means of a specific gravity bottle. The bottle used had a volume of about 50 c.c. It was of thin glass, but was not so thin as to be readily deformable, and was provided with an accurately ground perforated glass stopper. All determinations of density were made at 20° C. A bottle containing the solution and a thermometer was placed along with the specific gravity bottle in a bath slightly above 20° C. When the solution had taken the temperature of 20° it was at once poured into the specific gravity bottle, and the latter stoppered, dried, and weighed. The thermometer used had been provided with a table of corrections at Kew. Weighings for the determination of density were made in one pan only (always, of course, the same pan), the double weighings for the determination of mass having shown that the ratio of the lengths of the arms of the balance was practically constant. In calculating the densities from the observations, the usual corrections were applied.

In using the determinations of other observers, I found that in many cases they had not stated whether their published percentages were percentages of anhydrous or of crystallised salt in solution, and that in many cases

also they had omitted to state whether their specific gravities were referred to water at the same temperature as the solution, or to water at some other temperature as 0° C. or 4° C. In the former cases, however, comparison of the observations of different men usually showed whether anhydrous or crystallised salt was meant. In the latter it was often possible, especially when several observations of dilute solutions were given, to determine the temperature of the water which was taken as the standard substance by plotting a curve of concentrations against specific gravities, and noting the point of its intersection with the axis of specific gravities.

In the case of all salts for which the densities of sufficiently dilute solutions have been determined, either by myself or by other observers, I find that up to certain concentrations, varying from 1 to 5 per cent of anhydrous salt in solution, the excess of the density of a solution over that of water at the same temperature as the solution is directly proportional to the percentage of salt in the solution. In symbols, if D_t , d_t are the densities at the same temperature t of a solution and of water respectively, and if p is the percentage of anhydrous salt in the solution, we have thus—

$$D_t = d_t + k p,$$

where k is a constant for all sufficiently dilute solutions of any one salt. The value of the constant k for any one salt having been determined, the densities (in grms. per c.c.) obtained from the above formula, are found to agree with observed values to the fourth place of decimals within the limits of concentration specified above.

The following tables give the concentrations and observed densities of dilute solutions of a number of salts, together with the densities calculated by the aid of the above formula with the proper value of k . The fourth column gives the differences between the observed and calculated values. The values of the density of water used in these calculations are those given by Volkmann,* which are based on the observations of Hagen Matthiessen, Pierre, Kopp, and Jolly.

Zinc Sulphate.—ZnSO₄.

Observer:—The author.

Temperature:—20° C.

Formula:— $D_{20} = 0.99827 + 0.0103918 p$.

Percentage of anhydrous salt in solution.	Observed density at 20° C. Grms. per c.c.	Calculated density at 20° C. Grms. per c.c.	Difference.
1.1622	1.01032	1.01035	+0.00003
1.8698	1.01774	1.01770	-0.00004
2.7281	1.02662	1.02662	0.00000
5.9150	1.06104	1.05973	-0.00131

The above formula thus gives the densities of solutions of zinc sulphate accurately to four places of decimals, provided they do not contain more than about 3 per cent of anhydrous salt in solution.

Magnesium Sulphate.—MgSO₄.

Observer:—The author.

Temperature:—20° C.

Formula:— $D_{20} = 0.99827 + 0.0106324 p$.

Percentage of anhydrous salt in solution.	Observed density at 20° C. Grms. per c.c.	Calculated density at 20° C. Grms. per c.c.	Difference.
0.6907	1.00553	1.00561	+0.00008
1.6525	1.01584	1.01584	0.00000
2.5809	1.02525	1.02571	+0.00046
3.7689	1.03700	1.03834	+0.00134

The formula is thus applicable up to about 2 per cent. The following is another series of observations of solutions of the same salt:—

* From the *Trans. Roy. Soc. Canada*.
Ibid., vol. iii. (1885), sec. 3, p. 15.

* *Wied. Ann.*, xiv. (1891), p. 260.

Observer:—Schiff.*

Temperature:—23° C.

Formula:— $D_{23} = 0.99762 + 0.0098176 p$.

Percentage of anhydrous salt in solution.	Observed density at 23° C. Grms. per c.c.	Calculated density at 23° C. Grms. per c.c.	Difference.
0.4879	1.00241	1.00241	0.00000
0.9758	1.00720	1.00720	0.00000
1.4637	1.01199	1.01199	0.00000
2.4395	1.02176	1.02157	-0.00019

Thus in the case of Schiff's observations also, the formula holds up to between 2 and 2.5 per cent.

(To be continued).

NOTICES OF BOOKS.

The Chemistry of Iron and Steel-Making, and of their Practical Uses. By W. MATTIEU WILLIAMS, F.C.S., F.R.A.S. (formerly Chemist in the Works of Sir J. Brown and Co., Lim.). London: Chatto and Windus.

MR. WILLIAMS has produced several works both scientific and technical, as well as some of a more general nature. But, unlike some versatile authors whom we might name, he never comes forward to instruct the public on any subject without knowing something or other more about it than may be compiled from the literature of the day. He is not merely an acute observer, but one who can make his observations teach useful lessons. In his preface he divides working men into three great classes. The first, and unfortunately the largest, neither know, think, or care anything about the scientific basis of their work; the second treat the laboratory with contempt, and resent the interference of the chemist; the third class are awakening to a perception that practical men might after all "learn something from the theorists."

The present work is the completion of a few lectures which Mr. Williams delivered some years ago to an audience of this third section. He urges that the men of this class "crave to learn the why and the wherefore of the operations which they are daily performing. He protests against putting into the hands of such men a re-hash of mere scholastic treatises, and fears that forcing such matter upon them under the guise of technological instruction may drive the men back into the second class. He pleads for the scientific—not literary—education of the working man, so as to render him a better observer and more able to draw right conclusions from phenomena.

His introductory chapter is chiefly devoted to an account of the struggles of Dud Dudley, son of Edward, Lord Dudley. To him we are indebted for the reduction of iron ores with fossil fuel—a step greater than that effected by Messrs. Thomas and Gilchrist, since without it the English iron trade would be simply non-existent.

We are often told that by special good luck Britain is most abundantly supplied with coal and iron ores in immediate juxtaposition; but the author reminds us that our native iron ores are among the worst and the poorest in the world, and that the chief improvements in the manufacture of iron have been the result of struggles against the difficulties presented by impurities. He does not, however, consider that iron pyrites, even after its sulphur has been roasted out in the manufacture of sulphuric acid, has a future as an iron ore, though it may be useful as a source of certain salts of iron.

On the word "slag" the author entertains peculiar views. The vitrified matter which is run off from smelting furnaces he would name "cinder," and confine the term "slag" to the scales struck off from iron in forging. This proposal, if carried out, would, we fear, lead to confusion. "Cinder," except in iron-works, signifies coal

from which the hydrocarbons and all the more volatile matter has been burnt away, and which is thus converted into a kind of coke. But whatever we may agree to call the mixture of silicates run off down the furnace, its uses are not sufficiently numerous and extensive. The proposal to employ it as a raw material for coarse glass bottles seems, according to the author, not to have been successful. Slags rich in alumina and poor in lime, if dissolved in hydrochloric acid, form a crude aluminium chloride far superior to alum for the treatment of sewage and other foul waters.

The author's demand upon blast-furnaces is high, but not utopian. He writes: "Any blast-furnace which does not roast its own ores, coke all its own coal, and causticise its own lime, is an imperfect machine, with which the enterprising iron-master should continue to be dissatisfied." At the same time, if the blast-furnace cokes all its own coal, we fear that the ammonia and the tar with its bases will not be utilised. The same chapter concludes with a pithy hint to utilisers of waste materials. Where labour is dear and fuel abundant "the colliery proprietor who gets his coal at four shillings per ton and his labour at five shillings per day, is reasonably deaf and blind to scientific demonstration which shows how he may save a ton of coal at the cost of a day's labour."

The chapter headed "Fallacies Concerning Steel" is most instructive. Mr. Williams exposes the notion held even by men of repute that the differences between steel, wrought-iron, and cast-iron, "essentially depend upon differences in the proportion of carbon." It has been asserted that merchantable steel could be made from English pig-iron by simply stopping the "blow" before complete decarbonisation. Hence many inventors have been deluded. They have thought to produce steel by simply reducing the 3 or 4 per cent of carbon in cast iron down to 1 or 1½ per cent, quite forgetting the necessity of eliminating the phosphorus, sulphur, and silicon.

Another common and dangerous error has been to forget that metal of very high tenacity, as measured by the application of a strain gradually increasing, is able to bear a sudden shock. Hence mere tenacity, measured as above, is no proof of the suitability of a steel for girders, guns, armour plating, &c. The Tay Bridge had successfully borne the tests then in use, and had been pronounced satisfactory. But a comparatively slight vibration added to the strain of a tempest destroyed it in a moment. The author is of opinion that for rails, tyres, &c., mild steel is far superior to wrought-iron. But for boiler-plates, armour-plates, girders, angle-iron, &c., wrought-iron is superior.

The following remark is humorous:—"The spectro-scope is a wonderful instrument, one of its great merits being remarkable docility. An energetic man with a clearly defined theory before him appears to be able to discover in a well-constructed spectroscope whatever the theory demands."

We find a nobly indignant denunciation of the policy which equips our soldiers with brittle sabres and flexible bayonets. Why do we blame the ignorant public for buying "cheap and nasty" articles, when our authorities think it prudent to risk the life of trained soldiers—perhaps the loss of a campaign—in order to economise some fraction on a weapon?

We cannot, however, carry any further our examination of this most instructive book, which is, or should be, valuable to others besides metallurgists and engineers.

Practical Inorganic Chemistry—Analysis and Sketches. By E. J. Cox. London: Percival and Co.

THE author of this book is described on the title-page as head master of the "Technical Science School," Birmingham. If his work is to be taken as a fair index of the kind of teaching in this and similar institutions we can only say that the sooner they are abolished the better it will be for the progress of science in this country.

* *Ann. Chem. u. Pharm.*, cviii., p. 336; see also Watts' "Dictionary of Chemistry," Art. *Magnesium Sulphate*.

There is hardly a page in the book that does not show the author's want of practical knowledge of his subject. It will suffice to pick out a few of the most glaring examples from a list that would fill a column of this paper. On page 40, in the sketch illustrating the preparation of nitrous oxide, the gas is carefully dried by passing it over calcium chloride and is then collected *over water*! Sketch No. 21, again, on page 42, shows ammonia gas being collected at a pneumatic trough that must contain, at the lowest estimate, three hundred-weights of mercury (value about £40 sterling). It is evident from this—and, indeed, from the remarks on page 34—that the students are not intended to *perform* these experiments; that is a troublesome detail quite unnecessary for the object of the "Technical Science School," which is, of course, to get the maximum number of "passes" (with the minimum of trouble and knowledge) in the inevitable examinations. If we turn to the section on analysis we shall fare no better. On page 28 the student is directed to confirm the presence of calcium in a precipitate by dissolving it in HCl, and adding to separate portions of the solution ammonium oxalate and sodium phosphate. There is no hint of the necessity of first neutralising the acid; doubtless the author (who writes himself F.C.S.) prefers to let his students find out such details for themselves. On page 22 the method of testing for nitric acid given is to "*Boil well* with strong H_2SO_4 ," allow to cool, and then add ferrous sulphate. Has the author ever tried the experiment in this form, we wonder?

The statement (on page 6) that the fumes evolved on heating sulphates turn red litmus blue, may be charitably put down as a slip: but we have quoted enough to show that the book is a thoroughly bad one—a "cram book" of the worst type written by a man without an adequate knowledge of the subject he essays to teach. It is a standing reproach to the Science and Art Department, which unfortunately controls so much of the science teaching in this country, that it has taken no adequate means to put the teaching of science into the hands of really competent men. A step in the right direction has been taken within the last few years by raising the necessary qualification from a second-class to a first-class in the "advanced" stage; but it is to be hoped that this will not be considered a final settlement of the question.

CORRESPONDENCE.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—In the CHEMICAL NEWS, vol. lxii., p. 212, you published the circular-letter which has been sent round to the members of the Chemical Society by Messrs. Lloyd and Teed, and from which it seems they are desirous of inducing the Fellows to ignore the objects for which the Society was founded—viz., "the promotion of chemistry and of those branches of science immediately connected with it," or, as the Charter puts, "for the general advancement of chemical science,"—and to transform it into an eclectic body, which should only admit those who have "scientific claims," whatever that may mean, and thereby convert the Fellowship into a sort of Chemical Degree, or, as they express it, "The dignity of the Fellowship of the Chemical Society."

If this radical change were effected, it would have two results:—

1. As only a comparatively small number of the candidates for admission have attained any fame as scientific chemists, or, as Messrs. Lloyd and Teed put it, can advance "scientific claims," the number of Fellows would gradually become smaller, the income of the Society

would diminish, and the Council would be obliged to cut down the Journal, by omitting the Abstracts, and, possibly, also be unable to publish in full the original papers communicated to the Society.

2. The point to which I wish especially to draw attention, however, is that this is, whether designedly or not, a side attack on the Institute of Chemistry, which was intended by its founders to be *supplementary to the Chemical Society*, and is empowered by Royal Charter to grant certificates to those who are competent. The Fellowship of the Chemical Society neither is, nor is intended to be, evidence of an advanced knowledge in chemistry; on the other hand, the Fellowship of the Institute is recognised by the Government, as the following letter, recently addressed to the President, Dr. James Bell, will show:—

"SIR,—I am directed by the Local Government Board to advert to your letter of the 30th July last, and, in reply to state that they have already been in the habit of accepting the Fellowship of the Institute of Chemistry of Great Britain and Ireland as adequate evidence of a knowledge of analytical chemistry on the part of a person to be appointed as public analyst.

I am, Sir,
Your Obedient Servant,

EDMUND W. WODEHOUSE,
Assistant Secretary."

It is hard to guess whether this attack is intended mainly for the purpose of injuring the Chemical Society, or is made with the object of hampering the Institute of Chemistry in its endeavour to raise the *status* of the professional chemist, or is simply an outcome of the mania for change which seems to be epidemic just now. However that may be, its most immediate and important result, if successful, would be to enormously increase the commercial value of the letters F.C.S. for trade advertising purposes; and, although this may be greatly to the advantage of some few Fellows of the Society, I feel sure the larger number, those who love Science for its own sake, and not merely for what they can make out of it, would view any change which was likely to produce this effect with the strongest disfavour.—I am, &c.,

CHARLES E. GROVES,
Secretary to the Institute of Chemistry.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 14, October 6, 1890.

On a New Method for the Determination of Urea.—P. Miguel.—The author has formerly stated that in order to obtain the soluble ferment of urea by means of very active urophagous bacilli it was useful to add a little ammonium carbonate to the culture solutions. The sole object of this precaution was to render the medium strongly alkaline, so that these bacilli may easily grow in the liquid. In default of alkalinity the sowings generally remain sterile. But among the urophagous microbia many, especially the micrococci, can develop themselves in neutral or even acidulated broth. Many of these microorganisms grow exclusively at the bottom of the vessels, producing deposits more or less granular, which never interfere with the transparency of the liquid, but charge it with a considerable quantity of a soluble ferment. Such liquids of a high degree of transparency should be chosen by preference for the determination of urea. If it is merely required to determine urea dissolved in pure water the operation is of the greatest simplicity. The diastaseiferous broth and the solution of urea are mixed in equal volumes. An alkalimetric determination is immediately made, and

the mixture is kept for two hours at 50° in a vessel very nearly full and fitted with a ground glass stopper. At the end of this time a second alkalimetric determination shows the quantity of ammonium carbonate which has been produced, and in consequence the weight of urea originally contained in the solution. If the liquid in which the urea has to be determined is urine or any organic liquid it is well, in order to avoid error from the absorption of ammonia by acids, acid salts, or from the formation of double ammonical salts, to treat the liquid in heat with a slight excess of ammonium carbonate. The liquid when cold is filtered if needful, and treated like the solution of urea in pure water. This method admits of great precision. If the weight of urea in a liquid reaches 10 per cent—at which proportion it becomes poisonous to the ferment—it is diluted with pure water. Sodium chloride in slight proportions, uric acid, ammoniacal and alkaline salts, extractive principles, albumen, and sugar in very large quantities do not interfere, which is far from being the case when urea is determined as nitrogen gas. Certain substances do interfere, as the author will explain in a future paper.

Experiments on the Cultivation of Wheat in a Barren Quartz Sand.—M. Pagnoul.—Phosphates, especially if soluble, play a capital part in the production of wheat. A mean yield of 46 quintals per hectare with a complete manure falls to 12 on the omission of soluble phosphoric acid, and to 2 if phosphoric acid is totally absent. The absence of nitrogen reduced the yield from 46 to 11. Potash is especially necessary if the nitrogen is supplied in the form of ammonia. The proportion of nitrogenous matter in the grain depends on the quantity of nitrogen supplied in the manure. It may fall to 8 per cent or rise to 20.

Bulletin de la Société Chimique de Paris.
Series 3, Vol. iii., No. 12.

Thermo-chemical Researches on Textile Fibres (Wood and Cotton).—M. Leo Vignon.—The substance of this paper has been already inserted.

Determination of Lead by Phosphomolybdic Acid.—Henry Beuf.—This determination may be effected either volumetrically or gravimetrically. In the former case the solution of lead is gradually treated at a boil with an aqueous solution of phosphomolybdic acid until the whole is precipitated, which is recognised by the yellow colour which the liquid takes as soon as it contains an excess of the liquid. This precipitation must be effected at a boil in order to obtain a dense precipitate, easy to wash and to filter. At lower temperatures the precipitate traverses the filter. It is let settle for a few moments, when the precipitate collects at the bottom of the vessel. It is washed by decantation with hot water, passing the washings through a tared filter. When the washing is completed the precipitate is put upon this filter, washed at 90–100°, and weighed. The quantity of lead is calculated by multiplying the weight of the precipitate by 0.54802. If the solution of lead before precipitation is acid it is neutralised with a solution of soda (not potassa or ammonia), and any precipitate which forms is re-dissolved in a few drops of acetic acid. By this method we obtain a precipitate containing less lead than do the sulphate and sulphide, whence the errors, if any, are smaller. For a volumetric determination the precipitation is effected as above; the precipitate is washed, and the washings are filtered through a common filter (not tared) taking care to let as little of the precipitate as possible fall on the filter. When the washing is completed the filter is perforated, and that portion of the precipitate which has collected upon the filter is washed into the vessel containing the principal portion. There are then added 10 c.c. of sulphuric acid and 2 to 3 grms. zinc. The whole is then gently boiled for an hour, when the liquid becomes brown. A solution of permanganate is then dropped in

with a burette until the liquid takes a permanent rose colour. As the permanganate has been standardised with a known quantity of a lead salt, the quantity of lead present is determined from the volume of permanganate consumed. The metals which interfere with this process are iron, copper, zinc, potassium, besides arsenic and ammonium. Iron is easily eliminated. When the liquor is neutralised with soda before precipitation an excess of alkali is used, which throws down the iron as ferric hydroxide, whilst the lead is re-dissolved. The iron is then removed by filtration. In presence of copper the lead is precipitated as if no other metal was present. A part of the copper is thrown down, but a washing with ammoniacal water dissolves the copper, whilst the lead remains insoluble. Potassium and ammonium are precipitated only in nitric solutions, but if they should be carried down they are easily removed by washing with ammonia. Zinc, as well as arseniates and arsenites, interfere with the precipitation. The compound of lead with phosphomolybdic acid is a dense white powder, insoluble in ammonia, soluble in potassa and soda, soluble in nitric acid even if dilute, but less soluble in acetic acid. One part of this compound dissolved in 500,000 parts of water. It contains 54.802 per cent of lead. For preparing the solution of phosphomolybdic acid the author takes the ammonium phosphomolybdate, a salt easily obtained, and treats it with *aqua regia* on the water bath until completely dissolved, and then evaporates to dryness. The acid thus obtained is dissolved in water and the solution is filtered. It suffers no change in keeping.

On Raoult's Ebullioscope.—R. Lespieau.—This paper requires the accompanying figure.

Action of Chloral upon Resorcine.—H. Causse.—By this reaction the author has obtained $C_{14}H_{12}O_6$ in colourless crystals, insoluble in water and benzene, but soluble in alcohol, ether, and alkaline lyes. The latter solutions in contact with air take a splendid fluorescence analogous to that of the phthaleine of resorcine. The author has further examined the behaviour of these crystals with acetic anhydride, the action of glyoxylic acid upon resorcine, and that of ethylic aldehyd upon pyrogallol.

On Bees'-Wax.—A. and P. Buisine.—The results show that bees'-wax has a composition which is approximately constant. The authors promise to give a method for the examination of commercial waxes and the detection of their falsifications.

Journal für Praktische Chemie.
New Series, Vol. xli., Part 8.

On the mixed Fatty-aromatic Ketones and their Oxidation of Potassium Permanganate.—Ad. Claus.—A first portion only of a memoir, which awaits its completion.

On Artificial Silver-Bismuth Glance.—R. Schneider.—The natural silver-bismuth glance, $Ag_2S \cdot Bi_2S_3$, occurs in a mine at Morococha in Peru. The author has obtained artificially a compound of identical composition.

On the Combustion Heats of some Organic Isomers.—Iw. Ossipoff.—This memoir does not admit of useful abstraction.

ON THE DETECTION AND SEPARATION OF MINUTE QUANTITIES OF HYDROGEN DIOXIDE AND OF URANIUM.*

By THOS. FAIRLEY, F.R.S.E.

VARIOUS authors have given 0.5 m.grm. as the smallest quantity of hydrogen dioxide which can be detected by the chromic acid test (Denigès, *Bull. Soc. Chim.*, 1890, p. 797).

The author has detected less than this quantity as follows:—To 5 c.c. of a 0.005 per cent solution of H_2O_2 in a test-tube, add 1 to 2 c.c. of ether, and then a small drop of chromic acid by means of a small pointed glass rod dipped in a 10 per cent solution of the acid. Shake up, and allow the ether to collect, when the blue due to the solution of the perchromic acid in ether is distinctly visible, especially against a white ground. If thought necessary, the yellow aqueous liquid can be screened from the eye by means of a sheet of paper held so as to leave the ether alone visible.

Now, 5 c.c. of a 0.005 per cent solution of H_2O_2 contain 0.25 m.grms. of H_2O_2 . Solutions more dilute, such as a 0.001 per cent solution of H_2O_2 , have in numerous experiments given negative results with chromic acid. By taking a smaller quantity than 5 c.c.—say, 1 c.c.—of a 0.01 per cent H_2O_2 , adding 1 c.c. of ether, and then a very small drop of the chromic acid solution, shaking up in a small test-tube, and allowing the ether to collect; the blue colour due to the perchromic acid is very distinct. In this manner 0.1 m.grm. H_2O_2 can be detected.

In 1877 (*Journ. Chem. Soc.*, pp. 1—24 and 125—143), the author made a careful study of many of the reactions of hydrogen dioxide, and described fully the preparation and properties of the uranium tetroxide. He has now endeavoured to apply the reaction between the salt of uranium and hydrogen dioxide to its detection in very dilute solutions or in very minute quantities. One advantage is that the dioxide can be collected as a precipitate, even out of a large volume of liquid, not too dilute to react with the uranium solution. In the absence of interfering agents (*Journ. Chem. Soc.*, 1877, p. 128), it affords a process of separation so that the dioxide can be estimated by weighing the uranium precipitate, or by titrating it with permanganate.

Dilute solutions of uranium nitrate and of hydrogen dioxide were prepared and their reactions observed. In each case, 5 c.c. of the uranium solution and 5 c.c. of the H_2O_2 solution was taken.

The Table shows that in very dilute solutions $\frac{1}{100}$ th to

$\frac{1}{100}$ th m.grm. H_2O_2 and $\frac{1}{10}$ to $\frac{1}{2}$ m.grm. of uranium can be detected by this reaction. Though the precipitates in experiments 7, 8, and 9 are very minute, weighing less than 1 m.grm., the turbidity in the liquid is well marked.

NOTE ON THE PREPARATION OF DIASTASE.

By J. ARTHUR WILSON

HAVING to make occasional estimations of starch by O'Sullivan's method, the following is the best way I have found of preparing diastase of the highest activity. 2 lbs. of the best malt are allowed to stand soaked in 10 per cent alcohol for eight hours, after which time it is pressed and filtered. The perfectly bright filtrate is then precipitated by absolute alcohol, till a milkiness ensues. It is then allowed to stand some time, decanted or filtered, and the precipitate washed once or twice with absolute alcohol.

The precipitate is then treated with cold water, filtered from the insoluble matter, and re-precipitated by alcohol. By repeating this treatment once or twice, and drying over phosphoric acid *in vacuo*, a white, easily soluble powder of high activity is produced.

Tottingham, Oct. 20, 1890.

INTERNATIONAL STANDARDS FOR THE ANALYSIS OF IRON AND STEEL.*

EXTRACTS FROM THE WORK OF THE AMERICAN COMMITTEE.

By JOHN W. LANGLEY

(Concluded from p. 220)

Mode of Release of Carbon.

In pursuance of the special work assigned to Dudley, in a study of the phenomena attending the release of the carbon from its connection with iron in the steel, some quite surprising results have been obtained. It is, perhaps, not too much to say that sufficient work has already been done to throw doubt on the accuracy of all recent carbon determination made with preliminary solution of the steel in double chloride of copper and ammonium.

Dudley began his study of this problem of the release of the carbon by quite an amount of preliminary study on the reliability of his apparatus and method of making combustions. A number of modifications were tried, but finally the apparatus and method previously described under the heading, Dudley's Apparatus and Method, were settled upon, and this apparatus and method were checked up by the following determinations:—

Into an ordinary glass combustion tube some 60 grms. of the well-known combustion mixture of chromate of

lead and bichromate of potash were placed, taking care that the material did not reach to either end of the tube, and holding it in place at each end by asbestos plugs previously ignited. The tube was then placed in a furnace and a combustion made in the regular way, the position of the material, not reaching to either end, allowing the whole of it to be uniformly heated. This combustion was simply a blank to eliminate any possible error due to impurities in the combustion mixture. A small increase in weight in the absorption apparatus was found, and a second blank gave exactly the same results. This being done, three samples of three grms. each of the experimental standard ingot were treated with 200 c.c. each of the same double chloride solution rendered acid by 10 c.c. HCl. As this solution of double chloride will be referred to hereafter, we will say that it was made in Dudley's laboratory by obtaining from the market commercial chloride of copper and commercial chloride of ammonium, and dissolving these in water and mixing them in the proportions to form a double chloride containing one molecule each of the two salts. A small amount of free ammonia was added, enough to cause a perceptible separation of hydrated oxide of copper. The solution was then allowed to settle, and always filtered through previously ignited asbestos before using. This will be called solution "A." And it will be observed that the solution had not been crystallised. After solution was complete, the three tests were filtered into platinum boats, and three combustions made. Two of these combustions were made in glass tubes, using exactly the same amount of combustion mixture as in case of the blanks above described, and following the same manipulation, except that the boats with their carbon were buried in the combustion mixture in the tube. The third combustion was made in the apparatus, and by the method previously described under the head of Dudley's Apparatus and Method. The results obtained from these three combustions were as follows:—

	Per cent.
Combustion mixture No. 1, after allowing for blank, gave, carbon	1'102
Combustion mixture No. 2, after allowing for blank, gave, carbon	1'109
Combustion with Dudley's apparatus and method	1'106
Average	1'106

These results were regarded as showing that Dudley's apparatus and method gave fairly reliable results so far as the combustion was concerned.

But these results were confirmed by two further tests, as follows:—First—A direct combustion of crystallised and pulverised sugar in the same apparatus, and immediately following the last steel analysis above, gave,

Carbon	42'02 per cent.
Theoretical carbon in sugar	42'11 "

This was followed, secondly, by a blank combustion, everything being done exactly as in a regular combustion, except that nothing was put in the combustion tube. This blank showed a loss in the weight of the absorption apparatus of two-tenths of a m.grm.

The apparatus and method being regarded as satisfactory, attention was next given to the release of the carbon. Experiments were planned to demonstrate the effect of different states of dilution of the double chloride solution on the release of the carbon; also, to determine whether large or small amounts of double chloride solution changed results; and also to determine whether varying amounts of chloride of ammonium relative to the chloride of copper present produced any change. Before this part of the work was fairly entered on, however, a shipment of crystallised double chloride was obtained from the market. Since it had already been noticed in the work done on apparatus and method previously alluded to that discordant results were frequently obtained, it was at first

suspected that the apparatus and method were at fault, but after the tests of the apparatus, above given, were made, suspicion fell on the double chloride, and accordingly a nearly saturated solution was made from the shipment above alluded to. This solution will be called solution "B." Four combustions of the experimental standard ingot were made, using 200 c.c. of solution "B" rendered acid with 10 c.c. of HCl. These gave results as follows:—

No. 1	Carbon, 1'070
No. 2	" 1'067
No. 3	" 1'060
No. 4	" 1'065
Average	1'065

These results, it will be observed, are a trifle over 0'04 per cent lower than were obtained with the same steel, with the same apparatus and method, but using the uncrystallised double chloride solution "A." The problem at once arose how to reconcile these discrepancies. Obviously, if the apparatus and method could be trusted, either the solution "A" contributed to the absorption apparatus, which was weighed and counted as carbon, or solution "B" dissolved and carried off some of the carbon in the steel—or possibly both. Who could tell where the truth lay?

The first attempt to unravel the mystery consisted in taking 450 c.c. of solution "A" with 25 c.c. of HCl, and adding to it 1 grm. of steel. After the reaction was complete and the solution had been thoroughly mixed, it was filtered through asbestos. The result of this treatment was that this 450 c.c. of solution "A" had now in it some sub-chloride of copper, some chloride of iron, and also carbon liberated from steel had been floating around in it, affording an opportunity for any material which might be separated from the solutions by the reaction to attach itself and be filtered out. The reasoning was as follows:—If double chloride solution "A" contains any carbonaceous material in solution which separates when the solution is treated with steel, thus causing high results, a part, at least, of this material will separate when the 450 c.c. are treated with one grm. of steel, and be removed by the subsequent filtration, and consequently combustions made, using this treated double chloride solution "A," will show lower results. Two combustions were accordingly made of the experimental standard ingot, everything being exactly as in the previous combustions, except the use of the treated double chloride solution "A." These combustions gave:—

No. 1 Carbon	1'076 per cent.
" 2 "	1'070 "
Average	1'073 per cent.

Here was a reduction of a little over 0'03 per cent from the figures obtained using solution "A" untreated with steel, and the figures seem to indicate quite clearly that uncrystallised double chloride solution "A" contained something in solution that separated during the reaction with the steel, and gave erroneous and too high results.

In confirmation of this view, the following experiments were made: 200 c.c., the usual amount for a combustion, of solution "A" with 10 c.c. of acid, were treated with 5 grms. of experimental standard ingot, instead of 3; the assumption being, if there is a certain amount of carbonaceous matter in solution "A" which comes out during the reaction with the steel, lower results will be obtained if this error is divided over a larger amount of steel. Two combustions were made on this plan, which gave results as follows:—

No. 1 give Carbon	1'049 per cent.
" 2 " "	1'082 "
Average	1'065 per cent.

It is possible the first of these duplicates is a little low, as this carbon sponge from the larger amount of steel was a little difficult to manage in the boat; but as both the results are lower than those previously obtained from solution "A," it is evident they point in the direction that there is something in solution "A" that should not be there.

One more experiment was made on solution "A," as follows:—1000 c.c. of this solution was treated with 50 c.c. of HCl, and allowed to stand for some time. This solution was then filtered on the boat, and although nothing was visible to the eye, a combustion was made. The absorption apparatus showed an increase in weight of 34 m.grms. This corresponds to a trifle over 0.006 per cent of carbon in the steel which had been used in all the previous tests. This apparently indicates that although solution "A" probably contains something which it should not, that something only separates very slightly when the solution is treated with acid.

Thus far the evidence seems to point quite strongly in the direction that uncrystallised double chloride solution contains some carbonaceous matter which separates during the reaction with the steel. But who knows that crystallised double chloride does not also contain carbonaceous matter? And still further, who knows that either crystallised or uncrystallised double chloride does or does not dissolve some of the carbon of the steel during the reaction, and thus produce a loss?

Upon the first of these questions the following experiments were made:—450 c.c. of solution "B," which, it will be remembered, was made from crystallised double chloride obtained from the market, were treated with one grm. of steel and acid, as previously described for solution "A," and two combustions made. These two combustions gave:—

No. 1 Carbon	1.060 per cent.
" 2 "	1.061 "
Average	1.060 per cent.

These results are, it will be observed, only about 0.005 per cent lower than were obtained with the same solution untreated with steel, and seem to indicate that crystallisation removes at least the largest part of the carbonaceous material, such as was characteristic of solution "A." But the mother-liquor, from which the crystals forming solution "B" were obtained, may not have contained any large amounts of carbonaceous matter, and so the evidence seems most conclusive.

In continuation of this same study, four more combustions were made, two of them using solution "B," but no acid, and the other two likewise using solution "B" and no acid, but treating the solutions with steel, as previously described. These combustions showed as follows:—

	Untreated.	Treated.
No. 1 Carbon	1.036 per cent	1.030 per cent.
" 2 "	1.035 "	1.024 "
Average	1.035	1.027

These results show about 0.008 per cent lower for the treated double chloride than for the untreated, but the number of analyses and the number of samples of crystallised double chloride experimented on, seem hardly sufficient to set at rest the question as to whether crystallisation completely removes the probable difficulty due to carbonaceous matter in the mother-liquor.

Thinking that possibly carbonaceous matter might be introduced into the double chloride solution "A" by the commercial chloride of ammonium used in making it, four combustions were made, using some of the same shipment of chloride of copper alone which had been used in making solution "A." All four of the solutions had acid present, and two of them were made with the solution previously treated with one grm. of steel and filtered as already

described; the other two not treated. The same steel was used as in all the previous cases; these combustions gave the following results:—

	Untreated.	Treated.
No. 1 Carbon	1.072 per cent	1.040
" 2 "	1.056 "	1.050
Average	1.064	1.045

These figures, as will be observed, seem to indicate that part of the difficulty, at least, is due to the chloride of ammonium, since the chloride of copper alone gives nearly 0.04 per cent lower results than solution "A." They also seem to indicate that previous treatment with steel throws out something from even the chloride of copper alone. Too much importance should not, however, be attached to these results, as the reaction between the chloride of copper and the steel was very slow; and as acid was present, and it was impossible to keep the solution agitated continuously, it is probable a slight loss of carbon may have occurred. The variation in the duplicates may possibly be accounted for in this way.

Up to this point the evidence obtained seems to indicate:—1st, that uncrystallised double chloride made from commercial materials probably contains carbonaceous matter in solution; 2nd, that this may come partly from the chloride of copper, and partly from the chloride of ammonium; and 3rd, that crystallisation is probably advantageous in diminishing, if not completely removing, this difficulty. But some points are not quite certain, and accordingly the following experiments were undertaken to throw as much light as possible on the subject.

Commercial chloride of copper and commercial chloride of ammonium were obtained from the market. These were dissolved in hot water and mixed in the proportions to give a salt containing one molecule each of the two chlorides. On cooling the hot solution to a low temperature a large crop of crystals of the double salt was obtained. The mother-liquor was drained off from these crystals and set aside. Also a portion of the crystals obtained were rinsed with pure water and set aside. The remainder of the crop of crystals was again dissolved in hot water, evaporated a little, and cooled, giving a second crop of crystals, from which the second mother-liquor was drained off; they were then rinsed with pure water. The first and second crop of crystals were then each dissolved in water, forming nearly saturated solutions at ordinary temperatures. This gave three solutions to work with, viz.:—(1) The mother-liquor from the first crop of crystals, (2) a solution of the first crop of crystals, and (3) a solution of the second crop of crystals. In other words, solutions of uncrystallised, once crystallised, and twice crystallised double chloride. The mother-liquor solution was treated with ammonia sufficient to give a slight precipitation, and then filtered through asbestos. It was then divided into two parts, and one part treated with HCl to the amount of 5 per cent. The part treated with ammonia alone we will call basic mother-liquor and the other acid mother-liquor. Three combustions each were made with these two solutions, using the same steel and everything else as previously described. The results obtained were as follows:—

	Basic Mother-liquor. Per cent.	Acid Mother-liquor. Per cent.
No. 1 Carbon	1.086	1.145
" 2 "	1.081	1.130
" 3 "	1.067	1.150
Averages	1.078	1.142

Two results are quite noticeable in these figures:—1st, The acid mother-liquor gives higher results than any previous determination; and, 2nd. The differences between the basic and acid solutions is greater than in any previous case.

The second solution, viz., that from the first crop of crystals, was divided into two unequal parts. The

smaller of these was treated with ammonia and filtered as previously described, forming what we will call basic first crystals. The other part was filtered through asbestos and divided into two parts, one of which was treated with acid, as above described, and will be called acid first crystals. The other part was left without further treatment, and will be called neutral first crystals.

Three combustions each were made with these three solutions, showing as follows:—

	Basic First Crystals. Per cent.	Neutral First Crystals. Per cent.	Acid First Crystals. Per cent.
No. 1 Carbon	1.026	1.029	1.070
" 2 "	1.017	1.034	1.081
" 3 "	1.031	1.029	1.082
Average ..	1.027	1.031	1.077

The marked diminution in the amount of carbon between the mother-liquor and the first crop of crystals is very noticeable. In the basic results the difference is 0.051 per cent, and in the acid results the difference is 0.065 per cent. It will also be observed that there is a slight difference between the basic and neutral.

With the second crop of crystals only basic and acid combustions were made, the solutions being obtained as previously described. The results obtained were as follows:—

	Basic Second Crystals.	Acid Second Crystals.
No. 1 Carbon	1.016	1.049
" 2 "	1.028	1.056
" 3 "	1.023	1.052
Average ..	1.023	1.052

These results, taken in connection with what precedes, are, to our minds, exceedingly interesting. The marked diminution in the amount of carbon obtained with the second crystals over the mother-liquor, especially in the acid solutions, cannot fail to be noticed, and this would seem to indicate that double chloride made from commercial materials without crystallisation contains carbonaceous matter. This point would seem to be settled if it were not for the doubt whether the double chloride does not dissolve some of the separated carbon. Upon this point no positive data have yet been obtained. Two points further seem worthy of note. (1st.) The basic first and second crop of crystals give practically the same results, while the acids do not. And (2nd.) The farther away from the mother-liquor, the nearer the results from the basic and acid treatment come together. To our minds these facts, together with what precedes, seem to indicate that possibly the commercial material contains dissolved cellulose, and that crystallisation diminishes the amount of this, so that with the material used in the above experiments, once crystallising diminished the amount of cellulose, so that the basic liquid retained in solution what was left, since alkaline oxide of copper is a well-known solvent of cellulose, while the acid solution, even of the twice crystallised salt, still gives up a little cellulose to the carbon sponge.

In the special ground covered by Dudley in a study of the release of the carbon, the results of which are given quite at length above, the services of Dudley's principal assistant, Mr. F. N. Pease, have been found of the greatest value. He made all the combustions, and his suggestions have been most pertinent and useful.

A few attempts have been made to estimate the carbon in the Ex. Standards by methods not employing double chlorides, but with not much success.

Langley had proposed dissolving the steel in a hot solution of copper sulphate made as nearly neutral as possible, then filtering and burning the mixed copper and carbon sponge in oxygen. (*American Association Advancement of Science*, vol. xxiv., 1875.)

This method occasionally gives too low results, because

of the impossibility of being sure that the last particles of steel are dissolved. Dudley made the following trials on the Ingot Standard.

CuSO₄ was ignited to remove possible organic matter, then dissolved and filtered. The solution was made as neutral as possible, and allowed to stand on the steel several days. Result:—

Carbon.. .. 1.011 per cent.
" 0.972 "

Then to 300 c.c. of the sulphate solution was added 15 c.c. HCl. The attack of the steel was rapid, but some gas was evolved. Result:—

Carbon.. .. 1.002 per cent.
" 1.036 "
" 1.040 "

He then tried attacking the steel by solid silver chloride under water, and burning the silver and carbon sponge. Result on Hammered Standard:—

Carbon.. .. 0.796 per cent.

Langley made two determinations by putting the steel directly into the chromic-sulphuric acid mixture, without previous treatment by chlorides. Result on Hammered Standard:—

Carbon.. .. 0.788 per cent.
" 0.790 "

In this case more gas was evolved than what corresponded to the CO₂. It was found that methane would pass through the boiling chromic mixture without sensible oxidation; therefore, some of the carbon of the steel may have escaped in union with hydrogen.

Summary.

The conclusions here presented are not those of the committee in their official capacity. They are the views provisionally held by the members whose work is given above.

1. The combustion of carbon in a porcelain tube in a stream of purified oxygen, when the precautions indicated are used, gives sensibly accurate results.

2. If the carbon contains chlorine it is desirable to use a coil of metallic silver in the combustion tube, and it is apparently also *essential* to use some solution of silver, preferably the sulphate, in the purifying train.

3. The chromic acid method is capable of burning all the carbon used. If this carbon also contains chlorine, then it is *essential* to use some deoxidant in the purifying train, preferably pyrogallol acid with oxalate of potash; also a liquid silver absorbent must follow the deoxidising tube. Under these conditions this method gives sensibly accurate results.

4. The use of a small quantity of HCl in a solution of the double chloride of copper and ammonium invariably gives higher results than when a neutral solution is employed.

5. There is no evidence that the substitution of KCl for NH₄Cl in the double chloride is of any advantage.

6. The most important discovery made by the committee in this work pertains to the variable action of the double chloride solutions. This apparently throws doubts on the reliability of all carbon determinations previously made by this reagent, since they show variations on the same steel lying between 1.016 and 1.150.

When the degree of acidity is kept constant, the apparent quantity of carbon found is affected by the mode of preparation of the double chloride, by its age, and by the number of times it has been crystallised.

7. A carbon sponge derived from a double chloride solution does not appear to lose any carbon by drying at a temperature under 100° C., but loses if the heat is higher. The problems now before the committee, as suggested by the above results, are:—The determination of carbon in steel by some direct process not involving the use of double chloride; the direct combustion of finely divided

metal in oxygen or chromic acid is one of these, or by fusion in a mixture of bisulphate and bichromate of potash.

The determination, if possible, whether a neutral or alkaline double chloride liquid may not dissolve a portion of the carbonaceous residuum, and thus lead to results which are too low.

The determination whether the addition of acid simply prevents this tendency, or whether the use of acid may not favour the separation of pre-existing organic matter in the liquid, and its retention by the carbon sponge, thus leading to results which are too high.

The investigation of the cause of the influence of repeated crystallisations of the double chloride on the apparent quantity of carbon.

Finally, it is to be presumed that many, if not all of the above points, have attracted the attention of other analysts: and the committee will be glad to learn of the results and experience of others along these lines.

PHOSPHORUS IN PIG-IRON, STEEL, AND IRON ORE.*

By CLEMENS JONES, Hokendauqua, Pa.

(Concluded from p. 222).

Mr. Emmerton remarks that the "port-wine" colour is evidence of only incipient oxidation. On the contrary, this oxidation is very appreciable. It is only otherwise (*i.e.*, the molybdous acid oxidises slowly), as shown by Wernecke, when completely reduced.

The colour of these solutions, as ordinarily diluted, is always olive-green. By using the reductor this colour is invariably obtained. The following result from a piece of iron shows that it is applicable to very high phosphorus iron:

Weight. Grms.	KMnO ₄ . C.c.	Correction. C.c.	Phosphorus. Per cent.
0.5033	177.35	0.05	4.227

The colour of this solution was almost opaque until diluted. It was reduced instantly.

Dr. Drown's method I have found capable of being modified to great advantage. A large number of trials were made in strict accordance with the method as described, but neither the organic salts nor the acids gave acceptable results. Suspecting the trouble to lie in the use of these I substituted ferrous sulphate, which has the advantage of dissolving the manganic oxide immediately and being simultaneously oxidised. But the drawback to its use was that a correction for phosphorus had to be applied. None of the samples of ferrous sulphate received from a number of sources as "strictly C.P." were even low in phosphorus.

Messrs. Baker and Adamson, of Easton, Pa., kindly offered to experiment, and have succeeded in making the salt free from phosphorus. This was used in all of the determinations following.

The temperature of 90° C. was also found to be too high, molybdic acid precipitating in consequence. By adhering to 85° C., as recommended by Mr. Emmerton, this was overcome. Certain irons, high in manganese or fine graphite, cannot be easily oxidised before filtration. It is advisable always to test the solution with a few drops of KMnO₄ before adding the molybdate solution.

The method for pig-iron and steel now stands as follows:—

Dissolve in nitric acid of 1.135 specific gravity, according to Dr. Drown; allow the solution to boil one minute, then add the solution of potassium permanganate; after MnO₂ appears add a few small crystals of ferrous sulphate. Filter solution into flask; add sufficient NH₄OH

(0.90 specific gravity); when solution clears up add a few drops of KMnO₄, to insure oxidation, again dissolving if necessary. At 85° C. add to the solution 75 c.c. ammoniac molybdate solution (Dr. Drown's formula), and agitate violently for five minutes. Filter in Bunsen filter-flask, and wash thoroughly with ammoniac sulphate, observing all the precautions indicated by Mr. Colby. Dissolve the yellow phospho-molybdate in ammonia (0.96 specific gravity), *without* puncturing paper; wash once or twice with water, suck dry, and remove flask and stopper to suitable bell-glass. Pour the ammonia solution into small beaker, washing out flask with water three times. Place this flask under the bell-jar, and again filter the ammonia solution into it, this time washing paper thoroughly with water. Wash the zinc in the reductor, as required for ferric solutions; then add 30 c.c. to 50 c.c. sulphuric acid (1.32 specific gravity) to the ammoniacal solution, and filter through the reductor by strong suction, washing the same as indicated for ferric solutions and titrate as usual. The correction for zinc is obtained as described. I have made determinations in this way in half-an-hour. The following results were obtained in the above manner:—

The first is a "standard steel" which has been repeatedly tried by various chemists. The phosphorus is considered to be between 0.064 and 0.065. Below is a table giving the former results and the methods employed, the chemists being indicated by letters.

No. 4768.—Standard Steel.			
Chemist.	Phosphorus. Per cent.	Method.	
A	0.063	Emmerton.	
"	0.064	"	
"	0.065	"	
B	0.063	"	
"	0.065	"	
C	0.063	Not given.	
"	0.065	"	
"	0.065	"	
D	0.0603	"	
E	0.061	Weighs yellow ppt.	
F	0.0666	Magnesia method.	
"	0.0650	"	
"	0.0651	Weigh yellow ppt. original.	
G	0.0660	"	
H	0.061	Magnesia method.	
"	0.065	Titration of solution from the same NH ₄ MgPO ₄ .	

This steel yielded, by the method I have above described, the following results:—

Weight taken. Grms.	KMnO ₄ . C.c.	Correction. C.c.	Phosphorus. Per cent.
3.1264	16.89	0.05	0.0646
3.1267	16.86	0.05	0.0645

The following determination was made in fifty minutes from the start:—

Weight taken. Grms.	KMnO ₄ . C.c.	Correction. C.c.	Phosphorus. Per cent.
3.5014	18.52	0.05	0.0633

Value of 1 c.c. KMnO₄, 0.00012 grm. phosphorus.

A sample of Swedish pig-iron was tried in like manner. The former determinations were:—

No. 5009.			
Method.	Phosphorus. Per cent.		
Emmerton	0.023		
"	0.023		
"	0.023		
"	0.023		
Magnesia Gravimetric	0.023		
"	0.022		

This gave the following by my method:—

Weight. Grms.	KMnO ₄ . C.c.	Correction. C.c.	Phosphorus. Per cent.
3.5187	6.87	0.05	0.0232

* Transactions of the American Institute of Mining Engineers Washington Meeting, February, 1890.

A second determination completed in fifty minutes, P = 0.024.

The method was also applied to iron ore. This was dissolved in hydrochloric acid (1.12 sp. gr.) and filtered. The filtrate was evaporated with nitric acid in the usual way. The residue was fused with excess of sodium carbonate, and then dissolved in the original beaker in dilute sulphuric acid and water. This solution was added to the nitric acid solution, which was transferred to a flask, oxidised with potassium permanganate, and then treated like the iron solution.

No. 4995.—Rubio Ore.

Former Determination.	Phosphorus. Per cent.
Emmertton Method, residue not fused	0.012
fused	0.011
I. "By method" described above	0.013
II. In way described for results, Nos. 4260— 6r, this ore gave	0.0118

Another Bessemer ore, of which the former determinations were as follows:—

No. 5008.

	Phosphorus. Per cent.
Emmertton Method, not fused	0.016
"	0.016
"	0.016
Gave the results by the methods referred to in No. 4995, I. and II.—	
I. Method	0.017
II. "	0.018

There is no loss of time in fusing the residue by this plan, and it is a desirable precaution under any circumstance.

In pig-iron or steel arsenic and titanium interfere with the accuracy of the rapid method. The former must always be separated, and retards the process materially. In fact, the presence of arsenic may be regarded as an obstacle to the determination of phosphorus by any method.

Titanium, probably as titanomolybdate, has an apparent influence on the determination of phosphorus by the rapid method. When the Emmertton method of evaporating the original solution to hard dryness is used, this influence is lessened, but if titanium be present in any appreciable amount the results are vitiated. The following case by each method is a good example:—

No. 4706.—Pig-Iron (containing Titanium).

	Phosphorus. Per cent.
By Mr. Shimer, Mb-Mg method	0.659
By the Emmertton method, modified as in 3680— 81-82	0.649
By the Emmertton method,	0.643
By the "	0.654
By the "	0.650
By the "	0.647
By Rapid Method	0.726
By "	0.719

It may not be amiss to refer to the importance of using a freshly prepared solution of the molybdic acid, which should stand twenty-four hours at least before use. Dr. Drown's formula (*Trans.*, xviii.), has given the best result after several years' trial. The solution must be filtered through asbestos as required.

A summary of the procedure may be found convenient:—

Rapid Method for Pig-Iron or Steel.

- I. Dissolve in 60 c.c. nitric acid (sp. gr. 1.135).
- II. Boil one minute (after action ceases).
- III. Add 5 c.c. potassium permanganate (or until MnO₂ precipitates).

IV. Dissolve the MnO₂ with ferrous sulphate (a few grains usually).

V. Filter into flask (500 c.c. capacity).

VI. Add 10 c.c. NH₄OH (sp. gr. 0.90), or nearly neutralise.

VII. Test for oxidation (III. and IV.) This is done while solution is heating.

VIII. Add 75 c.c. molybdate solution at 85° C., and shake vigorously for five minutes.

IX. Filter and wash with ammoniac sulphate.

X. Dissolve in NH₄OH (sp. gr. 0.96). Observe precautions.

XI. Add 30 to 50 c.c. sulphuric acid (1:2 water) and filter through reductor, observing precautions mentioned (*Trans.*, xvii., 414.)

X. Titrate.

Rapid Method for Iron Ores.

I. Dissolve in hydrochloric acid (1:12 sp. gr.)

II. Filter. Evaporate filtrate with nitric acid (1:20 sp. gr.).

III. Fuse residue with excess of sodium carbonate, and dissolve in dilute sulphuric acid (1:2 water). Combine solutions when the filtrate with nitric acid is ready. Then proceed as above from III. to end.

An accurate determination of phosphorus in pig-iron or steel, in cases uncomplicated by arsenic or titanium, can thus be made in less than an hour. For iron ore but little more time will be necessary.

The three vital conditions of the volumetric method, solution, oxidation, and reduction, by visible reactions, give the method great advantages over any other. From the number of trials made with it the conclusion seems unavoidable that, compared with the "magnesia" method, the results are quite as accurate and certainly more closely accordant. The principles are correct, and I believe that the method can be demonstrated to possess all the requisites for filling the difficult rôle of a standard method.

I wish to acknowledge my indebtedness to Dr. Drown, Mr. A. L. Colby, and Mr. Porter Shimer for samples and valuable information.

ON THE

VARIATION OF THE DENSITY WITH THE CONCENTRATION OF WEAK AQUEOUS SOLUTIONS OF CERTAIN SALTS.*

By Prof. J. G. MacGREGOR, D.Sc.

(Concluded from p. 224.)

Iron Sulphate.—FeSO₄.

Observer:—The author.

Temperature:—20° C.

Formula:— $D_{20} = 0.99827 + 0.0099486 f$.

Percentage of anhydrous salt in solution.	Observed density at 20° C. Grms. per c.c.	Calculated density at 20° C. Grms. per c.c.	Difference.
0.8461	1.00666	1.00669	+0.00003
1.3618	1.01183	1.01182	-0.00001
2.4060	1.02229	1.02221	-0.00008
2.6064	1.02420	1.02420	0.00000

For solutions of iron sulphate, therefore, the above formula holds up to and beyond a concentration of 2.6 per cent.

Copper Sulphate.—CuSO₄.

Observer:—Gerlach.†

Temperature:—18° C.

Formula:— $D_{18} = 0.99866 + 0.0098427 f$.

* From the *Trans. Roy. Soc. Canada*.
† *Fres., Zeit. f. Analyt. Chem.*, viii. (1869), p. 279; *Landolt u. Börnstein's "Phys. Chem. Tabellen,"* p. 147.

Percentage of anhydrous salt in solution.	Observed density at 18° C. Grms. per c.c.	Calculated density at 18° C. Grms. per c.c.	Difference.
0.6390	1.00495	1.00495	0.00000
1.2781	1.01124	1.01124	0.00000
1.9171	1.01764	1.01753	+0.00011
2.5561	1.02403	1.02382	+0.00021
3.1952	1.03052	1.03011	+0.00041

Thus, according to Gerlach, the limit of concentration within which the above formula applies is somewhat less than 2 per cent.

Cadmium Sulphate.— CdSO_4 .

Observer:—Grottrian.*

Temperature:—18° C.

Formula:— $D_{18} = 0.99866 + 0.0097329 p$.

Percentage of anhydrous salt in solution.	Observed density at 18° C. Grms. per c.c.	Calculated density at 18° C. Grms. per c.c.	Difference.
0.282	1.0015	1.00141	-0.00009
1.011	1.0085	1.00850	0.00000
5.08	1.0495	1.04810	-0.00140

These experiments are hardly sufficient for our purpose. Nevertheless they seem to show that in the case of this salt the formula holds up to a concentration of about 3 per cent.

Aluminium Sulphate.— $\text{Al}_2(\text{SO}_4)_3$.

Observer:—Hassenfratz.†

Temperature:—12.5° C.

Formula:— $D_{12.5} = 0.99949 + 0.0092083 p$.

Percentage of anhydrous salt in solution.	Observed density at 12.5° C. Grms. per c.c.	Calculated density at 12.5° C. Grms. per c.c.	Difference.
0.5137	1.00418	1.00422	+0.00004
1.0274	1.00888	1.00895	+0.00007
1.5410	1.01368	1.01368	0.00000
2.0547	1.01838	1.01841	+0.00003
2.5684	1.02307	1.02314	+0.00007

These results show the formula to hold up to a concentration of 2.5 per cent. According to Reuss,‡ as reported in the *Beiblätter zu den Annalen der Physik und Chemie*, Bd. ix. (1885), p. 309, the density of aluminium sulphate solutions for concentrations ranging from 1 to 25 per cent of salt (whether anhydrous or crystallised is not stated) in solution, may be represented by the formula—

$$D_{15} = 1.007 + 0.01 p.$$

Now we know that for $p=0$, $D_{15} = 0.99915$. Hence either this formula is inadequate or the law of the variation of density with concentration is very different for solutions containing between 0 and 1 per cent of salt from what it is for solutions containing between 1 and 25 per cent. Possibly the curve showing the relation between density and concentration is so slightly curved that the densities of solutions within the given limits of concentration may be expressed by the above formula to three places of decimals.

Potash Alum.— $\text{AlK}(\text{SO}_4)_2$.

Observer:—The author.

Temperature:—20° C.

Formula:— $D_{20} = 0.99827 + 0.0095187 p$.

Percentage of anhydrous salt in solution.	Observed density at 20° C. Grms. per c.c.	Calculated density at 20° C. Grms. per c.c.	Difference.
0.7215	1.00512	1.00514	+0.00002
0.7438	1.00535	1.00535	0.00000
1.7260	1.01465	1.01470	+0.00005

According to these experiments the above formula holds up to a concentration of at least 1.7 per cent.

The following observations were made by Gerlach* on solutions of this salt at 17.5° C. The calculated densities are obtained from the formula—

$$D_{17.5} = 0.99875 + 0.009397 p.$$

Percentage of anhydrous salt in solution.	Observed density at 17.5° C. Grms. per c.c.	Calculated density at 17.5° C. Grms. per c.c.	Difference.
2.1792	1.01923	1.01923	0.00000
4.3584	1.04020	1.03971	-0.00049

The comparatively small difference between the observed and calculated density for a solution containing 4.36 per cent of anhydrous salt, makes it probable that the simple proportionality of excess of density of solution over density of water to concentration holds up to a concentration of about 2.5 per cent.

Potassium Sulphate.— K_2SO_4 .

Observer:—Hassenfratz.†

Temperature:—12.5° C.

Formula:— $D_{12.5} = 0.99949 + 0.008595 p$.

Percentage of anhydrous salt in solution.	Observed den. at 12.5° C. Grms. per c.c.	Calculated den. at 12.5° C. Grms. per c.c.	Difference.
1	1.00808	1.00808	0.00000
2	1.01658	1.01658	0.00000
3	1.02517	1.02527	+0.00010
4	1.03377	1.03387	+0.00010

The following is another series of observations of solutions of the same salt:—

Observer:—Gerlach.‡

Temperature:—15° C.

Formula:— $D_{15} = 0.99915 + 0.00816 p$.

Percentage of anhydrous salt in solution.	Observed density at 15° C. Grms. per c.c.	Calculated density at 15° C. Grms. per c.c.	Difference.
1	1.00735	1.00731	-0.00004
3	1.02363	1.02363	0.00000
5	1.04022	1.03995	-0.00027

The above sets of observations agree in showing that the excess of the density of solutions of this salt over that of water at the same temperature is, for solutions which do not contain more than about 2.5 per cent of anhydrous salt, directly proportional to the percentage of anhydrous salt which they contain.

Sodium Sulphate.— Na_2SO_4 .

Observer:—Gerlach.§

Temperature:—15° C.

Formula:— $D_{15} = 0.99915 + 0.0091267 p$.

Percentage of anhydrous salt in solution.	Observed density at 15° C. Grms. per c.c.	Calculated density at 15° C. Grms. per c.c.	Difference.
1	1.00824	1.00827	+0.00003
2	1.01734	1.01740	+0.00006
3	1.02653	1.02653	0.00000
4	1.03562	1.03565	+0.00003
5	1.04491	1.04478	-0.00013
6	1.05410	1.05391	-0.00019

These experiments would seem to show that the above formula holds in the case of sodium sulphate for solutions containing from 0 to 4 per cent of anhydrous salt. The following are other observations with the same salt:—

* *Beiblätter ann. phys. Chem.*, xi. (1887), p. 217.

† *Ann. de Chim.*, xxviii. (1759), p. 296.

‡ Gerlach's "Specifische Gewichte der gebräuchlichsten Salzlösungen," Freiberg, 1859; and "Jahresbericht u. Fortschritte d. Chem.," 1859.

§ Fresenius, *Zeit. f. analyt. Chem.*, viii. (1869), p. 279; and Landolt u. Börnstein's "Phys.-chem. Tabellen" (1883).

* *Weid. Ann.*, xviii. (1883), p. 191.

† *Ann. de Chim.*, xxviii. (1799), p. 296.

‡ *Chem. Ber.*, xvii. (1884), p. 2888.

Observer:—Ostwald.*

Temperature:—15° C.

Formula:— $D_{15} = 0.99915 + 0.0091875 p$.

Percentage of anhydrous salt in solution.	Observed density at 15° C. Grms. per c.c.	Calculated density at 15° C. Grms. per c.c.	Difference.
2	1.0176	1.01753	-0.00007
4	1.0359	1.03590	0.00000

Thus Ostwald's experiments give the same result.

Caustic Potash.—KHO.

Observer:—Thomsen.†

Temperature:—18° C.

Formula:— $D_{18} = 0.99866 + 0.0093717 p$.

Percentage of anhydrous salt in solution.	Observed density at 18° C. Grms. per c.c.	Calculated density at 18° C. Grms. per c.c.	Difference.
1.5344	1.01304	1.01304	0.00000
3.0224	1.02702	1.02698	-0.00004
5.8674	1.05359	1.05364	+0.00005

The following are other observations with the same substance:—

Observer:—Kohlrausch.‡

Temperature:—15° C.

Formula:— $D_{15} = 0.99915 + 0.0092959 p$.

Percentage of anhydrous salt in solution.	Observed density at 15° C. Grms. per c.c.	Calculated density at 15° C. Grms. per c.c.	Difference.
4.19	1.0381	1.0381	0.0000
8.42	1.0778	1.0774	-0.0004

Thomsen's experiments show that in the case of solutions of caustic potash, even up to a strength of more than 5 per cent, excess of density over that of water is practically proportional to the percentage of salt. Kohlrausch's results substantiate Thomsen's; for, as is seen above, a formula in which k is chosen so that the density given by it is exact for $p = 4.19$, gives a density for $p = 8.42$, which is not very far wrong.

Caustic Soda.—NaHO.

Observer:—Thomsen.§

Temperature:—18° C.

Formula:— $D_{18} = 0.99866 + 0.014563 p$.

Percentage of anhydrous salt in solution.	Observed density at 18° C. Grms. per c.c.	Calculated density at 18° C. Grms. per c.c.	Difference.
0.8528	1.01105	1.01108	+0.00003
1.6871	1.02323	1.02323	0.00000
3.3023	1.04719	1.04675	-0.00044

The formula therefore holds for solutions of strengths ranging up to about 2 per cent, but not for solutions of greater strength. Caustic soda thus differs in a marked manner from caustic potash.

The above are the only salts for which I have been able to obtain, or to find, data to determine the limits of concentration within which formulæ of the above kind hold—within which, in other words, the concentration-density curves of their solutions are, to the fourth place of decimals, straight lines. In the case of most salts, the weakest solutions, whose densities have been examined, are already beyond the limits referred to.

The table given below contains a list of the values of k found above for the various salts examined.

It will be noticed that in most cases the values of k do not differ from one another to any considerable extent. Now, k is the rate of increase of the density with the strength of a solution when its strength is but small; hence, the densities of dilute solutions of these salts increase with their strength at rates which do not differ

greatly in the case of the different salts; or, in other words, the concentration-density curves of sufficiently dilute solutions of these salts are not only practically straight lines, but are nearly equally inclined to the axis of concentrations.

NOTICES OF BOOKS.

Chemical Arithmetic. Part I. A Collection of Tables, Mathematical, Chemical, and Physical, for the Use of Chemists and Others. By W. DITTMAR, LL.D., F.R.S.E. (London and Edinburgh), Professor of Chemistry in the Glasgow and West of Scotland Technical College. Glasgow: W. Hodge and Co.

WHETHER the title of this work is quite appropriate or not, it differs broadly from two works which have recently come under our notice. Part I., now before us, is, according to the author, a new edition of his "Tables to Facilitate Chemical Calculations," though with changes and additions. He aims at supplying the chemist, scientific and technical, with a "collection of what he needs of mathematical auxiliaries, and of chemical and physical constants," and that without going further.

We scarcely see that any apology is needed for the utilisation of logarithm tables. Such matter has by this time become common property, and he who makes use of it is surely not open to the charge of "piracy." In such tables Dr. Dittmar's work is rich. There are two tables, Nos. 1 and 2, of three-place logarithms, a table of four-place and one of five-place logarithms.

Then follow a table of formula-values of a number of substances and radicles, and their logarithms.

The table headed "Analytical Factors and their Logarithms" is for the purpose of calculating from the weight of a substance found, as the result of some analytical process, the weight of some constituent required, e.g., found, barium sulphate; required, sulphuric acid. We do not see that the table here given is as convenient as that found in Rose's "Quantitative Analysis."

There are, in addition, certain empirical factors, e.g., in connection with the chloroplatinate method for determining potassium and ammonium; and for the determination of sugars by means of Fehling's solution.

We have also tables for gas, volumetric determinations for nitrogen, carbonic acid, nitric acid, and oxygen.

In the comparison between the metric and the British systems of weights and measures, the author proposes the fluid gramme as a more convenient unit for the measurement of liquids than the c.c. or the litre. This unit designates the volume at 15° C. of a quantity of water, the uncorrected weight of which, determined in air at 15° C. and 760 m.m. pressure by means of brass weights = 1 grm. Prof. de Koninck proposes to use the name "Mohr" for 1000 fluid grms., and "millimohr" for the fluid grm. itself. The author remarks that "what in commercial volumetric apparatus figures as c.c. litre comes, as a rule, nearer to our fluid grm. and litre respectively, than to the ostensible units."

* *Journ. f. prakt. Chemie*, xxii. (1880), p. 305.

† "Thermo-chemische Untersuchungen," Bd. i., p. 47.

‡ *Weid. Ann.*, vi. (1879), p. 21.

§ "Thermo-chemische Untersuchungen," Bd. i., p. 47.

We cannot help remarking that the British system loses much of its apparent complexity if, as units, we confine ourselves to the grain and the grain measure, with their multiples and sub-multiples, rigorously eliminating cubic inches, drachms, scruples, ounces, and minims.

In the table of Hydrometer Scales, the author gives only two of the varieties of Baumé's scale, not to speak of the arbitrary fluctuations which it experiences in the hands of careless glass-blowers.

Further sections of the work are taken up with the relations between specific gravity and percentage of solution in a number of solutions; corrections of weighings; the reduction of the specific gravities for solids and liquids; calibration of volumetric apparatus; gas-analysis; gas-absorption; and thermometry.

To all persons concerned with the study of general chemistry, or of chemical physics, this work cannot be too strongly recommended.

Book A; or, Arithmetical Chemistry. Part I. By C. J. WOODWARD, B.Sc. London: Simpkin, Marshall, and Co. Birmingham: Cornish Bros.

THIS little book, in many respects, reminds us of its companion volume "*Book D; or, Arithmetical Physics*," which it became our duty to notice a few weeks ago. The "General Preface" in both is admittedly the same, and is substantially a "defence of examination questions"; consequently, our remarks on that treatise must apply to the one before us.

In the "Introduction," however, we find a passage which must command approval. Says Mr. Woodward:—"Then came a period in which, at any rate to those who were guided by the requirements at South Kensington, a complete and unfortunate reversal took place. This was the age of graphic formulæ, when, owing to the necessity of turning out an article to bring the highest price to the producer, both teachers and students, intent on fitting "bonds" in order to satisfy the examiners, were apt to ignore the experimental evidence upon which the laws of chemical combination rest."

This quotation shows how little examiners are to be trusted. It is not too much to say that at the time referred to by the author a student, even if he were a rival of Mendeleeff in the philosophy of chemistry, if his analytical skill were equal to that of Fresenius, or his success in effecting novel and interesting syntheses on a level with that of Baeyer, still, lacking the power of playing at the game of bonds, would have been ignominiously rejected. That such could be the case is, of course, a fresh count in the indictment of the examination system to which officialism clings so devotedly, whilst the nation looks on in apathy.

Much of the matter here to be found is, in substance, what was formerly taught as stoichiometry.

Inorganic Chemistry: the Chemistry of the Non-Metals. By J. OAKLEY BEUTTLER, M.A. London: Relfe Brothers.

HERE is an addition to the numerous array of elementary works on chemistry. The author restricts himself to a consideration of the non-metals, possibly intending to treat of the metals in a future volume.

The object of the book is strictly examinational. We are, indeed, told in the preface that "these notes have been compiled to cover the ground required by the London Matriculation Examination, the Cambridge Local Examining Board, and the Science and Art Department." But, we cannot help asking, are there not manuals already in existence which cover this ground, and, if so, *cui bono*?

In the first chapter, the author defines an element as "that substance which cannot be split up any further." It would surely be safer to say which hitherto has not been split up any further. Mr. Beuttler apparently

recognises only sixty-four elements, and gives the atomic weights not, in all cases, according to the most recent and accurate determinations. Thus, the atomic weight of gold is here still stated to be lower than that of platinum.

In the occurrence of the non-metals in nature, the reader is told that sulphur occurs in volcanic districts, and "combined with various ores." Would it not have been better to say "combined with metals forming various ores"? The presence of carbon in the form of carbonic acid in many minerals, and that of phosphorus in apatite, vivianite, &c., is omitted.

The account given (on p. 26) of the reaction produced on dropping a piece of sodium into water is scarcely satisfactory, as we find no mention of the oxygen liberated from the water.

On pp. 32 and 33 we find the account of the uses of chlorine given twice.

Graphite, we read, is obtained from mines of Cumberland. Far larger quantities are now raised in Ceylon and Siberia.

It is in these days incorrect to say that fuming sulphuric acid is "principally manufactured at Nordhausen, in Saxony."

The preparation of free fluorine and its properties have been omitted.

The notice of Marsh's arsenic test is obscure. Mr. Beuttler writes:—"Add pure zinc and sulphuric acid, light the arseniuretted hydrogen, and a grey ring will be deposited or a cold piece of porcelain inserted in the flame." This passage can only be understood by reading *on* instead of *or*.

Five hundred grms. of potassium nitrate (p. 118) are to be strongly heated until it is entirely converted into "potassium nitrate." The chemist will at once see that here potassium *nitrite* must be meant in the second place; but will the "ordinary pupil" see his way out of the difficulty?

This book would be much improved by revision, in which some needless repetitions should be cancelled, and various typographical errors eliminated. If more examination manuals are needed, they should, at least, be correct.

CORRESPONDENCE.

THE ALCOHOL TEST FOR CASTOR OIL.

To the Editor of the Chemical News.

SIR,—The criticisms and observations by Mr. J. Arthur Wilson in CHEM. NEWS, vol. lxii., p. 215, have all been anticipated. In every reprint of the British Pharmacopœia issued in and since 1886, castor oil has been stated, correctly, to be soluble in *four* times its volume of spirit of wine—of course, of the official strength and at the official temperature.

Draper, Cripps, Allen, and Conroy have all preceded Wilson in drawing attention to the fact that the extent of the solubility depends either on the amount, the strength, or the temperature of the spirit.—I am, &c.,

THE ANNUAL REPORTER ON THE PHARMACOPŒIA
TO THE MEDICAL COUNCIL.

17, Bloomsbury Square, London,
November 3, 1890.

Assaying.—Mr. W. Heinemann will issue in a few days a new edition of Brown's "*Manual of Assaying Gold, Silver, Copper, and Lead Ores*." The work has been revised, corrected, and considerably enlarged; and a chapter on the Assaying of Fuels, by Dr. A. B. Griffiths, F.R.S.E., F.C.S., &c., has been added. The book contains 333 pages, crown 8vo., and is illustrated with 89 figures.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 15, October 13, 1890.

Combinations of Mercury Cyanide with the Salts of Lithium.—Raoul Varet.—The compounds here described are mercury lithium iodocyanide, and the corresponding bromine and chlorine salts.

Researches on the most Suitable Conditions for the Preparation of Mono-isobutylamine on the Large Scale.—M. Malbot.—The author has shown that the different terms of the amines are not produced simultaneously, according to the equations of Hofmann, but successively by a series of transformations, the totality of which forms the progression of the amines.

On a General Procedure for the Synthesis of the Nitriles and the β -Ketonic Ethers.—L. Bourcault.—This memoir is not adapted for abstraction.

On the Presence and the Disappearance of Trehalose in Mushrooms.—E. Bourquelot.—The author's experiments show that the disappearance of trehalose is really connected with the vegetation of the mushroom, and takes place much more rapidly than it has been supposed. They explain why the chemists who have analysed *Lactarius piperatus* have merely found mannite.

Moniteur Scientifique, Quesneville.
Series 4, Vol. iv., April, 1890.

Explosives without Smoke.—Sir F. Abel.—A discourse delivered before the Royal Institution.

On the Sensitiveness of certain Explosives to Percussion.—A. Werner Cronqueit.—From *Chemical Industry*.

Novel Applications of the Oleorefractometer.—E. H. Amagat and F. Jean.—According to the investigations made on behalf of the "Société des Agriculteurs" of France, this instrument may be successfully applied to the detection of sophisticated butters, oils, &c.

New Method of Analysis Applicable to Industrial Waters which have to undergo a Chemical Purification, and to Feed-waters for Steam Boilers.—Leo Vignon.—In order to determine the elements of chemical purification, or the anti-incrustation agents, it is sufficient to determine the free or the half-combined carbonic acid, and to determine the quantity of sodium carbonate necessary to convert the soluble salts of calcium and magnesium into carbonates which are chemically neutral.

Determination of Potassa and Humus in Soils.—J. Raulin.—(Already inserted; CHEM. NEWS, vol. lxi., p. 154).

Industrial Production of Aluminium Alloys by Electric Action.—H. J. Dagger.—From the *CHEMICAL NEWS*.

The Colourations of Tempered Steel.—Thomas Turner.—From *Proceedings of Birmingham Philosophical Society*.

Magnesium Bronze.—H. N. Warren.—From the *CHEMICAL NEWS*.

Contribution to the Study of Mineral Oils for Lubrication.—Aug. Lunkler (*Dingler's Polyt. Journal*).—This long essay does not admit of useful abstraction.

Ozokerite.—Platz (*Zeit. Angew. Chemie*).—The author condemns the method of extracting ozokerite.

Researches on Narcotine.—W. Roser.—From *Liebig's Annalen*.

Purification of Coal-gas by Means of Oxygen.—W. A. Valon (*Chemiker Zeitung*).—An account of the process as tried at Ramsgate.

Constitution of Antipyrine.—G. Patein.—This compound is now considered not as dimethyloxyquinizine, but as phenyldimethylpyrazole.

New Method of Determining Uric Acid in Urine.—Dr. Bayrac.—This memoir requires the accompanying illustration.

On the Analysis of Slates.—F. Reverdin and Ch. de la Harpe.—The destruction of slates is due to three causes: two of them chemical in their nature, and one—the most important—physical. These are:—The chemical action of atmospheric agents, — the least important; (2) the chemical action of gases emanating from the woodwork of the roof; (3) the physical action due to unequal thermic conduction. The chemical action is exerted on surfaces only, and renders the material pulverulent. The physical action extends to the entire mass and multiplies the surfaces capable of being attacked by chemical influences.—*Chemiker Zeitung*.

Conditions in which Portland Cement cannot Set.—Schiffner (*Chemiker Zeitung*).—Cement mortar kept covered and moist for twenty-seven days hardened perfectly. If, after being mixed, it is preserved from moisture it remains soft and friable.

On the Ramie Fibre.—J. Arnaudon.—If ramie is prepared with tannin and red liquor it dyes up much better with oranges, ponceaux, and bordeaux, and the colour is not removed by washing.

Silks Dyed and Weighted (*Romew's Journal*).—For practising this fraud upon coloured silks, there is used an extract of gall-nuts or of sumac, and the silk is then dyed with aniline colours. Pure whites, and light shades, cannot be obtained in this manner.

A New Process of Bleaching.—Dr. Kassner (*Romew's Journal*).—As an oxidising agent, the inventor proposes a mixture of potassa and potassium ferricyanide. The ferrocyanide formed is re-oxidised to ferricyanide as follows:—A solution of sodium carbonate is heated with calcium plumbite; the precipitate and lead bi-oxide is suspended in the exhausted ferrocyanide, heated, and a current of carbon dioxide from a coke furnace is passed into the liquid. Ferricyanide is re-formed, and a mixture of lead and calcium carbonate is deposited.

Journal für Praktische Chemie.
New Series, Vol. xli., Part 8.

Contributions to a Knowledge of the Analogies existing between Keton Acids and Sulphone-carbon Acids.—Adalbert Rössling.—The principal results of these results are:—1. The β sulphone-carbon acids do not undergo an acid splitting. 2. The metal atom of the sodium phenyl-sulphonacetate cannot be substituted by acid residues. Substituted esters containing an acetyl and a sulphone group on the same carbon atom cannot be obtained by the action of sodium benzoisulphonate upon mono- and dichloroacetic esters. 3. The action of iodine upon sodium phenylsulphone acetate in presence of water in alcoholic solution gives rise, not to a diphenylsulphonised succinic ester, but only to iodomethylphenylsulphone. The formation of mono- and diphenylsulphonised succinic acid cannot be effected by the action of a benzenesulphonate upon mono- and di-bromosuccinic acid. Chloroxalic ester acts upon sodium benzenesulphonate almost exclusively, with the formation of carbonic acid, benzenedisulphoxide, and oxalic diethylester; there is also formed a small quantity of phenyl-sulphonketonic ester. Nitrous acid produces from phenylsulphonacetate a compound $(C_6H_5SO_2)_2NHO$, with a simultaneous splitting off of carbonic acid and oxidation of the methylene group. Concentrated nitric acid produces

from phenyl-sulphonacetic acid phenyl-nitroso-sulphon, $C_6H_5SO_2NO$, with abscission of carbon dioxide and oxidation of the methylene group.

Parts 9 and 10.

The Constitution of the Cobalt Bases.—S. M. Jørgensen.—This memoir, though very interesting, does not admit of abstraction.

On Meta-Diamine Compounds.—S. M. Jørgensen.—We find here an account of ethylene diamine-dichloropraseo cobalt platinous chloride, ethylene diamine dichloropraseo cobalt bromide, the corresponding dibromo-praseo cobalt bromide, ethylene diamine dibromo-praseo cobalt bromide hydrogen bromide, ethylene diamine dibromo-praseo cobalt nitrate, ethylene diamine dibromo-praseo cobalt-platinum chloride, ethylene diamine dibromo-praseo cobalt mercuric chloride, ethylene diamine dichloro-violeo cobalt chloride, and a number of other analogous compounds of the purpureo-cobalt bases.

On the α -dichlor Substitute of Symmetrical Dimethylsuccinic Acid.—R. Otto and G. Hest.—The results of the experiments detailed are:—It is not possible to convert the α -dichlor acid dimethylsuccinic acid into a geometrically isomeric compound by means of its anhydride. The anhydride of the α -dichlor acid dimethylsuccinic acid can be converted into the ammonium salt of the α -dichlor acid dimethyl succinamic acid by alcoholic ammonia. On heating an aqueous solution (a) of the alkali salt, or on heating the free acid with water in a tube to 120° (b), there are produced α -methyl- β -chlorcrotonic acid and methylethylketone. If heated with strong hydrochloric acid to 140° - 150° in a tube α -methyl- β -chlorcrotonic acid yields no addition product of HCl, but at once splits off CO_2 , a dichlorotulian being probably formed.

Researches from the Laboratory of the University of Freiburg.—These comprise the following memoirs:—On the mixed fatty-aromatic ketones and their oxidation by permanganate, by Ad. Claus. On acetone chloroform, chlor-isobutyric trichloride, and acetone-chloroform ether, by C. Willgerodt and Schiff. On the stereo-chemistry of the compounds of the elements of the nitrogen group, by C. Willgerodt.

Lavoisier according to M. Berthelot.—L. Olivier.—This paper is in some sort a reply to the discourse of Professor Thorpe, delivered at the late meeting of the British Association. M. Olivier asserts that Professor Thorpe has merely revived "the ancient quarrel between sagacious inventors (he means discoverers) of particular facts and the men of genius who discover general theories." [We must be permitted to say that Professor Thorpe, as a careful and conscientious perusal of his address will show, has neither done nor attempted such a task. His great object has been to rebut the claim set up on behalf of Lavoisier as the first, or at least as an independent, discoverer of oxygen, and the assertion that the composition of water had been "prepared by Cavendish and realised by Lavoisier," and in this rebutter he is perfectly successful]. M. Olivier disclaims, on behalf of Lavoisier, the priority in the use of the balance and the authorship of the saying that "nothing is lost and nothing created."

Methyl Saccharine, a new Sugary Matter.—Kronberg.—This compound is a higher homologue of the "saccharine" of Fellberg and Remsen. The group common to the two compounds is—

The Liquefaction of the Alloys of Gold and Platinum.—E. Matthey.—Translated from the *Proceedings of the Royal Society*.

MISCELLANEOUS.

The Reorganisation of the Royal School of Mines.—Our readers will doubtless have learned from the morning papers that, by the Queen's command, the "Normal School of Science" and the "Royal School of Mines" will in future be known as the "Royal College of Science." We, however, wish it to be clearly understood that for the future, as in the past, those who pass in mining and metallurgy will receive the Associateship of the "Royal School of Mines." The distinctive character of the Associateship will thus be unequivocally retained.

The New Professor of Chemistry at the University of Aberdeen.—A meeting of the Aberdeen University Court was held on October 29th to appoint a Professor of Chemistry, *vice* the late Professor Carnelley. Dr. Francis R. Japp, Ph.D., F.R.S., Assistant Professor of Chemistry at the Royal College of Science, South Kensington, was unanimously elected. The new Professor, who is forty-two years of age, is a Master of Arts, and Honorary Doctor of Laws of the University of St. Andrews, and a Doctor of Philosophy of the University of Heidelberg, where he studied inorganic chemistry for three years under Professor Bunsen. He subsequently studied organic chemistry for a year and a half under Professor Kekulé, of Bonn, and worked in the laboratory of Professor Crum Brown, in Edinburgh. Twelve years ago he became a member of the teaching staff of the South Kensington Science Schools, where, in 1881, he was appointed to the newly-created assistant professorship of chemistry. He is the foreign secretary of the Chemical Society, and has served on the Council of the Institute of Chemistry of Great Britain and Ireland. He has contributed a number of memoirs to the Journal of the Chemical Society, and is the author of several articles in the revised editions of "Watts' Dictionary of Chemistry." We may mention that Dr. Japp was a candidate for the chair when Professor Carnelley was appointed.

NOTES AND QUERIES.

* * Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertisement columns.

Gelatinising Petroleum.—Can any reader inform me which is the best way of making a petroleum jelly by boiling it with soap? Does the quality of the petroleum affect the result, and what quantity of soap should be used? The jelly should be as soft as possible, and of as low a specific gravity as possible.—D. U.

MEETINGS FOR THE WEEK.

FRIDAY, 14th.—Physical. "On Certain Relations Existing among the Refractive Indices of some of the Chemical Elements," by the Rev. T. Pelham Dale, M.A. "Tables of Spherical Harmonics" (with examples), by Prof. Perry, F.R.S.

TO MANUFACTURING CHEMISTS AND OTHERS.

THE LONDON COUNTY COUNCIL is prepared to receive TENDERS for the SUPPLY of 1000 tons of SULPHURIC ACID.

Deliveries to be made in bulk at the Northern and Southern Outfalls, and in carboys to Stations within the Metropolis, commencing about the 1st May next.

Persons tendering will be required to declare in their tender that they pay such rates of wages and observe such hours of labour as are generally accepted as fair in the trade.

The Specification, Form of Tender, and other particulars may be obtained on application to the Chemist of the Council, at the Office, 40, Craven Street, W.C., until Saturday, the 22nd November, 1890.

Tenders must be addressed to the Clerk of the London County Council, Spring Gardens, London, S.W., endorsed "Tender for Sulphuric Acid," and be sent in not later than 5 o'clock on Monday afternoon, the 24th of November, 1890.

The Council does not bind itself to accept the lowest or any tender.

H. DE LA HOOKE, Clerk of the Council.

Spring Gardens,
3rd November, 1890.

TO MANUFACTURING CHEMISTS AND OTHERS.

THE LONDON COUNTY COUNCIL is prepared to receive TENDERS for the SUPPLY of 1500 TONS of MANGANATE OF SODA, to be delivered at the rate of not less than 50 tons nor more than 200 tons per week, from the 1st March, 1891.

Persons tendering will be required to declare in their tender that they pay such rates of wages and observe such hours of labour as are generally accepted as fair in the trade.

The Specification, Form of Tender, and other particulars may be obtained on application to the Chemist of the Council, at the office, 40, Craven Street, W.C., until Saturday, the 22nd November, 1890.

Tenders must be addressed to the Clerk of the London County Council, Spring Gardens, London, S.W., endorsed "Tender for Manganate," and be sent in not later than 5 o'clock on Monday afternoon, the 24th November, 1890.

The Council does not bind itself to accept the lowest or any tender.

H. DE LA HOOKE, Clerk of the Council.

Spring Gardens,

3rd November, 1890.

THE CHEMICAL NEWS.

VOL. LXII. No. 1616.

ON THE PHOSPHORESCENCE OF LITHIUM COMPOUNDS IN VACUO, AND THE SPECTRA OF COATED TERMINALS.

By E. E. BROOKS.

HAVING noticed the great brilliancy with which certain lithium compounds phosphoresce, when examined by Mr. Crookes's method in the negative discharge *in vacuo*, it may perhaps be of some interest to state the results obtained.

Lithium sulphate gave a bright lilac-blue glow.

Lithium phosphate was equally brilliant, the colour being a light Cambridge blue.

Lithium Chloride.—Pale lavender-blue, only moderate brilliancy.

Lithium Fluoride.—Very light flesh-coloured glow, about equal to the chloride in brilliancy.

Lithium Silico-fluoride.—Deep blue, with darker spots, but not so brilliant as the somewhat similar phosphorescence of the sulphate.

Lithium phosphate fused with sodium carbonate, gave a bright emerald-green glow, which existed unchanged for a second or two after circuit was broken, and then faded quickly away. The other salts above mentioned appeared to have no residual glow.

The nitrate, carbonate, and hydrate did not show any signs of phosphorescence.

Some lithium nitrate was fused and partly volatilised *in vacuo*, and the glass in contact with the fused salt received an opaque enamel-like coating, apparently unaffected by water or acids; and, when the tube was again exhausted, this white coating exhibited a distinct phosphorescence, similar to, but more yellowish than, the normal phosphorescence of the German glass tube.

Of the lithium minerals, I believe spodumene is the only one mentioned by Mr. Crookes. This gives a golden yellow glow.

Lepidolite phosphoresces with very great brilliancy. The colour is a deep red, with traces of blue.

Petalite is also exceptionally brilliant, glowing with a rich yellow, like a live coal.

The spectra of all the above salts and minerals are continuous, only showing a concentration of light in certain parts of the spectrum.

Rubellite and indicolite did not phosphoresce, and amblygonite gave only slight traces of a whitish glow.

While working with lithium salts, certain peculiarities were noticed, which led to extended experiment, but, at present it is only intended to give a brief preliminary notice of the results obtained. It was found that when a plate of aluminium or platinum was coated with a thin layer of a lithium salt, either by fusion or merely lying loosely upon it, and then made the negative terminal *in vacuo*, it glowed with a conspicuous red light, the spectrum of which consists of two lines, red and orange, of which the orange line is slightly the most brilliant.

By direct comparison, the red line was found to coincide with the flame line of lithium; and, although a similar test has not yet been applied to the orange line, which is not visible in the flame spectrum, it is most probably the well known β -line of lithium.

A similar effect was obtained in other cases.

A terminal coated with thallium sulphate gave a green line which coincided with the green thallium flame line.

A sodium coating gave a very strong D line, the yellow glow extending some distance from the terminal.

A calcium nitrate coating gave the orange and green bands of the metal, which were directly compared with the flame spectrum.

A barium nitrate coating gave several green lines, and an orange line near D.

These results were obtained with a 1-inch spark coil. Other metals gave only faint spectra, or none at all; but with a stronger discharge the method might be more successful.

It is important to note that these spectra almost wholly disappear in a high vacuum, and are only well seen through a comparatively small range of pressure. The best effects are obtained when the dark space extends about $\frac{1}{4}$ -inch from the terminal, and as at this pressure the lines due to the gas used are still fairly brilliant, the two spectra are seen together.

Countess Street, Leicester.

THE DETERMINATION OF SULPHUR IN COPPER.

By H. JOSHUA PHILLIPS, F.C.S.

ALTHOUGH modern refined copper is, as a rule, very free from sulphur, yet since such small quantities of this element seriously affect the physical properties of the metal, a very accurate method for its determination becomes imperative.

The estimation of sulphur in a nitrate solution, by precipitation with barium chloride or nitrate, gives results below the truth—owing to the solubility of the resulting basic sulphate in the solution of nitrate of copper, and, indeed, appreciable quantities may be overlooked altogether. Good results, however, can be obtained in a chloride solution.

The following is the process used by the writer:—

Ten grms. of the sample is dissolved in pure 16 E nitric acid (= sp. gr. 1.42), and evaporated to dryness on the water-bath, the residue is taken up with 400 c.c. of E nitric acid solution and filtered, if necessary, and any residue reserved. The filtrate is diluted to 800 c.c., and heated to 70° C., 1 c.c. of 5 E HCl is added, and the solution well stirred and allowed to stand in a dark place for twelve hours. The supernatant liquid is now decanted as far as possible from the precipitate of silver chloride, and finally filtered and washed, and the silver determined, if necessary, in the usual manner. The filtrate is now evaporated nearly to dryness, and 50 c.c. of pure 10 E HCl (= sp. gr. 1.16) added, and the evaporation continued to complete dryness. The residue is dissolved in a minimum quantity of water, and another 50 c.c. of 10 E HCl added and again evaporated to complete dryness. The residue is dissolved in 300 c.c. of E HCl and diluted to 700 c.c., heated to boiling, and 2 c.c. of E baric chloride solution added, stirred, and allowed to stand twenty-four hours. The baric sulphate is then filtered off and treated as usual. To test the method, 10 grms. of pure electrotype copper, free from sulphur, was treated as above, and a quantity of copper sulphate added, representing 0.1 per cent of sulphur on the 10 grms., and the result obtained gave 0.098 per cent sulphur. The reserved residue, insoluble in nitric acid, is fused and tested for sulphur; and, if any is present, it is estimated and added to the portion already found in solution.

Usually, the amount of lead present in a copper is over and above the theoretical quantity necessary to form sulphate of lead with the proportion of sulphur present on treatment with nitric acid, and one might expect the sulphur, present as lead sulphate, to be practically all in the insoluble residue, but since PbSO₄ is so soluble in the nitrate of copper solution, it frequently happens, in fairly pure coppers, that the whole goes into solution, and hence

has to be determined by some such method as the foregoing.

G. E. Ry. Laboratory, Stratford, London, E.

THE ACTION OF LIGHT UPON THE DIAZO COMPOUNDS OF PRIMULINE AND DEHYDROTHIOTOLUIDINE.*

(A METHOD OF PHOTOGRAPHIC DYEING AND PRINTING).

By ARTHUR G. GREEN, CHARLES F. CROSS, AND EDWARD J. BEVAN.

IN the early part of 1887, one of us (Green) discovered that by heating paratoluidine (2 mols.) with sulphur (4 to 5 atoms) at 200°–300° C. a very complex amido base was obtained, which, on treatment with fuming sulphuric acid at a low temperature, was converted into a sulphonic acid, the alkaline salts of which were easily soluble in water, and had the peculiar property of dyeing cotton primrose yellow from an alkaline or neutral bath without the use of a mordant. Further, the amido compound thus fixed upon the fibre could be diazotised *in situ* by passing the material through a weak solution of nitrous acid, and when diazotised could be combined with various phenols and amines, thus producing a variety of different colours, which, being formed within the fibre, were all distinguished by great fastness to washing, &c. The soluble amido sulphonic acid was named "Primuline" by its discoverer, and has found a very extensive employment in cotton dyeing; the colours produced from it within the fibre were called "Ingrain Colours."[†]

Although the chemical constitution of primuline base (of which primuline is the mono-sulphonic acid) has not yet been determined with certainty, there is no doubt that it is a condensed derivative of dehydrothiotoluidine, a body which always accompanies it in its formation, and that it differs from the latter in exactly the same way as dehydrothiotoluidine itself differs from para-toluidine. As there is scarcely any doubt that dehydrothiotoluidine has the formula—

i.e., is an amido-benzoyl-amido-thi-cresol, it follows that the formula of primuline, or rather of its chief constituent is[‡] probably

In a similar manner, by heating meta-xylylidine or pseudo-cumidine with sulphur, homologues of primuline are obtained, which, like primuline itself, dye cotton without a mordant, and can be diazotised and combined with phenols within the fibre.

It has been long observed by one of us (Green) that the diazo compound of primuline was very sensitive to the action of light, being readily decomposed thereby, and losing its property of combining with phenols and amines. Upon this fact we have now founded a photographic process, by means of which designs can be produced in fast colours upon cotton, silk, wool, linen, or other fabrics. It can also be applied to wool, xylonite, celluloid, paper, or to gelatin films upon glass, thus affording a very wide range of employment. The process, which is a very simple one, merely depends upon the fact that if a material containing diazotised primuline be exposed to light under a design, those parts which are acted upon by light will be decomposed, whilst the parts protected from the light will remain unaltered, and consequently, on sub-

sequent development with a phenol or amine, will produce colours, whilst the decomposed portions will not. The details will, of course, depend somewhat upon the material to be treated. As an instance we may take the production of a design upon cotton cloth, cotton velveteen, &c. The material is first dyed with primuline from a hot bath containing common salt until the required depth is obtained. It is then washed and diazotised by being immersed for a quarter of a minute in a cold bath containing about $\frac{1}{2}$ per cent of sodium nitrite, and strongly acidified with sulphuric or hydrochloric acid. The material is washed again and exposed damp (or if preferred after having been dried in the dark), to the action of light beneath leaves, ferns, flowers, or other natural objects, or beneath glass or transparent paper, upon which may be painted or printed any design which it is required to copy. Either the arc electric light or daylight may be employed; in the latter case the time of exposure will of course vary with the intensity of the light; under half a minute is required in bright sunshine, and nearly half-an-hour in very dark cloudy weather. When the decomposition is complete, which may be readily ascertained by means of a test slip, exposed simultaneously, the material is removed from the light and either passed into the developing bath at once, or is kept in the dark until it is convenient to develop it. The developing bath consists of a weak solution ($\frac{1}{2}$ to 1 per cent) of a phenol or amine made suitably alkaline or acid, the phenol or amine employed depending upon the colour in which it is required to produce the design, thus:—

For red, an alkaline solution of beta-naphthol.
" maroon, " beta naphthol-di-sulpho-phenol. [luc acid.
" yellow, " resorcin.
" orange, " phenylene diamine hydrochloride.
" brown, " alpha-naphthylamine hydrochloride.
" purple, "

If it is required to produce the design in two or more colours, the respective developers, suitably thickened with starch, may be applied locally by means of a brush or pad. After development the material is thoroughly washed and requires no further fixing.

Linen, silk, and wool are treated in exactly the same way. Paper for copying drawings, &c., is coated on the surface with primuline by means of a brush or roller. For the production of gelatin films upon glass the primuline is incorporated with the gelatin before being applied to the glass.

In place of ordinary primuline the homologues already mentioned may be used; for silk and wool the primuline may be replaced by dehydrothiotoluidine-sulphonic acid, by means of which colourless backgrounds may be obtained.

Concerning the reaction which occurs when the diazo-primuline or the diazo-dehydrothiotoluidine is decomposed by light, we cannot at present say anything definite, except that the diazo group is completely destroyed, for on treatment with sodium hydrosulphite (true hyposulphite), it cannot be converted into the amido-group (re-forming primuline or dehydrothiotoluidine). The reaction may consist in a replacement of the N_2 group by OH or by H, or may be even more complex. Although we cannot affirm that this reaction to light is a property of the diazo-compound of this group of bodies only, yet it is certain that they possess an extreme susceptibility to light far greater than that of other diazo-compounds, whilst at the same time they are far more stable to heat. It is thus possible that this property may depend in some way upon the sulphur which they contain.—*Chemical Trade Journal*.

Appointment.—Mr. Charles H. Southwell, Pharmaceutical Chemist (Exam.), of Boston, was appointed Public Analyst for the Holland Division of Lincolnshire at a Statutory Meeting of the County Council on November 7th.

DETERMINATION OF METALLIC ALUMINIUM IN THE ALUMINIUM OF COMMERCE.

By G. KLEMP.

THE striking solubility of aluminium in alkaline lyes, presents means—which do not prove available in the determination of zinc powder in consequence of the relatively sparing solubility of zinc—to effect the determination of aluminium in a simple manner. A weighed quantity of the aluminium is treated with potassa-lye, and the escaping hydrogen is determined either volumetrically as gas or gravimetrically as water. For the former purpose most of the apparatus used for gas volumetry may be employed (especially Lunge's improved gas volumeter), and for the latter method the apparatus which R. Fresenius proposes for his method of determining zinc powder.

Fr. Schulze made use of the gas-volumetric method in order to compare the quantities of hydrogen gas evolved by different sorts of aluminium in alkaline solutions, which he designated as approximately corresponding to the proportion of pure aluminium. But, according to the instances given, it is not possible to arrive at a decisive conclusion, either as to the quantity of the aluminium present or the applicability of the method. The author considers the gravimetric determination with the apparatus of Fresenius preferable to the volumetric method.

He uses a potassa lye containing in 100 c.c. 35 grms. KOH. The aluminium is reduced to thin fragments with a file; they were put on a weighing-tube, about 1 grm. emptied into an Erlenmeyer flask holding about 150 c.c., and the weighing tube was re-weighed. Upon the aluminium there was poured a little water, and some vaseline added to prevent frothing.

The hydrogen evolved was burnt to form water in the apparatus of Fresenius, and the water was collected in concentrated sulphuric acid. In order to prevent too violent reaction and too rapid development of hydrogen, the potassa lye was added in small portions, proceeding otherwise according to the directions of Fresenius for the determination of zinc powder.

The solution went on regularly, and was completed in about 45 minutes. Towards the end, when the escape of gas became slow, heat was applied. In the flask there remains a brownish-grey solution, and a black undissolved residue.

The author purposes ascertaining whether this method is applicable to aluminium alloys (ferro-aluminium, aluminium bronze, &c.).—*Zeitschrift Analytische Chemie*, vol. xxix., p. 388.

THE DETECTION OF FOREIGN CRUDE PHOSPHATES IN GROUND BASIC SLAGS.

By L. BLUM.

THE superiority of basic slag as compared with other crude phosphates, on account of its being readily assimilated, is generally admitted. As a proof of this recognition we need only look at the rise in price which it has recently undergone. Along with this advance there has been a decline in the price of natural phosphates. Thus, in Lille, on May 10th, grey phosphatic chalk from Mons, finely ground, containing 40 to 45 per cent calcium phosphate, was quoted at 0.53 franc per unit of calcium phosphate per ton, which corresponds to a price of 0.11 franc per kilo. of phosphoric acid. It is, therefore, possible that these cheap, finely-ground, crude phosphates, may either be sold alone as basic slag, or may be mixed with slag meal, especially as they may serve to increase the percentage of phosphoric acid in inferior ground slags.

The question whether ground phosphates may be substituted for ground basic slag for manurial purposes with equal advantage has been much discussed of late. That opinion has been proved erroneous by the researches of P. Wagner and other chemists. These authorities have proved that it is not possible, even by the finest grinding to convert every undissolved phosphate into a sufficiently effective manure. An addition of such phosphates to basic slag involves loss to the purchaser, and the question is put to the analyst how may the presence of raw phosphates in basic slags be detected. The ordinary determination of phosphoric acid—the solution of the substance in a mineral acid and precipitation as ammonium phosphododekamolybdate, or its direct determination in an alkaline solution as magnesium-ammonium phosphate—exclude any such detection. It would therefore be necessary to treat basic slags on the citrate method like the “reverted” phosphates.

But if we compare the total composition of basic slags with that of crude native phosphates, inferences may be drawn which show the presence of the latter in ground basic slag. We may here remark that for this fraud only such phosphates will be used as are low in phosphoric acid, but rich in substances which waste sulphuric acid (so-called “profligate constituents”), e.g., calcium carbonate, and which consequently do not admit of remunerative conversion into superphosphate. For high grades of phosphates the makers of superphosphates pay so high a price per kilo. of phosphoric acid that the sophisticator would find no advantage in their employment.

Let us take as an instance the above mentioned grey phosphatic chalk of Mons. It contains 40 to 55 per cent calcium phosphate, about 50 per cent calcium carbonate, and consequently 22 per cent carbonic acid, little iron, and no manganese or mere traces. Recent pure basic slag contains no carbonic acid, and often considerable quantities of iron and manganese.

If ground basic slag is mixed with this ground phosphatic chalk the resulting mixture contains, according to the quantity of the addition, a large proportion of carbonic acid. In addition, the proportion of iron and manganese is reduced. We have, therefore, in the presence of carbonic acid in a basic slag an indication of the presence of foreign admixtures, since the preparation of basic slag completely excludes the presence of carbonic acid. Against this representation it may be objected that basic slag contains free lime, which greedily absorbs carbonic acid from the air, so that consequently basic slag meal, which has been lying for some time, contains a certain quantity of carbonic acid. It is also not impossible that the tetra-calcium phosphate in the slag may be decomposed by the carbonic acid of the air so as to form calcium carbonate. The objection is not unfounded, and the author has sought to throw light upon it by the following experiments. He determined the carbonic acid in various samples which were at hand. As there exist in the slags sulphides capable of decomposition by acids (CaS.MnS), he used in carrying out the determination the apparatus commonly employed for burning the carbon by means of chromic and sulphuric acid. As a mixture of both acids was used for decomposing the slags, it was certain that no sulphur compounds were obtained in the absorption apparatus. The quantities of carbonic acid obtained in this manner were as follows:—

1. Recent basic slag, not ground	0.00
2. Sample of commercial slag, finely ground	trace
3. Another sample, finely ground	0.16
4. Weathered slag which had been exposed for three years in the open air, finely ground	2.28
5. The same coarsely ground	2.18
6. The same; the portion intended for analysis was rubbed finely in an agate mortar, and remained for eight days exposed to the air of the laboratory, spread out in a thin layer on a sheet of paper	2.47

H. Otto (*Chemiker Zeitung*, vol. ii., p. 225), found in an analysis of basic slag which he there gives only a trace of carbonic acid. The sample used for experiment 6 lost on ignition 2.87 per cent. The excess of 0.40 per cent was due to moisture and combined water. In this case it may therefore be assumed with certainty that 2.47 per cent is the maximum of carbonic acid which the slag in question was able to take up. This maximum may certainly vary in any case according to the composition of the slag.

The inducement to this communication was the analysis of a ground basic slag, which along with the stipulated proportion of phosphoric acid contained 10.3 per cent of carbonic acid. I had no doubt that the slag had been falsified with an inferior ground native crude phosphate, rich in calcium carbonate.

Although the presence of foreign crude phosphates cannot be directly proved by the determination of carbonic acid we have here an easy method of deciding whether a slag-meal can be objected to in this respect. For this purpose it is sufficient to determine the loss of the dried sample on ignition. If this is too high there is *prima facie* ground to question the genuineness of the article.—*Zeitschrift Analytische Chemie*, vol. xxix., p. 408.)

DETERMINATION OF ASH IN MOLASSES, HONEY, &c.

By H. W. WILEY and HUBERT EDSON.

THE use of metallic silver prepared by reducing the chloride with an alkaline solution of grape sugar or by

direct reduction with iron or zinc, has been recommended as an aid in the oxidation of the carbon in the preparation of the ash from sugars, molasses, &c. The metallic silver acts as a carrier of oxygen, and after the completion of the reaction can be easily recovered from the ash by solution in nitric acid or otherwise.

Lucien* recommends the use of the oxide of zinc for this purpose. The oxide of zinc easily gives up its oxygen to the carbonaceous material, and is again easily oxidised in the muffle where the incineration takes place. At the end of the process, therefore, the ash is burned perfectly free from carbon and the zinc remains in the state of oxide. The weight of the ash can therefore be easily determined by deducting the weight of the oxide of zinc which has been added. The amount of oxide of zinc used, as recommended by Lucien, is 50 m.grms. to 2½ g. of molasses or 5 g. of sugar. Platinum dishes were used, and the platinum appeared to suffer no injurious effect from the action of the zinc.

We have given this method of ash determination a thorough trial, and the results are given in the accompanying tables.

First ash burned with ZnO, April 4. The sample and ZnO were thoroughly mixed together with H₂O.

The second and third samples of same date were mixed with alcohol, evaporated on steam bath, and residue incinerated. The ashes in both cases much improved in appearance by this treatment.

As will be seen from the above table, the mean percentage of ash in the samples of molasses used, when burned in the muffle in the usual way, was 8.04 per cent. In no case was the ash perfectly white. In the same

samples in comparative determinations, where oxide of zinc was used (Table No. 2) the mean percentage of ash was 7'99. The ash in all cases was very much improved in appearance, and apparently should have weighed much less than when no oxide of zinc was used. In the determinations made on the 4th of April, the zinc oxide was thoroughly mixed with the molasses by means of water or alcohol, while in the determinations made previous to that date it was simply sprinkled over the mass in the dish. The samples of ash obtained by previous mixing of the oxide with water or alcohol were very much whiter than any of the others. In order to determine whether there would be any loss from the ignition of the zinc oxide alone at the temperature used, a series of determinations was made, which showed an average loss of nearly 2 m.grms. for each 50 m.grms. of oxide employed. It is doubtful whether this loss takes place after the zinc oxide is thoroughly mixed with the sample, but in Table No. 3 the percentage of ash is given after correcting for the possible loss of zinc oxide. The mean percentage of ash as corrected in this way would be 8'06.

It is seen by the above work that for quantitative determination the numbers obtained with and without the zinc oxide are so nearly identical as to render its use of no particular value. If the ash is to be analysed quantitatively after it is obtained, the presence of the zinc would probably be of more injury than the trace of carbon which would remain without its use. We are therefore of the opinion that the method in ordinary use of determining the ash directly by carefully incinerating in the muffle, is to be preferred to the methods depending upon the admixture of any other substance to be used as a carrier of oxygen.—*Journal of Analytical Chemistry*, Vol. iii., Part 3.

A LECTURE EXPERIMENT.

By SAVILLE SHAW, F.C.S.

THE following slight modification of a well-known lecture experiment may possibly prove of service to some of your readers.

The ordinary forms of apparatus for illustrating the indestructibility of matter by the increase in weight of a burning candle, have the disadvantage either of requiring the use of an aspirator, which is apt to draw the students' attention from the more essential part of the experiment, or in the modification, where the chimney itself contains the absorbing material, the draught is often uncertain, and a deposit of soot liable to occur and choke up the spaces between the lumps of soda-lime and caustic soda used.

Both these inconveniences are obviated by employing the apparatus shown in the figure, which consists of a small petroleum lamp, *a*, suspended in a wire framework beneath an ordinary lamp chimney, *b*, sufficient space being left to allow of the lamp being lighted without removal. The chimney contains a coil of coarse copper gauze, *c*, in the lower part of the narrow portion, above this is placed a rather open roll of iron gauze, *d*, provided with a handle of bent wire to facilitate its withdrawal, the roll being coated with caustic soda.

The covering of the gauze is easily performed either by dipping it in molten caustic contained in a nickel basin, or by ladling the melted substance over it.

The chimney may be removed from the apparatus and both ends closed by corks, enabling it to be used repeatedly without renewal. The gain in weight in three or four minutes amounts to about one gm., sufficient to show very appreciably on even a coarse lecture balance.

The Durham College of Science,
Newcastle-on-Tyne.

Micro-Organisms.—Messrs. Baillière, Tindall, and Cox will issue, in a few days, an octavo volume (360 pages and fifty-two figures), entitled, "Researches on Micro-Organisms," by Dr. A. B. Griffiths, F.R.S.E., F.C.S., &c. The work is an *exposé* of recent researches in various branches of bacteriology, and includes an account of the distribution of microbes in air, soil, and water; animal alkaloids (ptomaines, &c.), soluble ferments, action of heat, light, and electricity on microbes; action of germicides, biology of microbes, &c.

THE ELECTROLYTIC METHOD APPLIED
TO MERCURY.

SEPARATION FROM COPPER.*

By EDGAR F. SMITH and LEE K. FRANKEL.

THE electrolytic precipitation of mercury has been successfully performed by different chemists; thus, J. B. Hannay (*Berichte d. d. Chem. Gesellschaft*, vi., 270) recommends a solution of mercury sulphate for this purpose, but gives no quantitative results. F. W. Clarke (*Am. Journal of Science*, xvi., 200; *Zeitschrift für Analyt. Chemie*, xviii., 103) separated mercury from the solution of its chloride, freely acidulated with sulphuric acid, by using a current obtained from six Bunsen chromic acid cells. Classen and Ludwig (*Berichte d. d. Chem. Gesellschaft*, xix., 323) employed a mercury solution rendered slightly acid with nitric acid, and a current affording 0.5 to 1.0 c.c. OH gas per minute. The time occupied in the deposition at ordinary temperatures was twelve to sixteen hours. Hoskinson (*Am. Chem. Journal*, viii., 209) obtained good results with the nitrate. Smith and Knerr

(*Am. Chem. Journal*, viii., 209) employed a nitrate solution, in which there was considerable acid in excess, and with a current yielding 4 c.c. OH gas per minute deposited 0.1 gm. of mercury in forty-five minutes. In all of these methods, which permit of the separation of mercury from many other metals, the mercury is thrown out as a mirror-like deposit, and drops of metal are plainly discernible.

We have observed that this metal can be separated without difficulty from solutions containing a large excess of alkaline cyanide, and with a comparatively weak current. The solution used was the chloride. The conditions, time, strength of current, and results are as follows, with mercury alone. (See Table I.)

The deposits in the determinations were compact, rather grey in colour, and showed in a few cases the drop-like nature so characteristic of mercury.

For washing purposes it was found best to use water only, because when this was followed with alcohol, we noticed that the latter detached thin films of metal, causing a loss in consequence.

The heat of the hand is sufficient to dry the deposit, though a warm iron plate may be used. Some of the deposits were allowed to dry slowly over sulphuric acid. In our experience, with about a hundred mercury depositions, we observed but five in which there was a slight oxidation of the metal. This only occurred when

Copper precipi-
tated with silver.

a film of water remained in contact for some time with the deposited mercury.

In working with copper solutions, under conditions similar to those mentioned above, we discovered that this metal would not separate until the alkaline cyanide was completely decomposed. We therefore undertook a series of experiments with solutions containing both mercury and copper, hoping to effect their electrolytic separation. This seemed advisable, as the attempts in this direction had thus far not been as successful as might be desired (see Luckow, *Zeitschrift für analyt. Chem.*, viii., 24; and Classen, *Bericht d. d. Chem. Gesellschaft*, xvii., 2467; also *Zeitschrift für analyt. Chem.*, xxiv., 247).

Our mercury solution contained the same quantity of metal as in the first experiments. Seventy per cent of copper was added in each case. The quantity of cyanide varied from 0.65 grm. to 3.9 grms.; total dilution was 200 c.c., and the current strength varied from 0.1 to 0.4 c.c. OH gas per minute. Time, six to eighteen hours. Ten experiments were performed, and notwithstanding the mercury was completely deposited, slight quantities of copper were likewise thrown out of solution.

Thirty additional experiments were made; in each the quantity of mercury was 0.1945 grm., while the copper varied from 14 to 70 per cent. The quantity of alkaline cyanide varied from 3.9 to 8.5 grms.; total dilution remained 200 c.c. The current averaged 0.4 to 0.12 c.c. OH gas per minute. Time, eighteen hours. The best results were these:—

Hg taken. Grm.	Hg found.	Difference in per cent.
0.1945	0.1932	-0.66
—	0.1920	-1.28
—	0.1927	-0.92
—	0.1936	-0.46
—	0.1930	-0.77
—	0.1936	-0.46
—	0.1954	+0.46
—	0.1938	-0.36
—	0.1923	-1.13
—	0.1921	-1.23

These, as well as the results obtained in twenty experiments made later, seem to indicate that the presence of the copper exercises considerable influence upon the precipitation of the mercury—retards it. This fact, we think, was confirmed by ten or more experiments, in all of which a slight quantity of the mercury was retained in solution, notwithstanding the current was increased to 1.2 c.c. OH gas per minute, and the amount of cyanide considerably reduced. The time of each precipitation was continued through seventeen hours.

Our attention was next directed to ascertaining whether or not a stronger current might be used to throw out the mercury, and at the same time leave the copper in solution. The results with mercury alone are given in Table III.

Using the same quantity of mercury and varying amounts of copper the results were as follows. (See Table IV.). These results are recorded in the order obtained, while the differences in percentage from that required vary from +0.05 to -0.98 per cent, and in six cases out of nine show a deficiency in the mercury, yet a careful qualitative examination of each filtrate failed to detect this metal; the error must therefore be ascribed to other causes. It may not be improper to add that these determinations and separations were not always conducted in the same platinum vessels, and, further, those used by us ranged in weight from 61 to 135 grms.

Where the quantity of copper exceeded 20 per cent of the mercury, the results were unsatisfactory.

It is well known that silver can be separated qualitatively from its cyanide solution, but whether its separation from copper could be effected in the same manner as

that by which mercury and copper were separated was undetermined; to ascertain this, we made forty experiments; ten of which resulted as follows. (See Table V.)

Later, we diminish the quantity of copper, with no better results. On increasing the quantity of cyanide, and also the strength of the current, the silver was very notably retarded in its deposition. After carefully repeating the work with no better outcome, we feel justified in saying that the cyanide method cannot be applied in the electrolytic separation of these two metals.

The current employed by us was obtained from storage batteries of the Julien form. Each cell contains nineteen plates, each of which is five and three-quarter inches square. In a long experience, with almost every form of battery, in electrolytic work, we have not had the same even steady current for a series of hours as with the Julien form, and recommend it to all engaged in similar experiments. See, further, *Berichte d. d. chem. Gesellschaft*, xxi., 2892.

ON THE SO-CALLED PEROFSKITE FROM MAGNET COVE, ARKANSAS.

By F. W. MAR.

In 1877 it was shown by Knop* that the supposed perovskite of the Kaiserstuhl, contained besides titanium a considerable amount (23 per cent) of niobium and tantalum, and he accordingly made it an independent species and named it very appropriately *Dysanallyte*. The analysis of the similar mineral from Magnet Cove, Arkansas, the results of which are given below, shows that it is also distinct from perovskite, and is to be classed with dysanallyte. For the material for analysis I am indebted to the kindness of Professor E. S. Dana.

The method of analysis was as follows:—0.500 grm. of the carefully selected mineral was placed with about 15 c.m.³ of concentrated sulphuric acid in a platinum crucible of 150 c.m.³ capacity, and the whole being covered with a watch-glass that the progress of the decomposition might be easily observed, boiled for ten or fifteen minutes. The cooled product was poured into 600 or 700 c.m.³ of cold water and allowed to stand over night or until the calcium sulphate was completely dissolved. A small residue was usually found, and this was put through the same process. Any final residue is silica and sometimes a little tantalum or niobium oxide. The former was determined by evaporation with sulphuric and hydrofluoric acids and the remaining oxide was added to the main oxides.

The solution of the mineral was then made slightly alkaline with ammonia, and the precipitated earth filtered off. The lime was thrown out of the concentrated filtrate as oxalate, and after evaporation and volatilisation of ammonia salts, magnesia was determined in the residue. Alkalies should be found at this point if present; there were none.

The weighed earths obtained as above were fused in sodium carbonate, enough sulphuric acid added to the mass to bring about a bisulphate fusion, and then enough more to keep the whole in the liquid condition even when cold. After cooling, the mass was poured into 300 c.m.³ of cold water containing 1 grm. of tartaric acid, and after separating the iron in alkaline solution by hydric sulphide the titanium, with which go the niobium and tantalum, were separated by the acetic acid process of Professor Gooch.† The greater part of the manganese was separated by an ordinary acetate process, and the acid oxides by the strong acetate process. On neutralising the filtrate from this last with ammonia and boiling, only

a trace of some earth was found showing absence of alumina. The titanium was separated from the weighed oxides by Knop's chlorinating process, and finally the niobium was determined in the mixture of niobium and tantalum oxides by reduction in hydrochloric acid and titration with permanganate after T. B. Osborne.* Only a trace of titanium was found in the niobium and tantalum oxides by the Osborne process with hydrogen peroxides, and the titanium re-estimated by the same process gave practically the same result as before.

A portion of the oxides having been lost during the operation, having gone, as it appeared, with the manganese used to decompose the tartaric acid, another portion of mineral was treated in the same manner as far as this point, and the tartaric acid was destroyed by evaporation in platinum and ignition. No aluminum having been found, the titanium, tantalum, and niobium oxides were separated by boiling with dilute sulphuric acid. By evaporation of this filtrate a quantity of earths was obtained. To this was added another portion separated by ammonia from the filtrate (in the same portion of mineral) after separation of lime, evaporation and ignition, and solution in hydrochloric acid, and before the precipitation of the magnesia by microcosmic salt. The combined earths were precipitated in a slightly acid solution by oxalic acid in order to separate from any uranium, the cerium and yttrium groups separated by the sodium sulphate process, and each precipitated again as oxalate and weighed as oxide. As appears the main portion of the rarer earths belongs to the yttrium group.

An attempt was made to take the atomic weight, but the result obtained, 190, is probably too high, the colour showing that part of the sulphate was changed to a basic salt. This, however, with the colour of the oxides, a reddish brown, and the fact that the solutions do not yield an absorption spectrum, suggests that a chief portion of the earth is terbium oxide.

The result of the analysis is given in the Table.

Specific gravity = 4.18.

In conclusion I would express my thanks to Professor Gooch, of the Kent Laboratory, for the valuable advice and assistance freely given by him during the course of the analysis.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.
General Monthly Meeting, November 3, 1890.

SIR JAMES CRICHTON-BROWNE, M.D., LL.D., F.R.S.,
Treasurer and Vice-President, in the Chair.

THE following were elected Members of the Royal Institution:—Viriamu Jones, M.A.; C. N. Nicholson, M.A.; John Hartley Perks, J.P.; The Hon. Sir James Stirling.

* *Amer. Chem. Journ.*, vol. xxx., p. 329.

The special thanks of the Members were returned to Dr. J. A. Fleming for the presentation on behalf of Professor Elihu Thomson of the Apparatus employed by Prof. Thomson in his experiments on Electro-magnetic Repulsion; and to Hervey Pechell for his present of an old engraving (1809) of the Library of the Royal Institution.

The Managers reported that at their meeting held this day they had elected Victor Horsley, F.R.S., Fullerian Professor of Physiology for three years (the appointment dating from January 12, 1891).

The Presents received since the last Meeting were laid on the table, and the thanks of the Members returned for the same.

NOTICES OF BOOKS.

Sugar Analysis; for Refineries, Sugar-houses, Experimental Stations, &c., and as a Handbook of Instruction in Schools of Chemical Technology. By FERDINAND G. WIECHMANN, Ph.D. New York: John Wiley and Sons, 1890. 8vo., pp. viii.—187.

THIS admirable volume is the result of the author's experience as consulting chemist to the extensive sugar refining company of the Messrs. Havemeyers and Elder, Brooklyn, N.Y. Its aim is to supply the practical sugar-chemist with a concise and thorough treatise embodying the new methods of analysis that are so widely scattered throughout periodical literature. The author, being at the same time Instructor in Chemical Philosophy, School of Mines, Columbia College, has arranged the material in such a way that the work can be used for elementary instruction in this branch of analytical chemistry. Instead of describing in turn the different products met with in laboratory work, such as raw sugars, liquors, molasses, &c., the author deals with the individual constituents, as sucrose, invert-sugar, ash, water, &c., and thus avoids repetitions.

The volume opens with a discussion of polarisation, and the various instruments of precision used in sugar-analysis; it continues with the methods employed, introducing examples where feasible. A brief bibliography is given, but unfortunately the places of publication and dates of the issue are omitted.

The tables, nineteen in number, conclude a practical and useful work abreast of modern requirements. The table of English, French, and German synonyms on pages 108—109 is valuable, and rather a suggestive feature. We note the clear type and the index.

Republic of Uruguay. International Exhibition of Mining and Metallurgy, Crystal Palace, London, 1889.

WE have here, in the first place, a catalogue of minerals from the museum of the Consulate General of Uruguay. There are specimens of gold, silver, copper, and iron, pyrites being described as very common. Platinum, tin,

mercury, and cobalt are said to occur, though no specimens were shown at last year's Exhibition. The silver ore of Uruguay contains, according to Lettson, 87 per cent of fine silver. There are also copper ores at 56 per cent and magnetic iron ore at 72 per cent. Agates, rock-crystals, marbles, and even diamonds and topaz, have also been found. "Calcareous cement" occurs on the left shores of the Brujas, and on the sides of the Gerro of Monte Video.

The pamphlet further contains the mining-laws of Uruguay, summed up in 182 sections, and a map of the republic.

Griffin's Scientific Text-Books. A Treatise on Electro-Metallurgy; Embracing the Application of Electrolysis to the Plating, Depositing, Smelting, and Refining of various Metals, and to the Reproduction of Printing Surfaces and Art-Work. By W. G. McMILLAN, F.I.C., F.C.S. London: C. Griffin and Co.

LIKE not a few other technical monographs, this treatise is to some extent encumbered with matter for which the reader might have been quite as well referred to any of the multitudinous chemical and physical treatises which have been lately issued. The work before us does not differ very widely from that by A. Watt on the "Electro-Deposition of Metals." It is, perhaps, somewhat more comprehensive in its plan, but in some departments, at least, it goes less into detail.

As regards the early history of the art, Mr. McMillan considers it a "hopeless task to determine the question of real priority between the three inventors." Watt distinctly awards the palm to Jordan. In the work before us we find a table of the atomic weights of the elements, in which that of platinum is still given as higher than that of gold. We regret to find also that the author ignores the hydrometer scale of Twaddle and brings forward that of Baumé, which is ambiguous, as it exists in two, if not three, modifications. Further a reading on Baumé's scale cannot be at once reduced to direct specific gravity of a simple calculation, as can that of Twaddle.

The processes mentioned in Mr. McMillan's work are described with great clearness, and the operator is duly cautioned on the necessity of cleanliness in apparatus, in materials, work-tables, and in the air of rooms.

The working material of the electro-metallurgist, which has now assumed a considerable extent, is here given in full, and operators are duly cautioned against the poisonous nature of many of the articles. There is a salutary warning against putting such solutions in tumblers, wine-glasses, &c. A still better precaution is never to bring any article of food or drink into laboratories or workshops where poisons are stored or employed.

The work before us may be regarded as decidedly satisfactory both in plan and execution.

CORRESPONDENCE.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—It is impossible for us to communicate individually with the hundreds of Fellows of the Chemical Society who have signed and returned the circular issued by us relating to the present method of election of Fellows, we therefore ask that you will permit us to make the following facts known through your columns.

The Committee have addressed a letter to the President and Council of the Chemical Society, enclosing a copy of the said circular, thus formally placing the recommendations contained therein before the Council.

In addition the Committee have thought it right to forward a summary of the numerous further suggestions

which have been sent to them, some of which, it is hoped, may be finally adopted. We have expressed the hope that the Council will give the matter their immediate consideration. We have no doubt the Council will recognise the expressed opinions of a large proportion of the Fellows and give our letter a favourable reply. Meantime we shall be glad to receive the circular from any Fellow who may have delayed signing the same.—We are, &c.,

FREDK. J. LLOYD. } Hon.
FRANK L. TEED. } Secs.

THE INSTITUTE OF CHEMISTRY.

To the Editor of the Chemical News.

SIR,—While the correspondence is going on through the CHEMICAL NEWS about the Chemical Society, may I be allowed to say a word about the Institute of Chemistry?

Before one is allowed to take the examination for qualification as a "Fellow," he has to show proof of having attended a College for a three years' course in science (colleges named by the Institute).

Now there are a great many who have not had that opportunity, but who are quite qualified to pass the examination set by the Institute, even better than many who have had the college training, and who would perhaps be more useful to that body.

Would it not be more just to give the outsiders a chance of becoming "Fellows?"—I am, &c.,

"CHEMICAL."

THE PREVALENCE OF COPPER IN CEREALS.

To the Editor of the Chemical News.

SIR,—The occasional existence of copper in cereals, peas, beans, &c., as a natural constituent has long been known, but as the question is a very important one, especially in this country, where copper is looked upon as an article highly injurious to health, no apology is necessary from me for drawing the attention of your readers to the subject.

The question has very lately been prominently brought under my observation, and that in a novel and unexpected manner, necessitating the examination of a large number of samples of wheat and barley, which resulted in 15 per cent of the samples being found to contain copper in more or less quantity, particularly in the Scotch barley.

The existence of copper in cereals therefore becomes a serious question, especially to manufacturers of infants' foods, as they are liable at any moment to have proceedings instituted against them under the Sale of Food and Drugs Act. It was due to legal proceedings being threatened against a manufacturer of infants' food which caused the matter to be placed in my hands. The plaintiff's analyst certified that the food contained lead, which had caused serious illness to an infant. But upon closer investigation by myself it proved to be copper, and it was present there as a natural constituent of one of the cereals used in the preparation of that particular infants' food.

Granting that cereals do possess the remarkable property of taking up copper from the soils in which they are grown, provided that soil contains copper, the question immediately arises: What is the maximum quantity which barley or wheat are capable of taking up?

Few soils in this country contain copper to any appreciable extent. I am therefore inclined to attribute the presence of copper in Scotch barley and English wheat to the prevalent practice of dressing the grain and also the ground with sulphate of copper, so as to protect it from the ravages of vermin after the grain is sown.

The possible existence of copper in cereals may also account for some of those mysterious and unaccountable cases of illness which occur from time to time in families, and is therefore well worth the medical practitioner's

attention, and also the manufacturers of infants' food.—I am, &c.,

WILLIAM JOHNSTONE.

13, Fish Street Hill, E.C.

INTERNATIONAL STANDARDS FOR THE ANALYSIS OF IRON AND STEEL.

To the Editor of the Chemical News.

SIR,—In the account published in the CHEMICAL NEWS (vol. lxii., pp. 218 and 227) of the work of the American Committee upon the International Standards for the Analysis of Iron and Steel will be found a statement, well supported by experimental evidence, to the effect that the ordinary chloride of ammonium and copper contains some soluble carbonaceous constituent which is precipitated to some extent when steel is dissolved in it, thereby raising the apparent percentage of carbon in the metal. An hypothesis is put forward that this constituent is cellulose.

Attempts have been made to free the double chloride from such impurity, but not with complete success. These attempts have consisted in repeated re-crystallisations, and have not included endeavours to start with the ultimate constituents of the double salt free from organic impurity, and thus obtain a product of which the history and mode of preparation would be accurately known.

I am at the disadvantage of not having access to the original report at the time of writing, and therefore what I am about to say may be anticipated by statements not appearing in the abstract; but, premising that such is not the case, I would respectfully suggest to the Committee that by far the most satisfactory method of settling the whole question would be to prepare pure ammonio cupric chloride from pure metallic copper and hydrochloric and nitric acids and ammonia re-distilled in the laboratory. Then, provided the operations were performed with careful exclusion of dust, there should be no doubt as to the freedom of the resulting product from organic matter. This is so obvious a course, that it has doubtless received the consideration of the Committee, and my reason in writing is to ascertain wherein it has been found wanting.—I am, &c.,

BERTRAM BLOUNT.

Laboratory, Broadway, Westminster, S.W.,
November 10, 1890.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 16, October 20, 1890.

Researches on the Equivalent of Fluorine.—Henri Moissan.—The author remarks that Berzelius and Dumas, in determining the equivalent of fluorine, made use chiefly of mineral specimens of fluor-spar, as pure as possible. It may always be feared that such specimens may contain traces of silica or of phosphorus, as it has been shown by Berzelius and Louget. The author has therefore used synthetic calcium fluoride, distinctly crystallised. From his experiments, made with sodium and calcium fluorides, he finds the equivalent of fluorine = 19.05.

Action of the Aromatic Amines and of Phenylhydrazine upon the β -Ketonic Nitriles.—L. Bourcault.—The author, referring to a former memoir by M. Hanriot and himself, showing that methylpropionylacetone nitrile condenses with certain aromatic amines and phenylhydrazine with elimination of a mol. of water. He

now gives his results on the constitution of these compounds.

On the Manner of Combination of the Sulphuric Acid in "Plastered" Wines, and on a Method of Analysis rendering it possible to distinguish "Plastering" from Acidification with Sulphuric Acid.—L. Roos and E. Thomas.—The authors admit the equation proposed by MM. Bérard, Chancel, and Canvy, and afterwards by Dr. Magnier de la Source—

but they give a different interpretation to the secondary reaction, which occasions the presence of free tartaric acid. They maintain that this acid acts by preference on those organic compounds with a potassium base which, as Dr. Magnier de la Source has demonstrated, exist in wine in a notable proportion. The addition to wine of a little tartaric acid doubles the quantity of tartar which may be extracted from it. The analytical process adopted by the authors is as follows:—(a). Determine the chlorine present in the sample by the ordinary method. (b). Determine total sulphuric acid. (c). In 50 c.c. of the wine, mixed with a few drops of ammonium acetate, precipitate all the sulphuric acid as determined by the determination (b), with an absolutely exact quantity of barium chloride in a standard solution. (d). Determine chloride in the filtrate from operation (c). If we have to do with a neutral potassium sulphate all the chlorine of the barium chloride will be found in the state of potassium chloride. If we have an acid sulphate, hydrochloric acid (or ammonium hydrochlorate) will be set free, and will disappear during the slight ignition which precedes the determination (d) with standard silver solution, there being always a proportional loss of chlorine.

On Saccharine Matters in Mushrooms.—Em. Bourquelot.—Vegetable transformations go on in mushrooms even after they are gathered, and may in a few hours affect the disappearance of trehalose and the production of mannite. The author has therefore taken the precaution of plunging his mushrooms into boiling water immediately when gathered, so as to arrest all change. All the species, except *Amahita mappa*, if examined when young, contained exclusively trehalose. When older, they contain both trehalose and mannite, or mannite alone. In two species which were examined after desiccation at a low temperature (*Bolletus aurantiacus* and *Hypholoma fasciculare*) the trehalose had disappeared and was replaced by mannite.

Bulletin de la Société Chimique de Paris.

Series 3, Vol. iv., No. 1.

The Influence of the Different Fruit Ferments upon the Bouquet of Fermented Liquors on the Production of a Barley Cider.—Georges Jacquemin.—Already noticed.

Action of Lead Oxide upon Toluene. Production of Benzene.—C. Vincent.—Behr and Van Dorp let fall toluene drop by drop upon lead oxide heated to dull redness. The crude product being distilled to separate the unattacked toluene, the stilbene was crystallised in alcohol, whilst the diphenyl, the phenanthrene, the anthracene, and an oily hydrocarbon remain in solution in the alcohol. The author has resumed the study of this reaction upon toluene, under the same conditions, using pure toluene exempt from benzene. This reaction may be industrially utilised to transform a lot of toluene for which there is no demand into benzene, which is more valuable. The chief facts established in the paper are that lead oxide attacks pure toluene at a temperature below 335°, producing chiefly water, carbonic acid, and benzene. At higher temperatures, we obtain less benzene, more stilbene, and higher carbides. At dull redness, there are produced, along with the products above mentioned, the

carbides which are formed by the simple pyrogenous decomposition of benzene and toluene. The diphenyl, which appears in small quantities in this operation, does not come from the benzene originally contained in the toluene, but from the benzene formed by the action of lead oxide upon the toluene itself.

On Tetrachlorophenol.—Louis Hugounenq.—This compound is obtained by saponifying tetrachloroanisole with hydriodic acid at 1:7. The product, $C_6HCl_4.OH$, crystallises in white needles, fusible, if pure, at 152° . It is insoluble in water, very soluble in all the organic solvents, and capable of sublimation. It boils with decomposition at 278° ; its odour is peculiar, its taste caustic. The alcoholic solution behaves as an acid with indicators, and decomposes carbonates. The author has examined its ammonium, silver, lead, and copper salts.

Researches on Dispersion in Organic Compounds (Alcohols of the Fatty Series).—Ph. Barbier and L. Roux.—In the alcohols of the fatty series which the authors have examined, the dispersive powers are continuous functions of the molecular weights; and, contrary to what is observed in the aromatic compounds, they increase simultaneously with the molecular weights. Alcohols with a long chain, primary or secondary, have the same dispersive power, and follow the same laws; only the two primary abnormal alcohols (the isobutylic and isoamyl) possess lower dispersive powers, though their values do not deviate very notably from those of the alcohols with a long chain. In this series, as in that of the aromatic compounds, the elimination of the hydrogen determines a considerable increase in the dispersive power.

On Manganese Oxides obtained in the Moist Way.—A. Gorgeu.—The author studies manganous acids, describing nine methods for its preparation. He considers the two processes for obtaining manganous anhydride, and explains the properties of manganous acid, its behaviour with hydrate dioxides, and with metallic salts. The author raises the question whether the synthesis of potassium manganate does not result from the oxidation of manganous acid at the expense of potassium permanganate. He holds that the fact of the splitting up of manganic acid by water into two compounds, MnO_2 , Mn_2O_3 , the one richer and the other poorer in oxygen than the original acid, and without any escape of gas, is a fact which has been observed only in the case of osmious acid.

A New Biethylenic Carbide, β -Bipropylene.—F. Couturier.—This compound is formed by the elimination of 2 mols. of water from pinacone. Its composition is C_6H_{10} .

Journal de Pharmacie et de Chimie.
Series 5, Vol. xxi., No. 7.

Researches on the Preparation and the Properties of Aricine.—H. Moissan and Ed. Landrin.—The composition of aricine is expressed by the formula $C_{23}H_{26}N_2O_4$. Its rotatory power in an alcoholic solution is $\alpha_D = -58^\circ 18'$. In an ethereal solution it gives the figure $\alpha_D = -92^\circ 30'$. The hydrochloric solution has generally been regarded as inactive, but it possesses a rotatory power contrary to that of the alkaloid $\alpha_D = +14^\circ 30'$.

Action of Time on Coal-Tar Colours in Wines.—M. Monaron.—The author proves experimentally that a wine coloured with acid magenta preserves all its characters for a long time if protected from microscopic vegetation.

Reduction of Silver Nitrate by Oil of Bitter Almonds.—E. Le Noble.—This reduction takes place under a variety of conditions. The author concludes that benzoyl hydride behaves like the aldehyds, reducing silver oxide, and passing to the state of benzoic acid.

Determination of Total Phosphorus in Urine.—M. Chappelle.—The author heats 10 c.c. of urine with 5 c.c. of sulphuric acid for several hours until it becomes colourless. The liquid is made up with water to 50 c.c., neutralised with soda and treated with magnesia mixture. The determination is then completed in the ordinary manner.

The Analysis of Commercial Glycerins.—M. Vignier.—The only processes for the determination of glycerin in an accurate manner are the method of Benedikt (conversion of the glycerin into triacetate), and that of Hehner (decomposition of glycerin by potassium dichromate). It is, however, pretended by dealers that a crude glycerin containing not less than 80 per cent of pure glycerin should have a specific gravity of not less than 1.300 (at 15°) and a boiling point not below 155° . The author finds experimentally that there is no definite relation between the proportion of actual glycerin in a sample and its specific gravity and its boiling point. It is not possible to ascertain the value of a crude glycerin by its specific gravity and its boiling point.

Distinguishing Characters of Vanillin and Coniferin.—A. de Werre.—With sulphuric acid vanillin gives a yellow colour and coniferin a violet. With a mixture of sulphuric acid and resorcinic vanillin gives a deep carmine red, and coniferin a violet; phloroglucin and hydrochloric acid vanillin gives a red colour, whilst coniferin yields only a very fugitive violet.

Detection of Mercury in Urine and Organic Liquids.—E. Brugnatelli (*Annali di Chimica*).—The author acidifies the suspected liquid with a few drops of hydrochloric acid, adds powdered copper or copper wire well cleansed and reduced to redness, heats for five minutes in the water-bath to 50 to 60° , stirring occasionally, washes the copper, places it in a capsule, and along with it a fragment of porcelain on which is placed a drop of solution of gold chloride at 1 per cent. The capsule is covered and heated on the water-bath; the mercury deposited on the copper is volatilised and reduces the gold.

Excretion of Creatinin during Fasting and its Formation in the Organism.—Dario Baldi.—The author found in the urine of the fasting exhibitor, Succi, 0.40 grm. of creatinin on the seventeenth day of the fast and traces on the twenty-third day. He considers this observation a proof that creatinin is an ultimate product of the organic transformations.

Artificial Musk.—A. Baur.—The author obtains this substance by the nitration of isobutyltoluene. It is a solid substance, crystallising in small white laminae of the pure odour of natural musk and of an extraordinary intensity. The process has, of course, been patented and sold to certain perfumers who are manufacturing the perfume at Mulhouse. The musk-deer may therefore be considered as disestablished.

Determination of Ferric Oxide and Alumina in Phosphates.—E. Glaser.—The author dissolves 5 grms. of the phosphate in 25 c.c. of nitric acid of sp. gr. 1.2 and 12.5 c.c. of hydrochloric acid at sp. gr. 1.12, and dilutes to half a litre. He introduces 100 c.c. of the solution (corresponding to 1 grm. of the substance, into a quarter-litre flask and adds 25 c.c. of sulphuric acid at 1.84. It is let settle for five minutes, stirred repeatedly, 100 c.c. of alcohol at 95 per cent are added, the flask is cooled, filled up with alcohol, and well shaken. The stopper is withdrawn, and alcohol is added up to the mark (as contraction will have taken place), and the flask is again shaken. After standing for half-an-hour it is filtered; 100 c.c. (representing 0.4 grm. of the original substance) are evaporated in a platinum capsule so as to expel all the alcohol. To the liquid thus freed from alcohol there are then added in a glass vessel 50 c.c. of water, and it is heated to a boil. It is then removed from the source of heat, and ammonia is added until the reaction is alkaline.

The excess of ammonia is driven off by boiling, the liquid is let cool, filtered, washed with hot water, heated to redness, and the iron and aluminium phosphates are weighed.

Manufacture of Aluminium.—C. Nello.—In this paper, taken from the *Zeitschrift für angewandte Chemie*, the author gives an account of the manufacture of aluminium from cryolite, as carried on by the Alliance Aluminium Company.

Chemical Bibliography.—E. Fremy.—The author writes as follows:—"The chemists of the so-called modern school, wishing, mistakenly, to combat the admirable theories of Lavoisier, and to give an exaggerated extension to observations made on the influence of water in certain salts, have maintained that when an acid loses its water and becomes anhydrous, it is no longer an acid; they have given to dehydrated acids the name of anhydrides. The object of this theory is to maintain that a salt is not a compound of acid and of base, but a substitution of the hydrogen of the acid by a metal. I believe I have demonstrated that this theory ought to be absolutely rejected by citing thousands of salts which are produced by the combination of anhydrous acids with anhydrous bases, such as the carbonates, silicates, borates, aluminates, stannates, &c. In all these cases the acid being anhydrous, the phenomenon of substitution has no place; it is the anhydrous acid which combines with the anhydrous base, as the theory of Lavoisier demands."

No. 8.

On the Precipitate formed in Solutions of Copper Sulphate in Common Water.—MM. Grimbart and Barré.—If a solution of copper sulphate is poured into common water there is first produced an intense turbidity, then, on standing, a voluminous greenish-blue deposit of a crystalline aspect forms at the bottom of the vessel. This compound is a quadribasic sulphate, similar in composition to the mineral brochantite found in Mexico and Iceland. Its formation is probably due to the calcium bicarbonate present in ordinary waters.

Rapid Determination of Chlorides in Wines.—M. L. Roos.—The author prepares two standard solutions, one of silver nitrate at 5 per cent and the other of potassium ferrocyanide, which must saturate each other exactly. The so-called decimal solutions are perfectly suitable. To 20 c.c. of wine he adds an excess of the silver solution, and then he determines with the ferrocyanide the quantity of silver not taken up by the chlorine. The ferrocyanide is added by degrees, making from time to time spot-tests on filter-paper, and adding to each spot a small drop of solution of ferrous sulphate. The spot remains red as long as there is not an excess of ferrocyanide, and becomes distinctly blue as soon as the saturation is exceeded. The author admits that this procedure is not as precise as the ordinary method with silver nitrate and potassium chromate as indicator.

The Presence in Urine of some Substances which Reduce Copper Oxide on Boiling in presence of an Alkali.—H. Ashdown.—From the *Pharmaceutical Journal*.

Researches on the Pathogenic Microbia of the Filtered Waters of the Rhone.—MM. Lortet and Despeigner.—The drinking water supplied to the public of Lyon is taken above the city and filtered in galleries separated from the river by a bed of fresh gravel of the mean thickness of 15 metres. The subterranean chambers are walled on their four sides and filter only through the bottom. It appears from a bacteriological analysis published in 1886 that the free water of the river, opposite this installation contain 51,000 germs per litre. That taken in the filtering galleries contain only about 7000. Notwithstanding this purification these waters deposit quickly upon the Chamberland filters an unctuous, slimy mud, coloured deeply yellow by ferric oxide and formed of a fine marl along with organic matter. Under the microscope this deposit is found swarming with bacteria of

different forms, some of which when injected into guinea-pigs have occasioned various diseases.

NOTES AND QUERIES.

. Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertisement columns.

Nickel Capsules.—I shall be greatly obliged to any of your readers who can inform me, through your columns, as to their experience with the nickel capsules that have lately been introduced to the notice of chemists. I am anxious to know how far they may replace platinum in ordinary analytical work; and whether, in fact, they can be recommended as generally satisfactory apparatus.—C.

MEETINGS FOR THE WEEK.

WEDNESDAY, 19th.—Society of Arts, 8. Opening Address of the 137th Session, by the Attorney-General, Sir Richard Webster, M.P. (Chairman of the Council of the Society).

THURSDAY, 20th.—Chemical 8. Ballot for the Election of Fellows. "On the Estimation of Cane-sugar," by C. O'Sullivan and F. W. Thompson. "A New Method of Determining the Specific Volumes of Liquids and of their Saturated Vapours," by S. Young. "The Molecular Weight of Metals when in Solution," by Messrs. Haycock and Neville.

PATENTS.

Provisional Protection, from £2 2s.

Lowest cost of complete English and Foreign on application. Also, Designs and Trade Marks. Inventions financed.

WALLACE, WEATHERDON, & CO.

REGISTERED PATENT AGENTS,

57 & 58, Chancery Lane, and 11, Southampton Buildings, W.C.
Established 1849.

TO MANUFACTURING CHEMISTS AND OTHERS.

THE LONDON COUNTY COUNCIL is prepared to receive TENDERS for the SUPPLY of 1000 tons of SULPHURIC ACID.

Deliveries to be made in bulk at the Northern and Southern Outfalls, and in carboys to Stations within the Metropolis, commencing about the 1st May next.

Persons tendering will be required to declare in their tender that they pay such rates of wages and observe such hours of labour as are generally accepted as fair in the trade.

The Specification, Form of Tender, and other particulars may be obtained on application to the Chemist of the Council, at the Office, 40, Craven Street, W.C., until Saturday, the 22nd November, 1890. Tenders must be addressed to the Clerk of the London County Council, Spring Gardens, London, S.W., endorsed "Tender for Sulphuric Acid," and be sent in not later than 5 o'clock on Monday afternoon, the 24th of November, 1890.

The Council does not bind itself to accept the lowest or any tender.

H. DE LA HOOKE, Clerk of the Council.

Spring Gardens,
3rd November, 1890.

TO MANUFACTURING CHEMISTS AND OTHERS.

THE LONDON COUNTY COUNCIL is prepared to receive TENDERS for the SUPPLY of 1300 TONS of MANGANATE OF SODA, to be delivered at the rate of not less than 50 tons nor more than 200 tons per week, from the 1st March, 1891.

Persons tendering will be required to declare in their tender that they pay such rates of wages and observe such hours of labour as are generally accepted as fair in the trade.

The Specification, Form of Tender, and other particulars may be obtained on application to the Chemist of the Council, at the office, 40, Craven Street, W.C., until Saturday, the 22nd November, 1890. Tenders must be addressed to the Clerk of the London County Council, Spring Gardens, London, S.W., endorsed "Tender for Manganate," and be sent in not later than 5 o'clock on Monday afternoon, the 24th November, 1890.

The Council does not bind itself to accept the lowest or any tender.

H. DE LA HOOKE, Clerk of the Council.

Spring Gardens,
3rd November, 1890.

THE CHEMICAL NEWS.

VOL. LXII. No. 1617.

EXAMINATION OF OILS, FATS, AND ALLIED SUBSTANCES.

By THOMAS T. P. BRUCE WARREN.

BEFORE proceeding further with the analysis of mixtures of oils, I give a list of oils, &c., on which I have operated. The first division contains those which yield insoluble products with sulphur chloride; the oils contained in the second division do not yield such products, hence the oils of the first division can be separated from those of the second.

The oils, &c., of the first division, when heated strongly with sulphur, yield spongy elastic masses, except the oils of olive and cotton-seed, hence these oils may be separated from the others; the sulphur which they dissolve separates out on cooling, which may help to recognise their presence in a mixture. They all dissolve in ether, but, on addition of a few drops of alcohol, caoutchouc and gutta-percha separate out.

First Division.

Olive oil.	Walnut, decort.
Olive oil from green olives.	Sesame.
Olive oil from kernels of green olives.	Nigerseed.
Poppy oil, var. :—	Castor oil.
Papav., somnif.	Rapeseed.
Glaucium flav.	" blown.
Almond, var. :—	Cotton oil.
Amygd., dulc.	" crude.
" amar.	" blown.
Earthnut.	Beechmast.
" decort.	Hempseed.
Caoutchouc, gutta-percha, and allied substances. . .	And the resins naturally associated with them.

Second Division.

Petroleum and Homologues of the Paraffin Series. Distillates from Coal-Tar, Shale, and similar Minerals.

Sperm oil.	Beef fat.
Whale oil.	Mutton fat.
Cod oil.	Cocoanut oil.
Spermaceti.	Palm oil.
Lard.	Resin oil.
Lard oil.	Pine resins.
Butter.	Turpentine.
Bees'-wax.	Japan wax.

In this division must be included glycerin and the fatty acids of the first division; hence the blown oils give an increased weight of soluble product proportional to the loss of glycerin; this fact will explain why an old oil will give less insoluble matter than one comparatively new. By treating a mixture with ozonised oxygen, an oil easily oxidised can be separated from one not so readily acted on. Sulphur chloride will convert one into an insoluble product, whilst the fatty acids of the other can be washed out with carbon disulphide.

When acting on these products with nitric acid, as in estimating sulphur, a few drops of nitro-glycerin are formed, which should be carefully removed in the course of the analysis.

The presence of glycerin in many oils of the second division makes it difficult to understand why they behave so differently to those of the first division. A prominent feature is that they yield smaller weights of total magma than those of the first division, and which is readily seen

when oils of the two divisions are mixed. I give here a few oils of the second division, including a heavy lubricating petroleum, where the action of sulphur chloride may be taken as nil. 5 grms. being used in each case:—

Name of oil, &c.	Magma. Total.	Remarks.
Petroleum	5'01	} Entirely soluble in carbon disulphide.
Cocoanut	5'14	
Lard oil	5'80	
Sperm	6'16	

Petroleum and the distillates from coal-tar act simply as solvents of sulphur chloride, and it is by no means improbable that some of the oils of the second division act to some extent in the same way, and so prevent the formation of a magma; for, in every case, even with the oils of the first division, the solvent must be evaporated before the reaction sets in.

A mixture of two oils, both either belonging to the first or second division, or one of each division, can be quantitatively determined by the Hubl reagent, using equations (1) and (2) given in CHEMICAL NEWS, vol. lxii., p. 179.

In cases where an oil contains a peculiar isolable principle, we may apply the fact as chemical evidence of its existence, and neglect the separation for purposes of estimation. But when three or four oils are mixed, the isolation of a principle peculiar to one enables us to eliminate that one. We must be careful in applying this too rigidly; cocoanut oil may contain the glycerides of capric and butyric acids, according to the uses to which this oil may be applied. These acids are now commercial products, and, presumably, are not to be regarded simply as chemical curiosities.

A NEW METHOD FOR THE VOLUMETRIC DETERMINATION OF MANGANESE.

By G. VORTMANN.

THE iodometric determination of manganese has hitherto been effected by converting it into peroxide by means of any oxidising agent, and titrating this by treatment with hydrochloric acid and potassium. Such methods are mostly circumstantial, requiring careful filtration; and sometimes distillation according to Bunsen's process. The author endeavoured to determine manganese by oxidising it with standard solution of iodine in presence of an alkali, and ascertaining the quantity of iodine necessary for converting the manganous oxide into manganese dioxide. In all the experiments where he used a pure manganese salt alone, the values found were too low. To one atom of manganese there were consumed not two two atoms of iodine, but only 1'84 to 1'86.

The addition of a zinc salt, as in Vortmann's process, made no difference. But if there was added to the manganese salt, the salt of a sesquioxide, aluminium, or iron, the oxidation went off smoothly; two atoms iodine being consumed for one atom of manganese. If it is required to determine manganese alone, in the absence of other methods, the following procedure is followed:—

The weighed quantity of the manganese salt is dissolved in water, along with two or three parts of potash-alum, the solution is mixed with a measured quantity of a decinormal solution of iodine and pure soda-lye (free from nitrite). The whole is then heated in the water-bath for five to ten minutes, and, when cold, it is diluted to a known volume. An aliquot part of this is filtered off through a dry folded filter, the filtrate is acidulated, and the excess of iodine is titrated with solution of sodium thio-sulphate; the c.c. of the latter consumed are re-calculated for the total volume of the liquid and deducted from the quantity of iodine solution employed. Thus we obtain

the quantity of solution of iodine which was required for oxidising the manganous oxide.

Manganese can be conveniently determined in this manner in presence of aluminium or iron salts, or in crude iron.

Salts of ammonium must not be present.—*Berichte der Deutschen Chem. Gesellschaft*, vol. xxiii., No. 13, p. 2801.

AN IMPROVED PROCESS FOR THE MANUFACTURE OF POTASSIUM CYANIDE.

By H. N. WARREN, Research Analyst.

THIS method for the production of potassium cyanide, which depends, in the first place, upon the formation of potassium sulphocyanate, and the conversion of that substance into potassium cyanate, and, lastly, that of potassium cyanide, is brought about as follows:—

A proportionate quantity of carbon disulphide is blended with an equal bulk of mineral oil, to which is added a convenient quantity of water. Ammonia gas is now introduced until the whole of the CS_2 is converted into ammonium sulphocarbonate. The concentrated solution thus formed is separated from the remaining oil, and a fresh quantity of CS_2 added, the action proceeding as before. The solution containing the ammonium sulphocarbonate is now allowed to boil until all traces of ammonium sulphide have been expelled, the ammonium sulphocarbonate becoming converted into ammonium sulphocyanate. To the solution, while still hot, is introduced a sufficiency of KHO, and the heat maintained while any NH_3 gas continued to be evolved, the gas thus expelled being utilised for the production of a further quantity of ammonium sulphocarbonate; the resulting solution of KCNS thus formed is evaporated to dryness, and introduced into a deep crucible, being subjected to a dull red heat in contact with litharge; the KCNS thus being converted into potassium cyanate, with the production of PbS. The crucible with its contents is then allowed to settle, and the melt removed by decanting into a further pot, furnished with a perforated lid and containing lump carbon, the heat is now raised and continued at full redness as long as any traces of CO_2 or CO continue to escape. The resulting KCN thus obtained is poured from the pot and received into suitable moulds.

THE DETECTION OF IODINE.

By W. H. SEAMON.

THE reaction of potassium iodide with the platonic salts, mentioned in Watts's "Dictionary of Chemistry," vol. iii., p. 288, furnishes a valuable test for the soluble iodides, being characteristic and delicate. The manner of making the test is as follows:—

To the solution in a test-tube add one or two drops of solution of platonic chloride. As the platonic chloride mixes with the liquid, a beautiful red colouration is produced, due to formation of platonic iodide. If much iodide be present the solution becomes black with subsidence of a brownish precipitate.

Free potassa, ammonia, and hydrochloric acid require the addition of a large amount of the platonic chloride. It is therefore best to have it neutral or acid with sulphuric acid. The reaction is plainly visible if $\frac{1}{1000}$ part of iodine be present, and is readily seen, though faint, with $\frac{1}{100}$ part of iodine.

The test has been subjected to a large number of trials to prove its value with most satisfactory results.—*Journal Analytical Chemistry*, Vol. iii., Part 3.

A RE-DETERMINATION OF THE ATOMIC WEIGHT OF CADMIUM.

By EDWARD A. PARTRIDGE, MA., B.S.

THE atomic weight of cadmium had been determined by Stromeyer, Von Hauer,* Lenssen,† Dumas,‡ and Huntingdon.§ With O=16 for the basis of calculation the values obtained by these experimenters are the following: by Stromeyer 111.48, by Von Hauer 111.96, by Lenssen 112.08, by Dumas 112.25, by Huntingdon 112.24. From these results Clarke calculates 112.092 to be the most probable figure, and concludes his article on the subject with this remark: "It will be seen that Dumas's and Huntingdon's determinations both made with haloid salts of cadmium agree with wonderful closeness and so confirm each other. On the other hand, Von Hauer's data give a value which is much lower. Apparently Von Hauer's method was good, and the reason for the discrepancy remains to be discovered. Until that is ascertained, I prefer to use the above mean value rather than to adopt one investigation and reject the others."

This investigation was undertaken with the hope of arriving at a value for the atomic weight of cadmium more reliable than that given by former experimenters.

The following points were regarded as of first importance:—

1st. The most scrupulous care in the purification of the materials used in every stage of the work.

2nd. Avoidance of any method in which the reactions involved were uncertain or doubtful.

3rd. The utmost care and refinement in weighing.

4th. Use of a large number of determinations as the basis of calculation.

At the outset much time was devoted to making a pure cadmium salt by re-crystallisation of the sulphate, and much work was devoted to accumulating a stock of this as the starting point. This, however, was discarded in favour of the metal obtained by distillation.

The literature upon this subject is interesting, though somewhat meagre. Mercury has been purified by distillation for years. Demarcay|| in 1882 observed that zinc and cadmium are volatile in vacuo at comparatively low temperature, and suggests this as a means of purification. In 1884, Schuller¶ stated that zinc and cadmium can be distilled in vacuo, leaving the impurities as a residue. This method has been employed by Morse and Burton** for the purification of zinc. One of the means employed by Stas in his classical investigation upon atomic weights was the purification of silver by distillation. Whenever available, distillation ranks first among the processes for purification at the disposal of the chemist. This was effected in the case of cadmium in tube retorts of glass, about 30 c.m. in length, and 20–25 m.m. in diameter.

The tubes were closed at one end and drawn down at a point about 11 c.m. from the closed end, making a neck about 12 m.m. in diameter. 100 grms. of cadmium having been introduced, the open end was drawn down to a size suitable for a connection with the mercury pump. The portion of the tube between the neck and the end connected with the pump serves to condense and retain the distilled metal.

After having been supported on a combustion furnace, the retort was exhausted as completely as a rapidly acting three-fall mercury pump would effect in one hour; the gauge then standing only a fraction of a m.m. lower than the barometer. As the pump was self-acting this degree of exhaustion was readily maintained during the entire

operation. Heat was then slowly applied and so managed that the greater part of the metal condensed and ran down the sides of the retort, only the more volatile portion passing beyond the neck of the tube. A fractional distillation was thus effected, cadmium alone passing over. In an hour 60 grms. of cadmium had collected in the receiver, the distillation was then stopped, and when entirely cold the metal was removed by cutting open the tube. The greater part of it collected as a bar at the bottom of the receiver, while the sides and top were lined with crystals, many of which were quite perfect. The residue in the retort was covered with a brownish black scum, which was tested spectroscopically and found to consist mainly of lead, iron, and thallium, with a little copper. The lines of zinc were once very faintly seen.

The cadmium thus purified was distilled a second time in the same manner. The residue from this distillation, which was pushed no further than the first, remained perfectly bright to the end, and when tested with the spectroscope did not reveal a trace of foreign metals. All the cadmium used in this investigation was thus purified by double distillation.

One of the methods used for the determination of the atomic weight of cadmium is that of Lenssen, which, although good, was merely touched upon by him. His result was based upon only three experiments, using very small quantities of material. The method consists in changing cadmium oxalate to cadmium oxide, and observing the loss of weight, from which loss the atomic weight is calculated.

For working this method cadmium oxalate was made as follows:—

The perfectly pure metallic cadmium obtained by double distillation was dissolved in pure nitric acid, prepared by careful distillation, and the solution concentrated so far that on cooling the cadmium nitrate, $\text{Cd}(\text{NO}_3)_2 + 4\text{H}_2\text{O}$, separated in long fibrous crystals. The latter were drained at the filter-pump, dissolved in water, and a solution of the theoretical amount of pure oxalic acid added. Cadmium oxalate thus prepared is a heavy crystalline precipitate which can be easily washed. This was done several times by decantation. The precipitate was then placed on a filter and washed at the pump thirty times with distilled water, after which it was dried for 20 hours at 150°C . The salt thus obtained was tested for nitric acid by the phenol test, and showed not the slightest trace. The pure cadmium oxalate thus obtained was subjected to the following treatment:—

About one gram. of cadmium oxalate was placed in a porcelain crucible and was then dried in an air-bath at 150°C . for five hours. This length of time was usually sufficient to dry the salt completely. When this had been accomplished, i.e., when a constant weight had been attained, the crucible containing the oxalate was covered with a watch-glass, and very cautiously heated. This operation required the greatest care, since if the temperature became too high, reduction and consequent volatilisation of metal occurred. Four of the earlier experiments were lost in this way. That volatilisation of metal had taken place was made evident by a slight sublimate on the watch-glass. When the oxalate was completely decomposed (this was shown by the uniform brown colour of the resulting cadmium oxide) it was allowed to cool and moistened with a few drops of nitric acid in order to re-oxidise any reduced metal. The nitric acid employed for this purpose was especially purified by very careful distillation. Ten c.c. of it evaporated in a platinum dish left a visible but imponderable residue.

The crucible was then very carefully ignited until all the cadmium nitrate was decomposed, then placed inside a nickel crucible 4 c.m. high by 4 c.m. wide, and strongly ignited for half an hour by means of a Fletcher's improved Bunsen burner. In all cases the ignition was repeated until a constant weight was obtained. There was rarely, however, any loss of weight after the first ignition. To prevent the possibility of any reducing gases reaching the

cadmium oxide, the nickel crucible inside which the porcelain crucible was placed was forced into a circular hole cut in a piece of asbestos board 13 c.m. square. The top of the nickel crucible was flush with the upper surface of the board, the joint being air-tight.

Ten experiments made by the above method gave the following results:—

Series I.

	Weight of cadmium oxalate taken.	Weight of cadmium oxide found.	Atomic weight.

Mean value			111.8027
Maximum			111.834
Minimum			111.759
Difference			0.075
Probable error			0.010

Another method used for the determination of the atomic weight of cadmium is that of Von Hauer. It consists in reducing cadmium sulphate to cadmium sulphide in a stream of hydrogen sulphide and observing the loss of weight. As the result obtained by Von Hauer is considerably lower than those obtained by other experimenters doubt has been cast upon its accuracy. The following possibilities have been suggested as tending to make Von Hauer's results low:—(1) That the cadmium sulphate as weighed by him contained hygroscopic moisture. (2) That the presence of metallic iron in the ferrous sulphide used in making the hydrogen sulphide would lead to the generation of hydrogen and consequent reduction and volatilisation of cadmium. (3) That some cadmium sulphide might have been volatilised in the stream of hot hydrogen sulphide.

It was, therefore, determined to carry out a series of experiments by this method in order to determine if any of these objections were well grounded.

In the experiments about to be described, the first danger was overcome by weighing the sulphate in stoppered glass tubes. The second was shown to be groundless, as in some experiments the hydrogen sulphide used was prepared from antimony trisulphide, and in others from ferrous sulphide with perfect agreement of results. The third objection was disproved experimentally, as the highest heat that hard Bohemian glass will withstand did not cause any volatilisation of cadmium sulphide. That there was no volatilisation of sulphide was proved by the weight of a sample of the same which was heated in a stream of hydrogen sulphide to the extent just mentioned, remaining absolutely constant, and also by the fact that there was not the slightest sublimate on the tube.

The hydrogen sulphide employed in this and in the following series of experiments was washed by passing it through water and dried by passing through a long calcium chloride tube. The carbon dioxide was dried by passing through a wash bottle containing sulphuric acid, and then over calcium chloride. By means of a three-way cock the carbon dioxide could be run into the apparatus without changing the connections.

The cadmium sulphate was prepared in the following manner:—Cadmium nitrate, prepared as above described, was dissolved in water and a slight excess of pure sulphuric acid added. Five c.c. of this acid were evaporated in a platinum dish, leaving a visible but imponderable residue.

The solution was evaporated to dryness in a platinum dish and heated long after fumes of sulphuric acid ceased to come off. The sulphate was dissolved in water, recrystallised, and dried for six hours at 200° C.

The following is a description in detail of the method used in the experiments, the results of which are tabulated below. (Series II.)

The dry cadmium sulphate was placed in a porcelain boat and heated for some time in an air-bath to about 300° C. While still warm, the boat was placed in the weighing tube, allowed to cool, and weighed. Cadmium sulphate parts with its hygroscopic moisture very readily at 300° C. After weighing, the boat containing the cadmium sulphate was placed in a hard glass tube, 50 c.m. in length, supported over a small combustion furnace. A stream of pure dry hydrogen sulphide was then passed through the tube, and heat applied. It was heated moderately for 45 minutes, and to dull redness for as much longer. By this time its reduction to sulphide was always complete. It was then allowed to cool to about 200° C. in a slow stream of gas. When the temperature had fallen to this degree the hydrogen sulphide was displaced by a stream of pure dry carbon dioxide, and while still warm the boat containing the cadmium sulphide was placed in the weighing tube, allowed to cool, and weighed. Ten experiments by this method gave the following results:—

Series II.

	Weight of cadmium sulphate taken.	Weight of cadmium sulphide found.	Atomic weight.
1	1.60514	1.11076	111.793
2	1.55831	1.07834	111.789

9	1.53873	1.06481	111.796
10	1.70462	1.17962	111.801
Total	15.93505	11.62717	(111.7969)
Mean value			111.7969
Maximum			111.818
Minimum			111.778
Difference			0.040
Probable error			0.008

In the course of the work the experiment of passing hydrogen sulphide over gently heated cadmium oxalate was tried. This salt was completely transformed into the sulphide at a temperature much below that which is necessary for its conversion into cadmium oxide. This reaction was then made the basis of a new method for the determination of the atomic weight of cadmium. The method used in the ten experiments, the results of which are given below (Series III.), was as follows:—

Cadmium oxalate was placed in a porcelain boat and dried at 150° C. to a constant weight. It loses all of its moisture at that temperature. While warm the boat was placed in the weighing tube, allowed to cool, and weighed. The boat containing the cadmium oxalate was then placed in a tube arranged for passing hydrogen sulphide and supported over a combustion furnace as above described. The reducing gas was passed through the tube and heat slowly applied. When the contents of the boat had been completely changed to sulphide, the heat was raised to incipient redness, and kept at that temperature for about one hour. The cadmium sulphide was allowed to cool to about 200° C. in a slow stream of hydrogen sulphide, which was then displaced by a stream of pure dry carbon dioxide. While still warm the boat containing the cadmium sulphide was placed in the weighing tube, allowed to cool, and weighed. In every

case the sulphide was re-heated in the stream of hydrogen sulphide. There was never any volatilisation of cadmium sulphide, as the weight always remained the same, although in some experiments the sulphide was heated three times as long as in others. Moreover, there was never any sign of volatilisation either on the boat or on the tube. Ten experiments by the above method gave the following results:—

Series III.

	Weight of cadmium oxalate taken.	Weight of cadmium sulphide found.	Atomic weight.
1	1.57092	1.13065	111.812
2	1.73654	1.24979	111.786
3	2.19276	1.57825	111.824
4	1.24337	0.89492	111.823
5	1.18743	0.85463	111.807
6	1.54038	1.10858	111.771
7	1.38905	0.99974	111.806
8	2.03562	1.45617	111.833
9	2.03781	1.46658	111.774
10	1.91840	1.38075	111.814
Total	16.85228	12.12906	(111.8050)
Mean value			111.805
Maximum			111.833
Minimum			111.771
Difference			0.062
Probable error			0.009

The mean of the three series gives 111.8015 as the atomic weight of cadmium, with $O=16$.

The following is a description of the methods and apparatus used in the weighings:—In the experiments by Lessen's method two crucibles were used, one as a counterpoise. This dummy was treated in every respect in the same manner as the crucible containing the material operated upon. For weighing the crucibles, small beakers, with glass covers ground on, were provided. These beakers were adjusted so that their weights were approximately equal. The balance being provided with two riders, one of them was used to obtain adjustment with the beakers on the pans, while the other was used in the actual weighing after the crucibles were introduced. The beakers were never touched with the hands, but were taken in and out of the balance case by means of tongs, and the crucibles were introduced into the beakers with platinum forceps. The adjustment of the balance with the beakers on the pans was tested before and after every weighing, and during the entire series of experiments the greatest variation was 0.0001 grm.

For weighing the boats used in the second and third series of experiments, light glass tubes, with accurately fitting stoppers of glass, were made. Two boats were used in every experiment, one as a counterpoise. The boats, while still warm, were placed in the tubes and the tubes stoppered. When quite cold the stoppers were momentarily loosened to restore the atmospheric equilibrium inside the tubes.

The balance used was most accurate and highly sensitive, of the short arm pattern, with an aluminium beam. With a load of 30 grms. in each pan the resting point was displaced two whole divisions by 0.0001 grm. The weights were adjusted with the utmost care, especially for this work. The weighings in all experiments were reduced to the vacuum standard.—*American Journal of Science*, Vol. xl., No. 239.

Determination of Carbon Dioxide by Difference of Weight.—H. Bornträger.—The author recommends the use of nitric acid for the expulsion of the gas in preference to hydrochloric. Any nitrogen compounds formed are absorbed in the state of nitrose by the sulphuric acid used for drying the gas.—*Zeit. f. Analyt. Chem.*, xxix., 2.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, November 6th, 1890.

Dr. W. J. RUSSELL, F.R.S., President, in the Chair.

CERTIFICATES were read for the first time in favour of Messrs. Gustavus Anthony Abrines, Waterport Street, Gibraltar; William Baxter, Fordingbridge, Hants; T. St. John Belbin, Bolton Mansions Hotel, Scuth Kensington; John Thomas Brierley, 249, Bolton Road, Chorley, Lancashire; William J. Butcher, Emanuel College, Wandsworth Common; William Waters Butler, Elmdon, Selby Park, near Birmingham; Frank Brownsword, Heaton Moor, Stockport; M. Kelway Bamber, The Lodge, St. Waltham, Chelmsford; Ernest Bentz, 147, Bishop Street, Alexandra Park, Manchester; Arthur E. Barrows, Bloomfield Iron Works, Tipton, Staffordshire; W. E. B. Blenkinsop, 15, Earlsford Road, Wandsworth Common; Thomas Arthur Cheetham, 29, Park Road, Glasgow; Arthur William Crosskey, Bentcliffe, Accrington; Arthur William Cooke, 15, Belle Vue Terrace, Leeds; Frederick Hudson Cox, 79, Angell Road, Brixton, S.W.; William L. Dudley, Nashville, Tennessee, U.S.A.; Thomas Edwards, Brewery House, Rhymney, Monmouthshire; Walter N. Edwards, 4, Herne Hill Road, S.E.; Thomas S. Goodwin, Montgomery Cottage, Newton, Glasgow; Alfred Henry Green, Oaklands, Lowton, Newton-le-Willows; William Mahowe Heller, St. Dunstan's College, Catford, S.E.; John C. Hewlett, Elm-hurst, Beckenham, Kent; Charles Terry Holloway, Apsley Villa, Lewisham High Road, S.E.; John Richard Jackson, 51, Abbotsof Place, Glasgow; John Jackson, Tredegar Road, Rhymney; Joseph Lunt, 5, South View, Eccleston Road, Ealing, W.; George Griffiths Leason, Ashfield Cottage, Stoke-on-Trent; Harry C. Myers, Strassburg, Germany; William Mackeay, 2, Victoria Mansions, S.W.; Thomas Smith Murray, 7, Gayfield Square, Edinburgh; William Reginald Ormandy, Park Road, Newton-le-Willows; James Alexander Pond, Auckland, New Zealand; Thomas Platts, 7, Victoria Street, London; Henry Ramsen Redman, 10, The Gardens, Dulwich, S.E.; G. The following papers were read:—

83. "The Magnetic Rotation of Saline Solutions." By W. H. PERKIN, Ph.D., F.R.S.

On account of the remarkable results given by solutions of the halohydrides and their compounds with ammonia and organic bases when examined as to their magnetic rotatory power (*cf. Chem. Soc. Trans.*, 1889, 740), it became important to study the solutions of metallic salts in a similar manner, and although the work which has been done in this direction is incomplete, and may occupy some time yet, the results, as far as they go, are of interest, especially in relation to the question of the condition of substances in solution. The substances which have been examined up to the present are chiefly chlorides, bromides, iodides, nitrates, a nitrite, sulphates, and phosphates, also hydroxides of the alkali metals.

In the following comparisons, the values taken for the halogens are those found for them in their compounds

with the alcohol radicles, *i.e.*, Cl = 1.733, Br = 3.562, I = 7.757. Those for the metals are deduced from the rotations of their nitrates, because in the case of ammonium nitrate, it was found that this salt gave a rotation which was practically normal, and the salts of the metals have been found to behave in a similar manner to those of ammonium. Should there be any errors in these calculated values of the metals they will be but small, and therefore will not materially influence the character of any deductions that may be made from the rotation of their compounds. They are Na = 0.558, K = 0.809, Li = 0.398, Ca = 0.691, Mg = 0.577.

The solutions examined were for the most part either saturated or supersaturated; in the case of sodium iodide, lithium nitrate, and sodium hydroxide, two strengths, varying considerably from each other, were taken, but the results were found to be practically the same. In the case of lithium chloride, which forms much stronger solutions than any of the other chlorides, bromides, or iodides examined, the rotation increased on dilution, as in the case of hydrogen chloride.

LiCl + 3.213 mol. OH ₂	gave 4.166 mol. rot.
" + 7.411 "	" 4.559 "
" + 11.760 "	" 4.697 "

At present, this is the only salt known the rotatory power of which changes with the amount of water used, and probably, like hydrogen chloride, it will be found to give a stationary value before the above dilution of 11.760 mols. of water is reached; but further experiments must be made to establish the facts of the case.

In two instances, the effect of varying temperature was tried. A solution of sodium bromide was examined at 16° and 78.5°; in this case there was a small reduction in the molecular rotation at the higher temperature of 0.105; with a solution of potassium iodide, examined at 16° and 84.4°, there was also a small diminution at the higher temperature, but only of 0.024. Substances, especially if they have high rotations, give a slightly lower rotation at higher temperatures, like the above, than at lower temperatures: so that, allowing for errors of observation, these results indicate that practically little or no change in the nature of the solutions took place when they passed from one temperature to another.

The following tables show the calculated and found rotations of the substances examined and their relation-ship to each other:—

Haloid Compounds.			
	Calculated.	Found.	Ratio.
NaCl	2.291	5.068	1 : 2.212
KCl	2.542	5.377	1 : 2.115
LiCl	2.131	4.697	1 : 2.204
CaCl ₂	4.157	9.085	1 : 2.185
MgCl ₂	4.043	9.103	1 : 2.252
NaBr	4.110	9.030	1 : 2.197
KBr	4.371	9.222	1 : 2.110
NaI	8.315	18.867	1 : 2.269
KI	8.566	18.690	1 : 2.182

It will be seen that the rotations of these salts, when in aqueous solution, are practically 2.2 times greater than the calculated values for the dry substance; they are even greater than those of the analogous ammonium compounds, the calculated values for which now given differ by 1 from those previously published, which were to this extent incorrect.

	Calculated.	Found.	Ratio.
NH ₄ Cl	3.305	6.906	1 : 2.084
NH ₄ Br	5.134	10.196	1 : 1.985
NH ₄ I	9.329	19.996	1 : 2.144

A solution containing equi-molecular proportions of NaI and NaOH gave a rotation for NaI = 18.454, or 0.413 lower than that given by the iodide alone.

Hydroxides of Alkali Metals.

	Calculated.	Found.	Ratio.
NaOH	1'006	2'433	1 : 2'418
KOH	1'257	2'658	1 : 2'114

Here, again, a remarkable increase of rotation is obtained, quite as great, or even larger in one case, than with the halogen salts.

Potassium hydroxide in alcoholic solution gives a somewhat lower number than the above for its aqueous solution; but it is possible that some of the potassium in this instance may be in combination as alcoholate, and this may account for the difference.

Sulphates.

	Calculated.	Found.	Difference.
NaHSO ₄	2'419	2'525	0'106
Na ₂ SO ₄	2'513	2'877	0'364
Li ₂ SO ₄	2'099	2'379	0'280

In this table the difference is given instead of the ratio, and it will be seen that it is but small compared with the foregoing, but it increases with the number of atoms of metal.

Phosphates.

	Calculated.	Found.	Difference.
NaH ₂ PO ₄	3'328	3'481	0'153
Na ₂ HPO ₄	3'678	4'076	0'398
Na ₃ PO ₄	4'036	5'079	1'043

As in the case of the sulphates, the rotation increases beyond the calculated with the number of atoms of metal; in the last case the difference is considerable.

Potassium Nitrite.—This salt is interesting, because it allows of a comparison being made between it and potassium nitrate, which can be placed side by side with a similar comparison between isobutyl nitrite and nitrate.

	Difference.
KNO ₂	1'943
KNO ₃	1'535
C ₄ H ₉ NO ₂	5'510
C ₄ H ₉ NO ₃	5'180

From this it is seen that in both cases the nitrites give larger rotations than the nitrates, and the differences do not vary very greatly, though sufficient to show that the rotation of potassium nitrate undergoes some change when that salt is in solution.

Nitrates.

NaNO ₃	1'284
KNO ₃	1'535
LiNO ₃	1'124
Ca(NO ₃) ₂	2'143
Mg(NO ₃) ₂	2'029

It has been assumed that the solutions of the nitrates give practically normal results, and the values of the metals have been deduced from them: the reasons for this have already been given; it may be added that of all the salts examined the nitrates give the lowest numbers for the metals. Nevertheless, experiments are in progress to test the validity of this method of determining the values of the metals.

In considering the numbers given in this communication, it is well to remember that, owing to the method employed in calculating the results obtained from solutions, all experimental errors fall upon the numbers obtained for the dissolved substance, and consequently will also influence the differences found in comparing the results, as in the tables given above. When the solutions contain large percentages of dissolved substance, the errors are but small, but when the percentages are small the errors naturally increase; on this account it will be difficult to get good results with compounds that are sparingly soluble in water.

It is very difficult to understand why the haloid acids, their metallic derivatives and also caustic alkalis should give such extremely large rotations when in aqueous solution. If dissociation takes place there does not seem to be any reason why any very considerable change of rotation should occur, but whatever the cause, the change evidently indicates some very important difference existing between dissolved and undissolved substances of these classes.

DISCUSSION.

Dr. GLADSTONE remarked that similar excessive values were obtained on determining the refractive powers of solutions of metallic chlorides, &c., although the difference between the calculated and observed values were much smaller than in the case of Dr. Perkin's measurements. It was all-important to determine the difference in the behaviour to light of a substance in its solid state and when in solution, but this was difficult as few solids were uniaxial; as an example of the difference he mentioned that in the case of sodium chloride the solid has a refraction of 14'4, while that of the dissolved substance is 15'3.

Mr. PICKERING said that Dr. Perkin's results must have a very important bearing on the question of the nature of solutions. When salts caused a double depression of the freezing point, the physicists held it to be due to dissociation into ions; but here was a case of a similar effect which cannot well be attributed to dissociation. As far as can be seen, dissociation would not double the rotation, still less would it make it more than double, and even if it could be held to do so, such an explanation would be inadmissible in the case of saturated solutions, for in such solutions the physicists themselves held that there is little or no dissociation.

Professor RAMSAY thought that the abnormal results may not be entirely connected with dissociation into ions, the optical phenomena were probably much more complex; it was conceivable that the separated atoms might be much more powerfully affected in a magnetic field than when combined.

84. "Note on Normal and Isopropylparatoluidine."—By E. HORI and H. F. MORLEY.

Desiring to distinguish with certainty between normal and isopropylparatoluidine, the authors have prepared the pure substances and several of their derivatives.

The normal compound boils at 230-233°; its density at 20° is 0'9243 grm. per c.c., and at the boiling point 0'7543; hence its molecular specific volume is 197'53 (theory 199'5); its molecular refractive energy is 82'5 (theory 79'3).

Isopropylparatoluidine boils at 219-221 (uncorr.); its density at 20° is 0'9226 grms. per c.c., and at the boiling point 0'7466; hence its molecular specific volume is 199'57; its molecular refractive energy is 81'4.

The isopropylnitrosamine is a crystalline solid, whereas the isomeride is an oil.

The normal and iso-compound form oxalates differing in solubility and stability.

85. "The Action of Light on Ether in Presence of Oxygen and Water." By ARTHUR RICHARDSON.

In a recent paper by Professor Dunstan and Mr. Dymond (*Chem. Soc. Trans.*, 1890, 574), it is stated that hydrogen peroxide is not formed when pure ether is exposed to light in contact with air and water, and these authors consider that the formation of this substance is due to the impurities contained in the ether, which can be removed by treatment with potassium bichromate or iodhydric acid. The author describes experiments made with ether which had been purified by some of the methods described by Dunstan and Dymond; he finds that hydrogen peroxide is formed in the liquid in every case after exposure to light in contact with moist air or oxygen, but not in the dark at the ordinary temperature. The methods employed to prepare and purify the ether are described in full in the paper; they were as follows:—

1. Commercial "pure" ether, from which the alcohol had been removed by repeated shaking with water, was afterwards agitated with potassium bichromate.

2. Ether obtained by the action of pure sulphuric acid on pure alcohol was shaken with potash solution and with water, and one portion was treated with potassium bichromate, another with iodhydric acid.

3. The liquid from 2 was collected after exposure to light, and again agitated with potassium bichromate.

4. Ether prepared from an entirely different sample of pure alcohol and pure sulphuric acid was treated as before with potassium bichromate; it was distilled after being allowed to stand over calcium chloride and then over metallic sodium. The ether boiled constantly at 34.6° at 760 m.m. pressure corr. to 0° .

The ether prepared by these methods was placed in colourless bottles, and air or oxygen was passed into the space above the liquid before the stoppers were inserted.

Some experiments were made on the influence of temperature in bringing about the formation of hydrogen peroxide; it was found that ether and moist oxygen exposed to a temperature of $75-88^{\circ}$ in the dark contained, after four days, considerable quantities of this substance; similar results were obtained when ether and oxygen were heated to 60° for a period of forty hours. Ether vapour and moist oxygen gave practically no peroxide when so heated. It was found, however, that liquid ether kept at 0° contained hydrogen peroxide after exposure to light for four days.

Hence, it appears that when special precautions are taken to ensure the presence of oxygen over the ether, hydrogen peroxide is formed at ordinary temperatures, and even at 0° in the light, but not in the dark; it is, however, formed in absence of light at about 60° .

DISCUSSION.

Professor DUNSTAN said that Mr. Dymond and he had made their experiments on the conditions necessary for the formation of hydrogen peroxide from ether, because there was no evidence that previous workers had employed the pure substance. They had been unable to detect hydrogen peroxide in ether that had been exposed at a low temperature to the electric light and diffused daylight. For the detection of hydrogen peroxide, reliance had been placed on the characteristic chromic reaction which they had proved to be capable of indicating 0.0002 grm. of the substance. Dr. Richardson, who meanwhile had purified ether by the method employed by the speaker, and still adhered to some of his original statements, asserted that he had detected hydrogen peroxide in ether exposed at a low temperature to white light by means of titanium oxide, but it appeared that he had failed to obtain the chromic reaction. The suggestions which Dr. Richardson had made to explain why hydrogen peroxide had not been formed in their experiments were quite untenable. At least 2 litres of air were in contact with the exposed ether. There could be no doubt as to the purity of the ether they had used. The slight greenish tint of the bottles was shown not to be detrimental by the circumstance that hydrogen peroxide was produced from specimens of impure ether contained in them. They had employed the electric light partly because they had failed to obtain results with diffused sunlight in London, and partly because they wished to ascertain whether pure ether was affected by violet rays acting at a low temperature. They had recently obtained evidence which seemed to show that certain specimens of unpurified ether could form hydrogen peroxide even in the dark. The whole purport of Dr. Richardson's first paper on this subject was to prove that when hydrogen peroxide is formed from moist ether, the water and not the ether is oxidised. They had opposed this view as they were in possession of good evidence that the ether is oxidised. It now appeared that Dr. Richardson had abandoned his former view, although he still contended that hydrogen peroxide could be formed from water and oxygen alone in the presence of light.

But they had also failed to confirm this statement. No evidence could be obtained of the presence of hydrogen peroxide in acidulated water which had been exposed to intense sunlight or to the electric light (*cf. Chem. Soc. Trans.*, 1890, 988). They were also unable to confirm the statement that pure ether yields hydrogen peroxide when heated with air and water to $50-60^{\circ}$.

Mr. DYMOND said that Dr. Richardson had not stated whether he had tested his ether for the impurities which are known to be invariably present, some of which may be produced during the process of purification employed, and which are particularly difficult to remove, viz., aldehyd and ethylene. In his previous paper, Dr. Richardson had stated that after hydrogen peroxide had been produced in ether, the ether remained unaltered. Did he adhere to that statement now that he had convinced himself that the ether was concerned in the production of the peroxide? In the experiments made by Professor Dunstan and himself, it was always noticed that when peroxide of hydrogen was produced from ether, the ether afterwards contained aldehyd, acetic acid, and other substances.

Mr. GROVES, referring to Dr. Richardson's statement that he had found that pure dry ether was acted on when exposed with oxygen, said that this result was contrary to recent experience as to the influence of water in promoting chemical change; it was difficult to conceive how hydrogen peroxide could be produced in such a case.

Mr. PICKERING inquired why so minute an amount of peroxide was obtained; if pure ether afforded hydrogen peroxide when oxidised, it was to be expected that the action would continue, and that a larger proportion would result.

Dr. PERKIN said that the alcohol was best removed from ether by means of phosphoric anhydride. Dr. JAPP mentioned that Professor Frankland had always used this substance in purifying the ether used in preparing zinc methide; and Professors RAMSAY and DUNSTAN subsequently stated that they had employed it with good results.

Dr. RICHARDSON, in reply, stated that he did not see that Professor Dunstan's ether had any claim to greater purity than that used by himself. On the contrary, the fact that Professor Dunstan's ether distilled only within $\frac{1}{2}$ degree showed that it was not so pure as that used by him, which distilled within 1-10th degree. The ether used by the speaker was found to be without action on potassium iodide in the dark after contact with the solution for two weeks. With regard to the remarks made on the quality of the bottles used, it appeared to him that the fact that methylated ether was found to contain H_2O_2 after exposure to light in greenish glass bottles, did not show that the formation of this body was in this case brought about by light at all, for, as Professor Dunstan had just pointed out, impure ether which had been kept in the dark was found to contain this substance. He did not see that the absence of H_2O_2 in Dunstan's ether could be accounted for by the use of the electric light, for Professor Dunstan states (*Chem. Soc. Trans.*, 1890, 579) that in one series ether was exposed for two months to much sunlight during August and September, the temperature ranging between $15-25^{\circ}$, but, under these circumstances, no H_2O_2 was formed. The speaker would like to point out that in all except the last sample of ether he had obtained sufficient H_2O_2 after exposure to give the blue colouration with $K_2Cr_2O_7$; in the last case, however, the time of exposure had been necessarily short, and the light exceedingly poor, so that the presence of H_2O_2 could only be detected by the more delicate tests such as KI and H_2TiO_3 . He was not surprised to learn that Professor Dunstan had failed to obtain H_2O_2 on exposing H_2O to light, for in the formation of this body, under these conditions, many special precautions must be observed, such as keeping the temperature low, &c., as he found that the H_2O_2 first formed was very readily decomposed.

In reply to Professor Pickering, Dr. Richardson wished to point out that other products of decomposition were

formed when ether was exposed to light, some of which might probably decompose the peroxide first formed; thus a specimen of ether which had been exposed with water and oxygen to light for 18 months contained no H_2O_2 , the smell of the ether had changed, and black particles were seen floating in the liquid—this was a point which the author hoped to further investigate, however.

86. "Action of Ammonia and Methylamine on the Oxylepidens." By FELIX KLINGEMANN, Ph.D., and W. F. LAYCOCK, Ph.D.

This investigation was undertaken with the object of ascertaining whether the analogy which was shown by Japp and Klingemann to prevail between the interactions of $\alpha\beta$ -dibenzoylcinnamene and those of dibenzoylstilbene (Zinin's "acicular oxylepiden") was preserved in the behaviour of these compounds with ammonia and amines. The authors find that this is the case.

On heating dibenzoylstilbene with alcoholic ammonia at 200° , it is converted into a mixture of two isomeric compounds of the formula $C_{28}H_{21}NO$: *dibenzoylstilbenimide*, which is deposited from benzene in crusts of yellow prismatic crystals melting at 180 – 182° , and corresponds with bibenzoylcinnamenimide; and *tetraphenylpyrrholone*, which crystallises in pale yellow square plates melting at 206 – 207° , corresponding with triphenylpyrrholone. Dibenzoylstilbenimide is converted by heating at 310° into tetraphenylpyrrholone, just as dibenzoylcinnamenimide is converted into triphenylpyrrholone. The constitution of tetraphenylpyrrholone is shown by the fact that it is also obtained by heating tetraphenylcrotonolactone (Zinin's "tabular oxylepiden") with alcoholic ammonia at 200° :—

By the action of nascent hydrogen (from sodium and boiling amyl alcohol) tetraphenylpyrrholone is converted into *tetraphenylpyrrholidone*,—

which crystallises from alcohol in slender pale brown needles melting at 237° .

When dibenzoylstilbene is heated with an alcoholic solution of methylamine at 200° , it is converted, with elimination of water, into *methyltetraphenylpyrrholone*,—

which crystallises from hot alcohol in thin faintly yellowish asymmetric plates melting at 161° .

On the other hand, tetraphenylcrotonolactone unites directly with methylamine at 150° , forming *benzoyltriphenylpropiomethylamide*,—

which crystallises from glacial acetic acid in lustrous plates melting at 267° . When this compound is distilled under reduced pressure, it parts with water and is converted into methyltetraphenylpyrrholone. The crystalline form of the compound thus obtained differed, however, from that of the same substance from dibenzoylstilbene, and the melting-point was found at 158° , instead of 161° ; but the authors attribute these differences to dimorphism, as in the case of the corresponding triphenyl derivatives prepared by Japp and Klingemann.

87. "Condensation of Acetone-phenanthroquinone." By G. H. WADSWORTH.

The author finds that by the dehydrating action of a mixture of concentrated sulphuric acid and absolute alcohol, acetone-phenanthraquinone is converted into a compound of the formula $C_{34}H_{22}O_3 = 2C_{17}H_{11}O_3 - 3H_2O$. It crystallises from benzene in tufts of minute needles melting at 238° C.

88. "Contributions to the Knowledge of Mucic Acid. Part IV. Action of Phosphorus Pentachloride on Mucic Acid." By S. RUHEMANN, Ph.D., M.A., and S. F. DUTTON, B.A., B.Sc.

The authors find that mucic acid is converted by the action of phosphorus pentachloride into a crystalline compound which, assuming dichloromuconic acid to be an acid of the formula—

may be represented by the formula—

On dissolving this substance in water and carefully concentrating the solution, large colourless rhombic crystals of the corresponding *phosphorodichloromuconic acid* are obtained; several salts of this acid are described, among others, one formed by the combination of $6NH_3$ with the acid. The phosphochloride is converted by the action of phosphorus pentachloride at 120° into dichloromuconyl chloride, hydrogen chloride, and phosphorus oxychloride.

The authors have succeeded in converting the isomeride of Bode's dichloromuconic acid discovered by Ruhemann and Elliot (*cf. Chem. Soc. Trans.*, 1890, 931) into Bode's acid, by adding a small quantity of bromine to the cold aqueous solution; they therefore conclude that the isomeric dichloromuconic acids are related to each other much as are maleic and fumaric acids.

89. "Halogens and the Asymmetrical Carbon Atom." By T. H. EASTFIELD.

At the suggestion of Professor Emil Fischer, the author has endeavoured to prepare active haloid derivatives similar in constitution to Le Bel's optically active secondary amyl iodide, $CH_3 \cdot CHI \cdot C_3H_7$, which at present stands alone as the only active compound in which a halogen is united to the asymmetric carbon atom. His results are negative. Thus active mandelic acid gave inactive phenylbromacetic acid when heated with bromhydric acid at a temperature not exceeding 50° ; and no resolution of the acid into active constituents was effected by means of alkaloid salts.

The following are the Titles of Papers received and printed in the *Transactions* during the recess :—

PHYSICAL SOCIETY.

November 14, 1890.

Prof. W. E. AYRTON, F.R.S., President, in the chair.

THE following communications were made:—

"On Certain Relations existing amongst the Refractive Indices of the Chemical Elements." By the Rev. T. PELHAM DALE, M.A.

The first part of the paper corroborates the results announced in a communication made in May, 1889, on the same subject, and says that, as far as experimental data are forthcoming, the refraction ($\mu - 1$), divided by the vapour density (d), is equal to a constant multiplied by some integer. Several metals whose refractions have since been determined conform to this law. On examining the relation between molecular weight (M) and refraction, similar conclusions are arrived at, for, to a fair degree of approximation, the ratio $M/\mu - 1$ is a constant or a simple multiple of this constant.

The question as to how far the relation $\mu - 1/d = c$ holds good for the same element in the three states of vapour, liquid, and solid, has been examined as far as data exist for this purpose. The resulting numbers are not identical, but some of the data themselves are doubtful.

Another relation is between the molecular distances (h) (see *Proc. Phys. Soc.*, vol. ix., p. 167), and the atomic weight (a) of the elements, h being nearly proportioned to $\sqrt{a}$. In the case of selenium, sulphur, and phosphorus, the agreement is close, but for bromine, chlorine, and carbon, not so good.

A fifth relation appears to exist between the upper limit of refraction and the line spectra of elements. For example, the upper limit of refraction for selenium occurs at wave length 5295.7, whilst its spectrum exhibits a remarkable series of strong lines about this wave length. A similar relation apparently holds with sulphur, phosphorus, and bromine. Gold also shows a series of strong lines about C, in the vicinity of which the metal has the greatest reflective power.

The author finds that selenium polarises and reflects nearly all the light that falls on it at a large angle, and suggests that it may be used in polariscopes.

He has also endeavoured to connect together the phenomena of a limit of refraction and anomalous dispersion. In the case of fuchsin the dark space coincides with the limit of refraction, and the same is probably true of cyanin. If one of the anomalous indices be given the other can be found. He also believes that bodies of high molecular weight give anomalous dispersion, and thinks solutions of iodine will exhibit the phenomenon.

The mathematical investigation of the whole subject involved difficulties arising from the want of reliable data, and the author hopes that some member will take up the necessary experimental determinations.

Dr. GLADSTONE thought the author under-estimated the amount of work done and in progress on the subject; for the question whether $\mu - 1/d$ is constant or not is being investigated by many. The French physicists, he said, had found the quantity nearly constant, but Lorenz's expression, $\mu^2 - 1/\mu^2 + 2$, is slightly better when applied to compounds in the liquid and gaseous states. Metals were difficult to deal with, especially as, according to the recent paper of Du Bois and Reubens, their refractions do not follow the law of sines.

Mr. DALE here suggested that they might be related to hyperbolic sines.

Dr. GLADSTONE, continuing, said that by taking solutions of metals, it was found that their specific refractive energies were nearly inversely as the square of their combining weights, but, at present, the known cases were not sufficient to establish a law.

Prof. RÜCKER said that of the two expressions, $\mu - 1/d$ and $\mu^2 - 1/\mu^2 + 2$, the latter seemed preferable, for it could be converted into electrical quantities by writing κ for μ^2 . The expression then became $\kappa - 1/\kappa + 2$, and if this can be shown to be constant by electrical work, this would be an argument in its favour.

On the subject of anomalous dispersion, he directed Mr. Dale's attention to Mr. Glazebrook's "Report on Optical Theory" made to the British Association.

Mr. DALE, in reply, pointed out that from the nature of the two formulæ, an inaccuracy or variation in μ would affect theirs more than Lorenz's. He thought that $\mu - 1/d$ was a limit towards which the numbers tend.

"Tables of Spherical Harmonics." With Examples of their Practical Use. By Prof. J. PERRY, F.R.S.

The author defined a Spherical Harmonic as a homogeneous function of x, y, z , satisfying the equation—

$$\frac{d^2V}{dx^2} + \frac{d^2V}{dy^2} + \frac{d^2V}{dz^2} = 0,$$

stated the fundamental properties of such functions, and pointed out their importance in problems on heat, electricity, and hydrodynamics. Referring to zonal harmonics (homogeneous functions of $(x^2 + y^2)^{\frac{1}{2}}$ and z), he showed that these harmonics are symmetrical with respect to the axis of z , and might be expressed as functions of the angle (θ) which the line joining the point (x, y, z) to the origin makes with the axis of z , multiplied by r^i ; where r is the radius vector, and i the degree of the homogeneous function. These functions of θ are called zonal surface harmonics, and are designated by P_0, P_1, P_2 , and P_i , according to the degree of the function. It was the values of these quantities which form the tables brought before the Society.

The tables comprise the values of P_1 to P_8 , and are calculated to four places of decimals, and for every 1° between 0° and 90° .

As an example of the use of such tables, the case of a spherical surface covered with attracting matter, whose density varied as the square of its distance from a diametrical plane, was taken. It was required to find the potential both outside and inside the sphere, and to determine the equipotential surfaces and lines of force. The potentials inside (A) and outside (B) were shown to be given by—

$$\frac{A}{\pi} = 8 + \frac{16}{5}r^2P_2 \text{ and } \frac{B}{\pi} = \frac{8}{r} + \frac{16}{5}\frac{1}{r^3}P_2$$

respectively. By giving A and B definite values, and choosing values of r , the corresponding P_2 's can be calculated, and the values of θ determined from the tables. Hence, any equipotential surface can be easily determined, and lines drawn to cut the surfaces orthogonally are lines of force.

Another problem which had been tried consisted in

finding the directions of the lines of force near a circular coil of rectangular cross-section, when an electric current circulates in the coil. This was treated approximately by first calculating the potential at six points along the axis in the neighbourhood of the coil, and then finding, by Gauss' method, the coefficients A_0, A_1, A_2 , &c., of an expression in ascending powers of s , which agreed with the calculated potentials at the points chosen. The formula $V = A_0 + A_1 r P_1 + A_2 r^2 P_2$, &c., or its corresponding expression in inverse powers of r , was then assumed to give the potential at any point in the space considered. By giving V definite values, a series of equipotential surfaces were determined, and the lines of force drawn. On putting the calculations to the test of experiment, the approximate solution of this very difficult problem was found to be very nearly correct.

NOTICES OF BOOKS.

Asbestos: its Properties, Occurrence, and Uses. With some Account of the Mines of Italy and Canada. By ROBERT H. JONES. London: Crosby Lockwood and Son.

THIS work took its origin in a pamphlet on the Canadian Asbestos Mines, and, as the author followed up the subject, it has expanded into an account of asbestos deposits throughout the world, and a summary of the industrial applications—actual or suggested—of this singular mineral.

It is a singular fact that, whilst the fire-proof character of asbestos was known and studied in antiquity, the material afterwards fell into disuse, and has only lately come again into notice.

Whilst fully accepting what Mr. Jones has to say on the many valuable attributes of asbestos, we cannot accept his statement that "occupying the position of a connecting link between the animal, vegetable, and mineral kingdoms, it possesses some of the characteristics of all three."

Concerning its fire-proof properties, he gives a hint which may prevent disappointments. Some varieties, we are told, have resisted a temperature of 5000° F., but the hydrous varieties lose their flexibility and become brittle at high temperatures.

The traditions handed down concerning the use of cloth woven from this fibre, and capable of being cleansed by throwing it into a charcoal fire, are sufficiently vague.

The possession of such a cloth is ascribed to Charlemagne, or, according to another version of the same story, to Charles V.

Marco Polo, about A.D. 1300 mentions the occurrence of this mineral in the region now known as Siberia, and gives a very accurate account of its extraction and preparation for use.

The economic importance of the Canadian deposits of asbestos does not seem to have been recognised prior to 1877. It is humiliating to find that in a work on the capabilities and productions of Canada which was got up by occasion of the "Colinderies," and intended for gratuitous distribution in the Dominion section, no mention was made of asbestos.

Asbestos, we are reminded, is not the name of any one particular mineral species, but is a generic term common to several minerals. They are all silicates of lime, magnesia, or alumina, varying much in density and colour, and most of them being flexible and elastic. *Asbestos proper*, which unfortunately does not occur in Canada, is a fibrous variety of hornblende. The Canadian mineral is a fibrous serpentine containing 12–14 per cent. of water.

Mountain wood, mountain cork, mountain leather, and mountain paper are sub-varieties in which the fibres instead of running parallel are matted and interlaced.

Various forms of asbestos occur in Australia and South Africa. The deposits in the United States are not of a quality and quantity to admit of successful working.

The author is of opinion that, though the chief supply of this mineral is from Italy and Canada, yet these countries will find Africa in the near future a formidable competitor.

The Italian mineral contains more magnesia and water than the Canadian and less alumina. It is less easy to work, and the product is less uniform.

It appears that the trick of "salting" mineral grounds intended for sale is not peculiar to the far side of the Atlantic. The Italian mine-owners drive fine asbestos fibre into the crevices of rocks, and give it, as far as possible, the appearance of the genuine formation.

Mr. Boyd, an authority here quoted, says that in Italy, "if asbestos is found on the surface of a rock exposed to the south or south-west, the product is generally fairly abundant, and of good quality."

If exposed to the east there is fine quality, but very small quantity; whilst if exposed to the north the quantity is plentiful, but dry and hard, and on entering the rock all traces of it are lost.

The Canadian asbestos, or chrysotile, has a very different character from the Italian. On its first appearance in the market it was met with contempt. Now, however, it is proved that mining for asbestos in Canada, if properly conducted, shows a more steady return for the money invested, with less elements of risk, than mining for any other material. The great difficulty to be encountered in working a mine is drink! and that especially in parts where the sale of spirits is interdicted. The liquors sold seem to equal in vileness the "cango" manufactured by the Boers of South Africa. The author has found from experience that a tumbler of hot tea flavoured with a slice of lemon is not only palatable and comforting, but will carry a man twice as far as any concoction of alcohol."

It would scarcely be just to the author were we to quote his interesting suggestions for the utilisation of asbestos. Suffice it to say that he has produced a most interesting and valuable monograph, which, we trust, will be duly appreciated.

Origin of the Auriferous Region of Tacuarembó, its Analogy and Concordance with Others (i.e., Ore-Regions), on the American Continent. By CLEMENTE B. POSADA. London: The Consul-General of Polina.

THE author of this work has an annoying fondness for quotation marks. We find not only names of places—some of them well known, such as Potosi, Minas Geraes, and Matto Grosso—thus enclosed, but even the names of rocks, such as dolomite, and trachyte, and basalt, and what is yet more gratuitous the names of elementary bodies, such as chlorine and hydrogen, and compounds such as chlorhydric acid and silica. "Calcium" is an element with which we have not had the opportunity of becoming acquainted. What, further, we must ask is an "albant" condition?

Of sulphur it is said "How can one otherwise conceive that sulphur was not to be found among them (the elements), which is of so volatile a nature, when even now-a-days we see it adhere tenaciously to electricity, which seems to be its necessary attendant following in all its evolutions, and even at the moment when it huris itself upon the earth in the form of the lightning's flash or the thunderbolt."

Don Barrial Posada appears—as far as we can understand his extraordinary language—to be a believer in the catastrophie geology of the past. He speaks of the "ossaries of the existences ship-wrecked in the world in which they lived," of the "arterial and venous (sic) system of the *saxus igneus* (igneous rocks)" "Azote," the author pronounces "more abundant, more sensitive, and subtil than oxygen." To electricity he decidedly assigns a material, ponderable character, as one of the elements. He speaks of "the vast ocean of igneous electrical liquid,

gaseous and electro-dynamic substances." Such utterances and many more which we might quote, even if translated into the Queen's English and freed from typographical errors, form a curious introduction to a work essentially industrial and technical, and which seems intended to convince European capitalists that there is ample room for them to invest in the gold mines of Tacuarembó. Of the room we do not doubt, but to pronounce on the probable returns we must leave to our financial contemporaries.

We will merely quote the following statement.

"The region of New Granada, which comprises nine districts, and which we may consider of equal or even more importance than that of California, is less so than that of Matto Grosso, and this is not richer than the region of Tacuarembó." If either New Granada, or Matto Grosso, or Tacuarembó can put out as much mineral wealth as California, the fact will soon speak loudly for itself.

Statistical Returns of the Commerce, Navigation, &c., of the Republic of Uruguay for the Year 1889. Issued by Authority of the Consul-General of Uruguay. London: Dunlop and Co.

THIS pamphlet, though containing nothing which can legitimately come under the cognisance of the CHEMICAL NEWS, is rich in matter well worth the notice of commercial journals and commercial men.

CORRESPONDENCE.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—The dilemma in which the Chemical Society is now placed may be briefly stated as follows:—

1. By continuing the *status quo*, unlimited admission of persons likely to use the letters F.C.S. as a qualification for trade purposes cannot be effectually checked.

2. By adopting any severe scrutiny of qualification, such as has been proposed, in order to prevent the evils above-mentioned, two worse misfortunes would accrue.

(a) All those at present registered as Fellows would have their position as chemists legitimatised and their competence certified—a result scarcely desirable.

(b) The original object for which the Chemical Society was founded, namely, to provide what is in effect an intellectual club for the advancement of chemistry, would be wholly frustrated, and a severe injustice done to many in all ways worthy of admission.

It appears to us that there is but one way of escape, *viz.*, that the present method of election be retained, but that the Society take immediate steps to make it publicly known that Fellowship in it confers no professional status upon the holder thereof.—We are, &c.,

A. G. BLOXAM.
BERIAM BLOUNT.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—In the CHEMICAL NEWS, vol. lxii., p. 247, Messrs. Lloyd and Teed appear again, this time to return thanks for the "hundreds" of replies to their recent circular.

There is, however, a somewhat naïf admission that the "hundreds" are not quite satisfying contained in their last lines; a sort of extra thankfulness for small mercies to come in the shape of a hope for a reply from "any Fellow" who may have delayed signing the circular,

just so; the party "on the fence" is always a desirable addition at election times, and the approved method of securing him is to produce to him convincing evidence that the majority has alighted on your side. Can Messrs. Lloyd and Teed's inability to answer the "hundreds" have arisen from a feeling of this sort? Meanwhile some of us would feel greatly obliged if the authors of the document would answer the following little query, *viz.*:—How many of the "hundreds" who answered the circular did so under the idea (fostered by its remarkable resemblance in type and paper to official Chemical Society notices), that it was a communication from the secretaries, and accordingly returned the circular to *them* at Burlington House.—I am, &c.,

R. J. FRISWELL.

THE PREVALENCE OF COPPER IN CEREALS.

To the Editor of the Chemical News.

SIR,—Mr. Johnstone's remarks in the CHEMICAL NEWS (vol. lxii., p. 247), reminds me of a similar experience I had in the year 1878. I had prepared two tons of malt syrup with great care. Dr. Atfield stated it contained the largest proportion of diastase of any he had examined up to that date, but unfortunately it contained copper also. At first I attributed the contamination to the copper of the vacuum pan, but as this had been in constant use in the manufacture of sugar, in which no copper was found, I had to seek elsewhere. It was finally traced to the malt, which was of the finest quality I could obtain.

Being desirous of testing the soil on which the barley was grown I applied to the Mark Lane broker, from whom I purchased the malt, but nothing would induce him to give me any information on the subject. I stopped the manufacture and used up the syrup in feeding my pigs, who, notwithstanding the presence of copper to considerable extent, thrived on it over a period of above twelve months.—I am, &c.,

EDWARD BEANES.

Moatlands, Paddock Wood,
Kent, Nov. 17th, 1890.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 17, October 27, 1890.

Electrolysis of Aluminium Fluoride by Igneous Fusion.—Adolphe Minet.—The author has shown in previous papers (*Comptes Rendus*, February 17th, and June 9th, 1889) that he has produced aluminium by the electrolysis of its fluoride in a state of fusion. He now gives the composition of the electrolytic bath which yields the best results at given temperatures, and at a given density of current at the electrodes. The bath is formed of a mixture of sodium chloride and double aluminium sodium fluoride, corresponding to the chemical formula (expressed in equivalents) $6\text{NaCl} + \text{Al}_2\text{F}_3 \cdot 3\text{NaF}$. The melting-point was 675° ; the point of the emission of vapours 1035° ; specific gravity at 820° , 1.76; coefficient of expansion in the melted state 5×10^{-4} ; electric conductivity at 870° 3.1.

On the Amylamines.—A. Berg.—This paper does not admit of useful abstraction.

Revue Générale des Sciences Pures et Appliquées.
Vol. i., No. 20, October 30, 1890.

Fire-Damp and its Accidents.—H. Le Chatelier.—In a general survey of the question of coal mine explosions,

the author lays little weight upon coal dust in the absence of explosive gases. Possibly he overlooks the serious calamities produced in flour-mills by the dust of flour—a much less combustible substance—in the total absence of gaseous hydrocarbons. His chief reliance is laid on ventilation.

In an Annual Review of Physiology, by Prof. Léon Fredericq, the author mentions the fact that peptone, the normal product of the digestion of the albumenoid matters, is a true poison, which fails to prove fatal merely because it is progressively re-converted into albumenoids.

Another curious fact is that, according to Hermann, the excreta do not consist chiefly of the undigested portions of the food, but of the products of the secretion and the desquamation of the intestine.

In a review of Prof. A. Marshall's "Principles of Economics" we find the following laudable deliverance:—"The mania for elementary works, the production of the ignorant, who apologise for insufficiency of their works by the plea of being intelligible to the young, has inundated our book stores with ridiculous works. The 'manual,' the elementary book, is, in certain departments, the wound of instruction.

A New Gas, Azothydric Acid.—Prof. Curtius, of Kiel, has obtained a compound, N_3H , for which he proposes the constitutional formula—

It is very soluble in water, and the solution dissolves zinc, copper, and iron, with evolution of hydrogen and the formation of nitrides, in which the metals are substituted for the hydrogen set free.

MISCELLANEOUS.

The Determination of Fat in Milk.—The Dairy Association of Kiel offers a prize of £150 (3000 marks), for an improved method for determining the fatty matter in new milk, skimmed milk, and butter milk, without the use of a chemical balance as accurately as by the gravimetric process. It must be free from danger, cheap, and so simple in execution as to allow of comparative determinations of the fat in the milk of individual cows; and it must be distinctly preferable to all the methods now in use. Applications marked with a motto and accompanied with a sealed envelope containing the name and address of the sender, and with the apparatus required, may be addressed to Herr C. Boysen, Kiel, up to October 1st, 1891.

The Sale of Poisons.—From a circular sent out under the auspices of the British Medical Association, it appears that certain physicians and surgeons are dissatisfied with the existing state of the law on the sale of poisons. The first point urged in objection to the present law is that "the present poison schedule includes only a limited number of substances, many well-known and powerful poisons, notably the mineral acids." We submit that any restriction upon the sale of the mineral acids, the most commonly used of all reagents, could not fail to act as a check upon chemical research. Against any such interference we protest most earnestly, and trust that our protest will be followed by that of our scientific contemporaries, and by that of the Fellows of the Chemical Society and of the Institute of Chemistry. It would be indeed deplorable if chemistry in Britain should be fettered and humiliated in a manner similar to that which has befallen physiology. The fatal accidents from poisoning in this country are not so numerous as to furnish any *raison d'être* for a new agitation, whilst at the same time no more stringent regulations are asked for

concerning the common sale of revolvers, which have far fewer legitimate uses than poisons, which occasion far more mischief, and which now readily find their way into the hands of burglars, madmen, conspirators, and heedless boys. We should be strongly in favour of the proposal to restrict the sale of poisons, quack medicines, and indeed of all "patent" or proprietary nostrums, to the pharmacist. At present they are sold chiefly by grocers, oilmen, and even by house-furnishers and "general providers."

MEETINGS FOR THE WEEK.

- MONDAY, 24th.—Medical, 8.30.
Society of Arts, 8. (Cantor Lectures). "Gaseous Illuminants," by Prof. Vivian B. Lewes.
TUESDAY, 25th.—Royal Medical and Chirurgical, 8.30.
Institute of Civil Engineers, 8.
WEDNESDAY, 26th.—Geological, 8.
Society of Arts, 8. "Physical Tests in Competitive Examinations," by Francis Galton F.R.S.
THURSDAY, 27th.—Royal, 4.30.
Institute of Electrical Engineers, 8.
FRIDAY, 28th.—Physical, 5. "Notes on Secondary Batteries," by Dr. Gladstone and Mr. W. Hibbert. "An Illustration of Ewing's Theory of Induced Magnetism," by Prof. S. P. Thompson.

TO CORRESPONDENTS.

Inquisitive.—We regret we are unable to say where the mineral can be procured.

THE CHEMICAL NEWS.

VOL. LXII. No. 1618.

NOTE ON PRIESTLEY'S METHOD OF MEASURING OXYGEN IN AIR.

By J. ALFRED WANKLYN.

PRIESTLEY'S method of measuring the oxygen in the air is certainly the quickest, and is easy of execution, and is accurate when properly carried out; indeed there are possibilities of accuracy in this method which promise to place it in that respect before every other. It is the oldest, or at any rate one of the oldest, methods of measuring oxygen, dating almost as far back as the discovery of oxygen itself.

I have an old book open before me, date of publication 1806. Turning to the article "Eudiometer," I read—

"The eudiometers proposed by different chemists may be reduced to five.

"1. The first eudiometer was made in consequence of Dr. Priestley's discovery that when nitrous gas is mixed with air over water, the bulk of the mixture diminishes rapidly in consequence of the combination of the gas with the oxygen of the air and the absorption of the nitric acid thus formed by the water." . . . "Dr. Priestley's method was to mix together equal bulks of air and nitrous gas in a low jar, and then to transfer the mixture into a graduated glass tube about three feet long in order to measure the diminution of bulk." The article goes on to refer to the work of Falconer, of Bath, Fontana, Cavendish, and Humboldt, and then concludes, "But after all the exertions of these philosophers, the method of analysing air by means of nitrous gas is liable to so many anomalies that it cannot be depended upon."

Further on we learn that "the result of the numerous experiments which have been made with nitrous gas is that the proportion of oxygen in atmospheric air varies in different places and at different times." And the maximum percentage of oxygen in air is given at 30 per cent, the minimum at 22 per cent.

"2. The second kind of eudiometer was proposed by Volta," and the account goes on to state that this explosion of air mixed with hydrogen gas, and Volta's method is condemned even more emphatically than Priestley's.

Three other methods of measuring the oxygen in air are then described and approved of. Such was the state of the chemist's knowledge in 1806—thirty years after the discovery of oxygen. Since that date, Volta's method by explosion with hydrogen gas has risen into favour, and in Bunsen's classical work on "Gasometry," published in 1857, occupies the post of honour. The vindication of Priestley's method has been long delayed, even until the year 1890. The question suggests itself why did the Priestley method fail in the early days? The answer is not far to seek. This method failed because the manipulation was wrong. Water holds oxygen in solution, and the circumstances of the old experiments were such that the oxide of nitrogen employed in the experiments expended itself partly in combining with the oxygen dissolved by the water. The mixture of equal bulks of oxide of nitrogen and air in a low jar, and then the direction to transfer to a graduated tube about three feet long, points plainly enough to the employment of large volumes of water. Operating in that manner the operator is bound to mistake the oxygen dissolved by the water for the oxygen of the air, and consequently to arrive at too high a figure for the oxygen of the air.

If the reader will now turn to the description given in the air analysis recently published, he will perceive that

by the employment of the Hempel apparatus as therein described, this source of error is avoided. The directions are to measure the air in the gas-burette, and then to pass it into an absorption-pipette containing water. Then the oxide of nitrogen is introduced into the gas-burette and measured, and then (without bubbling through water) immediately passed to the air in the absorption-pipette. The nitric peroxide fumes which result are rapidly absorbed by the water in the absorption-pipette, and the gas is passed back and measured in the gas-burette. In short, in the Priestley process as now carried out, there is no mistaking oxygen dissolved for oxygen in the air; hence the success of the method in our hands.

ON THE SPECIFIC HEATS OF GASES AT CONSTANT VOLUME.

PART I.—AIR, CARBON DIOXIDE, AND HYDROGEN.*

By J. JOLY, M.A., B.E., Assistant to the Professor of Civil Engineering, Trinity College, Dublin.

IN this first notice the specific heats at constant volumes of air, carbon dioxide, and hydrogen are treated over pressures ranging from seven to twenty-five atmospheres. The range of temperature is not sensibly varied. It is found that the specific heats of these gases are not constant, but are variable with the density. In the case of air the departure from constancy is small and positive; that is, the specific heat increases with increase of the density. The experiments afford directly the mean value 0.1721 for the specific heat of air at the absolute density of 0.0205, corresponding to the pressure of 19.51 atmospheres. A formula based on the variation of the specific heat with density observed in the experiments ascribes the value 0.1715 for the specific heat at the pressure of one atmosphere. The formula assumes the specific heat to be a linear function of the density, which must as yet be regarded only as an approximation, the exact nature of the relation being concealed by variations among the experiments.

These results appear to be in harmony with the experiments of Wiedemann on the specific heat at constant pressure, and of Rowland on the mechanical equivalent of heat, from which the value 0.1712 is deduced for C_v at 760 m.m.

The experiments on carbon dioxide reveal a more rapid variation of the specific heat with density, the variation in this case being again positive in sign. The formula—

$$C_v = \rho \times 0.2064 + 0.16577$$

appears with considerable reliability to express the relation between specific heat and density.

The relation between specific heat and density in the case of hydrogen is of a negative character; that is, the specific heat diminishes with increase of density. The experiments are chiefly directed to elucidate this point, for, owing to the difficulty of preparing pure hydrogen, it was found that variations in the quantitative results of experiments on different samples of the gas were unavoidable. Accordingly the experiments were directed to a comparison of the specific heats of like samples of the gas at different densities. The variation with density is small, but (with one exception) all experiments on the purer hydrogen ascribe a negative character to it.

The nature of these variations of specific heat with change of density is, in the case of the three gases, in accord with their behaviour as regards Boyle's law, within the limits of pressure.

The experiments were effected in the steam calorimeter, a differential method being used in which an empty or idle vessel is thermally compared with the vessel holding the gas at high pressure. The vessels possessing ap-

* Abstract of a paper read before the Royal Society, Nov. 20, 1890.

proximately the same calorific capacity, the result, theoretically, is as if the gas was dealt with isolated from any containing vessel. Although practically this is not attained many sources of error are eliminated by the procedure adopted.

ACTION OF NATURAL ORGANIC COMPOUNDS ON IRON PLATES.

By Dr. T. L. PHIPSON, F.C.S., &c.

SOME little time ago M. L. Vignon called attention to the action of tannin upon iron plates when this substance is used as an anti-incrustator in boilers. He expressed the opinion that it was injurious to boilers on account of its corrosive action. Latterly this opinion has been attacked by Mr. L. Manstetten, who has made some experiments on a small scale, and concludes that the action is not of much consequence, as the quantity of iron taken up from iron vessels used in the extraction of tannin materials is very small, &c.

I am of opinion that M. L. Vignon is right, and that the use of glucosides as anti-incrustators may be fraught with much danger to the iron plates of a boiler. I may refer to the corrosive action of the leaves and stalks of the Virginia creeper upon iron netting, when they are battered by the wind and rain against the metallic surface. It is surprising in how short a time the netting is utterly destroyed. I alluded to the subject in a note published in the *CHEMICAL NEWS* a few years ago. It is true that the juice of that plant is very acid, but perhaps, not much more so than many decoctions of tannin materials, and I think the greatest caution should be used in applying vegetable extracts of any kind as anti-incrustators for iron boilers on account of their evident tendency to develop acids, and to corrode the plates.

THE SYNTHESIS OF UREA.

By F. E. MATTHEWS.

ALTHOUGH the credit for the first synthesis of an organic substance from inorganic material must be given to Wöhler on account of his synthesis of urea, in 1828, yet it is an interesting fact which appears to have escaped notice, that this substance was produced by John Davy as early as 1811 or 1812 from purely inorganic substances.

Unfortunately Davy did not sufficiently investigate the product he obtained, which was a mixture of ammonium chloride and urea, or the study of organic synthesis would have been accelerated by a period of 16 years.

In the *Philosophical Transactions* for 1812 the following paper appears:—"On a Gaseous Compound of Carbonic Oxide and Chlorine. By John Davy. Communicated by Sir Humphry Davy, Knt., LL.D., Sec. R.S. Read February 6, 1812."

The quotations here given are taken from the *Abstracts of the Philosophical Transactions*, and the account does not differ materially from that in the original paper.

"Although it has been asserted by Messrs. Gay-Lussac and Thenard, and also by Mr. Murray, that carbonic acid (this is a misprint for carbonic oxide, which occurs in the original) and chlorine have no action upon each other, Mr. J. Davy has observed the contrary to be the case. A mixture of equal parts of these gases, previously dried over mercury, being exposed to bright sunshine for about one quarter of an hour, lost all colour of the chloric gas, and were found condensed into half their former volume. The smell of the gas was more suffocating than that of chlorine. It occasioned a very painful sensation in the eyes; it reddened litmus-paper; it combined with ammonia, forming a salt perfectly neutral and dry, but deliquescent, by

attracting moisture from the atmosphere. This salt was decomposed by sulphuric, nitric, and phosphoric acids, and also by liquid muriatic acid; but sublimed unaltered in carbonic, sulphurous, and muriatic acid gases.

"In those instances where the salt was decomposed, the products were carbonic and muriatic acid gases. It is remarkable, that in the formation of this ammoniacal salt the new gas combines with as much as four times its bulk of ammoniacal gas."

The last paragraph quoted contains sufficient detail to show that Davy must have synthesised urea, the equation for its formation being—

In Roscoe and Schorlemmer's treatise (New Edition, vol. i., p. 647) the references given for the synthesis of urea by the action of ammonia upon carbonyl chloride are Nathanson, *Ann. Chem. Pharm.*, xcvi., 287; Neubauer, *Ibid.*, ci., 342.

Cooper's Hill, Staines.

NOTES ON SOME HOT SPRING WATERS.*

By A. LIVERSIDGE, M.A., F.R.S., Professor of Chemistry,
University of Sydney.

(a). Note upon the Hot Spring Waters, Ferguson Island, D'Entrecasteaux Group.

THE specimens forming the subject of this note were collected by Sir W. Macgregor, K.C.M.G., Governor of British New Guinea, who thought that these waters might prove to be of scientific interest, and therefore forwarded them to me for examination.

Accompanying the specimens was the following description of the hot springs, prepared by Mr. Basil Thomson, together with two photographs of the locality:—

"The evidence of volcanic action on the east end of Ferguson and Goulvain Islands in the D'Entrecasteaux Group were plainly visible from the sea, but a few miles to the westward gave place to a schistose slaty formation, of which the island seems mainly composed. It was therefore with no little surprise that, on the evening of our anchoring in Seymour Bay, we noticed a strong smell of sulphur, the fumes being sufficient to discolour the white paint on the vessel during the night. Seymour Bay lies in the narrow straight named by Captain Moresby after himself, and is fringed with mangrove and dense scrub and backed by low hills.

After forcing our way through mangrove and sago swamps for about half a mile, we came on a well-beaten native path, which led to a rapid stream. Some of the party who stopped to prospect for gold, found the gravel in the bed of the stream too hot for the hands, although the water of the stream was cold.

Making our way southward, we emerged from dense scrub upon a flat, bare of vegetation, and dotted with little hillocks of pure sulphur, from which vapour was rising.

The vegetation surrounding this flat was identical with that in the non-volcanic country, and terminated suddenly, but on the flat itself a few eucalypts were trying to exist. This is the most easterly point at which this tree was found in British New Guinea.

Passing over this flat, which gave a hollow sound to the feet, showing that the crust was very thin, we climbed a low hill, and looked down upon a small lake shut in by hills, having a margin of dazzling whiteness, made by the crystallisation of salts, which tasted strongly of alum. At the foot of the hill was a spring of boiling water, which discharged into the lagoon.

* From the *Transactions of the Australasian Association for the Advancement of Science*, Melbourne Meeting, 1890, Section B.

The low hills surrounding the lake were composed of sulphur and the white salt referred to above. The water of the lake, which was covered with wild fowl, was of a light yellow colour, and tepid, and the margin was surrounded by a thin crust, which gave way when trodden on, and let one of our party through into three feet of black slime.

All round the base of the hills was a succession of holes full of boiling mud. Near the summit of one of the low hills we found a larger hole, which was throwing up liquid mud to the height of several feet with loud reports. (Photograph enclosed).

Further to the northward we found a similar lake and hot springs, and some of our party, who were obliged by the hostility of the natives to pass the night on the top of one of the sulphur hills, experienced much inconvenience from the fumes. At night the hills give out a bluish light.

(Signed) B. H. THOMSON."

Sydney, 8th March, 1889.

None of the specimens were in sufficient quantity to permit of a full analysis being made of their mineral constituents, the largest samples being contained in a so-called quart brandy bottle.

The only quantitative determinations which could be conveniently made were the total solids, fixed solids, loss on ignition, and chlorine and sulphuric acid.

The loss on ignition includes any organic matter which may have been present, water of combination, volatile and decomposable salts, together with some sulphur.

There were four samples in all.

SAMPLE No. 1.—Labelled "*Seymour Bay, Ferguson Island 11th November, 1888. Boiling Water from Hot Spring.*"

This sample was contained in a soda-water bottle, and as one-half of it consisted of solid matter, it would be more correctly described as a mud.

The sediment, or solid matter, was of a bluish grey colour, and was found to contain a few diatom frustules and small crystals of selenite (calcium sulphate), and a good deal of sulphur. At some future time it is intended to make a more complete examination of this sediment, as there is sufficient for a quantitative analysis.

The sulphur was carefully tested for selenium, but none was found to be present; neither did this residue contain either arsenic or phosphorus.

The supernatant liquid was filtered off from the mud after allowing the specimen to stand for two or three days; the filtrate had a strong smell of sulphurous acid, and strongly reddened blue litmus-paper, showing the presence of free acid, and, on exposure to the air, soon became milky from the separation of sulphur.

On evaporating the filtrate down to dryness in a platinum dish over a water-bath, a pale brownish residue was left, which rapidly absorbed moisture. On ignition it intumesced strongly, and gave off dense white acid fumes (of sulphur trioxide), the ignited residue being yellow when hot and brown when cold.

The weighings gave—

Loss on ignition . . .	9.63 parts per 1000
Fixed solids . . .	4.47 " "
Total solids . . .	14.10 " "

The chlorine and sulphuric acid were not determined in this sample. The fixed solids left on ignition were found to contain both soluble and insoluble silica—sufficient of the former to gelatinise with hydrochloric acid—much iron, mainly present in the original water in the ferrous condition, some magnesia, lime, and a considerable quantity of sodium chloride.

Lithium was sought for, but no indication of it was obtained, although the other three samples gave the lithium band most readily.

SAMPLE No. 2.—Labelled "*Hot Springs, Seymour Bay, 11th November, 1888. Water after Boiling.*" Contained in an ordinary pickle bottle.

This also showed a large amount of a powdery yellow sediment, about 10 per cent perhaps, which consisted mainly of free sulphur.

The water contained a good deal of free sulphuric acid, and on evaporating down to dryness over a water-bath, the residue blackened from the action of the free sulphuric acid upon the organic matter present, and on ignition copious fumes of sulphur trioxide were evolved. Much gelatinous silica was left, together with iron, lime, magnesia, and soda. This residue showed a well-marked lithium band.

The iron was present in the original water mainly in the ferrous state.

Loss on ignition . . .	1.274 parts per 1000
Fixed solids . . .	3.630 " "
Total solids . . .	4.904 " "
Chlorine . . .	1.240 " "

SAMPLE No. 3.—Labelled "*Seymour Bay, 11th November, 1888. Boiling Water from Small Spring.*" Contained in a soda-water bottle.

This, like No. 2, contained a yellow powdery sediment of sulphur and other matters. It possessed a strong acid reaction, and gave off a smell of sulphurous acid, together with that of sulphuretted hydrogen.

On evaporating down to dryness, a light coloured residue was left, brown in the centre, and on ignition this blackened considerably, but only gave off a small quantity of sulphur trioxide fumes. The salts present were the same as in No. 2, and the lithium band was equally well marked.

Loss on ignition . . .	0.630 parts per 1000
Fixed solids . . .	4.470 " "
Total solids . . .	3.100 " "
Chlorine . . .	0.730 " "

SAMPLE No. 4.—Labelled "*Seymour Bay, 11th November, 1888. Water from Lagoon, Hot Springs, Saline Lake, margin surrounded by sulphur.*" Contained in a wine bottle.

The sediment from this was but small in amount, and of a dark brown colour. There was also a little black flocculent matter. The water possessed a strong acid reaction, and smelt of sulphuretted hydrogen.

On evaporating down to dryness, a large quantity of iron was found to be present, mostly in the ferrous condition, much gelatinous silica, some lime, magnesia, and soda, together with lithium.

On ignition, the residue became intensely black, gave off slight fumes with an acid reaction and decrepitated (from sodium chloride crystals), and left a dark ferruginous-looking residue.

Loss on ignition . . .	2.110 parts per 1000
Fixed solids . . .	5.470 " "
Total solids . . .	7.580 " "
Chlorine . . .	1.390 " "

These waters present the usual characters of hot spring waters occurring under similar conditions, and require no special comment except as to the presence of lithium, and I regret that none of the samples were sufficient to allow the amount of this element to be estimated; but, perhaps, on some future occasion it may be possible to bring away a larger supply of the water, or in default of that, the residue left by the careful evaporation (on the spot) of a fair quantity of the water.

Lithium was formerly regarded as a very rare element, but the spectroscopic shows that, although it only occurs in small quantities, it is one of the most widely distributed elements, and is found in many minerals, rocks, soils, and in the ashes of numerous plants.

It may prove to be present in these waters in sufficient quantity to render them useful at some future time, for either medicinal or other purposes.

(b). *Note on Water from a Hot Spring, Savo Island, Solomon Group.*

This specimen, received from Mr. Charles M. Woodford, in February, 1889, was contained in an ordinary fruit bottle.

On opening the bottle, a strong smell of sulphuretted hydrogen was emitted, and the gas continued to escape for two or three days, the sides of the measuring flask were marked by small bubbles of the gas as it slowly escaped, and the previously clear water became milky from the deposition of sulphur.

The bottle contained rather a large amount of black sediment, which, under the microscope, was seen to consist of black opaque granular masses, fragments of quartz and other transparent mineral, together with a few diatom frustules; the black particles were soluble in hydrochloric acid and gave off sulphuretted hydrogen, and the solution reacted for iron; hence they were proved to consist of iron sulphide, probably of quite recent origin, just as is seen in the New Zealand hot springs. (Liver-side, New Zealand Hot Springs, *Four. Roy. Soc. of N.S.W.*, 1887).

With litmus paper the reaction of the water was slightly acid, as might be expected.

The clear water, on decantation, after long standing, so as to be free from sediment, was found to contain 0.764 grms. of total solids per litre (53.48 grains per gallon) in solution, and after ignition 0.422 grms. (29.54 grains per gallon of fixed solids per litre).

The residue left on evaporation was whitish, with a silky lustre, and emitted an odour of sulphur compounds, as is usual in such water residues; and on ignition gave off much steam from water of combination. It rapidly blackened, and the carbonaceous matter present burnt off but slowly.

The amount of water at my disposal rendered it impossible to make a quantitative analysis of the salts in solution, but the qualitative analysis showed the presence of hydrochloric, sulphuric, and sulphydric acids, together with silica, the metals iron, aluminium, calcium, magnesium, and sodium, and ferrous sulphide, as already mentioned.

As far as can be ascertained from the above necessarily imperfect examination, there is nothing unusual in the character of the water; the spectroscope did not show the presence of any of the rarer alkaline metals, such as lithium. A much larger quantity of the water would be required to make a satisfactory examination for them, but there was quite sufficient of the water to show that they are not present in any quantity.

The following notes are appended, as it may be of interest to some of the members to have the accounts of other Pacific hot spring waters for comparison.*

Samples of Water from the Island of Simbo and Santa Anna. Collected by Dr. H. B. GURFFY, Surgeon, H.M.S. *Lark*.

Bottle 49.—Containing water from the fresh-water lake of Wailava, in the Island of Santa Anna, collected in April, 1882. I have seen no reference to this lake in any of the works which bear on these islands. The Island of Santa Anna has the character of a raised atoll, with the large central depression occupied at its lowest part by the waters of the lakes of Wailava and Waipiapia. Wailava is about half-a-mile across in length, and has a depth of 15 fathoms, as ascertained by Lieut. Oldham. On carefully examining this lake, I found that its waters are at about the sea level, though they are not affected by the rise and fall of the tides. On one side it is only separated from the sea by a low, swampy tract about one-third of a mile across, and not elevated more than 20 feet above the

sea. The surface of this tract is strewn with coral fragments, and the more swampy portion abounds with *Auricula*. It is evident that this lake has been only cut off from the sea by recent elevation. On making a rough examination, I found the density about that of fresh water, with *chlorines* abundant, *lime* two or three grains per gallon, *ammonia* unmistakable, *taste* flat and fresh. The water rapidly decolourises a solution of permanganate of potash.

Bottles 142 and 143.—Containing water from the boiling spring in the island of Simbo, collected in May, 1882. The island of Simbo is formed of trachytic rocks, and contains in the southern part an extinct crater, a solfatara, and numerous fumaroles, which pierce the rocks, occurring from the sea up to the highest summit, about 1100 feet above the sea. This water was collected from the boiling spring on the shores of a lagoon (very probably an old crater) on the south-west side of the island. The spring is placed amongst decomposed trachytic rocks, a foot or two above the sea level. Its temperature is 212°, and large quantities of H₂S are exhaled. Iron oxide stains the rocks around, which are encrusted with sulphur and chloride of sodium in some places. Numerous fumaroles pierce the slopes overlooking the springs: sulphur, alum, milk-white opal, &c., from deposits around their orifices. As this spring is close to the edge of the lagoon of salt water, with the tidal movements of which its waters rise and fall, I am of opinion, from a cursory examination of the water, that its composition may be regarded as sea water, plus the substances discharged by a fumarole.

Bottle 150.—Water condensed from one of the fumaroles in the solfatara on the south-west point of Simbo, in May, 1882. A little sulphur, which unavoidably fell in, forms a sediment at the bottom of the bottle. For two hours the thermometer retained in the orifice of the fumarole varied only between 208° and 210° F. Watery vapour, sulphuretted hydrogen, and sulphurous acid were evolved, flaky crystals of sulphur encrusting the sides of the aperture. A strip of paper, soaked in a solution of acetate of lead, was immediately blackened, and the black metallic silver sulphide was formed in the interior of a piece of glass-tubing, moistened with silver nitrate, whilst the presence of sulphurous acid appeared to be indicated by the suffocating smell of burning sulphur, by the presence of sulphur deposits, and by the reddening of litmus paper. No turbidity was produced in lime-water, nor was the presence of hydrochloric acid gas shown on exposing a solution of silver nitrate.

The interior of the solfatara was whitened by the decomposing influence of the vapours evolved. The elevation of the fumarole in question was rather under 300 feet above the sea.

Bottle 151.—Water condensed May, 1882, from one of the fumaroles on the summit of the South Hill, in the island of Simbo, elevated about 1100 feet above the sea. The temperature of the fumarole varied during two hours between 175° and 180° F. Employing the same rough field tests, I ascertained that watery vapour was the principal substance discharged. No effect was produced on acetate of lead, silver nitrate, or lime-water, and litmus paper was very slightly reddened after a prolonged exposure. No deposits were formed around the orifices of the fumaroles on this hill summit. The trachytic rock was much decomposed, and a little of the decomposed rock unavoidably fell in, and forms a sediment at the bottom of the bottle.

For an additional example of water from hot springs at Suva, Fiji, see "At Home in Fiji," by F. M. Gordon Cumming.

Exsiccators.—R. Frubling (*Zeitschrift Angewandte Chemie*) proposes an instrument which differs from the ordinary form merely by its greater diameter. C. Liebermann (*Berichte*) uses exsiccators of yellow glass for bodies which are affected by light.

AUSTRALIAN METEORITES.*

By A. LIVERSIDGE, M.A., F.R.S., Professor of Chemistry,
University of Sydney.
(ABSTRACT).

THE *Thunda meteorite*, found near Windorali in the Diamantina district, Queensland.—The mass received by me originally weighed 137 lbs., and the specific gravity is 7.78. In composition it consists essentially of nickeliferous iron, containing a trace of cobalt, together with a little sulphur, phosphorus, and carbon. The crystalline structure is extremely well marked, which is not only shown by the fractured surface, but by the cut and polished sections when etched by acids, bromine, or copper sulphate. This meteorite is also remarkable for the many nodules of sulphide of iron which it contains, from which fissures proceed in such a way as to show that the iron sulphide must have crystallised last; in fact, it looks as if it had been the cause of the fissures.

Barratta Meteorites, Nos. 2 and 3.—The first meteorite found at Barratta, near Deniliquin, in New South Wales, has already been described in the *Journal of the Royal Society of New South Wales* for 1872 and 1880.

These later ones, also in the possession of Mr. Russell, F.R.S., Government Astronomer, Sydney, were found near the site of the first; the second one has a weight of 31 lbs., and a specific gravity of 3.706; the third weighs 48 lbs., and has a specific gravity of 3.429; the first having a specific gravity of 3.429. In structure and appearance all three are very much alike, and they consist essentially of silicates of magnesia (as enstatite), iron, with small quantities of other substances, intermingled with a network of nickeliferous iron.

Gilgoi meteorite, in the possession of Mr. Russell, F.R.S., Government Astronomer, Sydney, found on the station of that name, near Brewarrina, N.S.W.—This weighs 67½ lbs., and has a specific gravity of 3.857. It is very much more cracked and fissured, and contains rather a larger proportion of nickeliferous iron than the preceding one, but in other respects closely resembles them.

Eli Elwah—This meteorite is also an earthy one, containing nickeliferous iron, with a chondritic or granular structure; it weighs 33½ lbs., and has a specific gravity of 3.537.

Photographs and micro-photographs of sections of the four earthy meteorites were shown, as well as specimens of each.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING OCTOBER 31ST, 1890.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;
and C. MEYMOTT TIDY, M.B., F.C.S., Barrister-at-Law,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, Metropolis Water Act, 1871.

London, November 6th, 1890.

SIR.—We submit herewith the results of our analyses of the 189 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from October 1st to October 31st inclusive. The purity of the water, in respect to

organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 189 samples examined, the whole were found to be clear, bright, and well filtered.

Throughout the month of October the character of the water supply to the metropolis continued to be entirely satisfactory, in respect alike to freedom from turbidity, from colour-tint, and from any excess of organic matter. The mean proportion of organic carbon present in the Thames-derived water was only 0.136 part in 100,000 parts, with a maximum of 0.160 part in any single sample examined. The mean ratio of brown to blue tint of the same water was as 10.4 : 20.0; while the mean amount of oxygen taken up in the oxidation of the organic matter present in a gallon of the water was just under 0.4 grain.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES.
WILLIAM ODLING.
C. MEYMOTT TIDY.

THE ATOMIC WEIGHT OF MAGNESIUM AS DETERMINED BY THE COMPOSITION OF ITS OXIDE.

By W. M. BURTON and L. D. VORCE.

THE method employed by Dr. H. N. Morse* and one of us (B.) for the preparation of pure zinc and the determination of its atomic weight yielded such satisfactory results that it seemed desirable to employ the same process for the purification of other metals and for the re-determination of their atomic weights. Among others, magnesium was suggested as being suitable for the purpose, because, like zinc, it can be distilled at a comparatively low temperature, and its nitrate upon ignition yields an oxide of definite composition and stable when heated to a very high temperature.

Therefore, in accordance with an understanding with Dr. Morse, we have undertaken the re-determination of its atomic weight. Several investigators have determined the atomic weight of magnesium, but in almost every instance either some impurity was found to exist in the materials used, or else some defect was discovered in the method employed, thereby creating doubt as to the accuracy of the results obtained. The following methods have been used:—

1. Composition of sulphate by action of sulphuric acid on the oxide (Berzelius,† Bahr,‡ Svanberg and Nordenfeldt,§ and Marignac||).

2. Determination of sulphuric acid in the sulphate by precipitation as barium sulphate (Scheerer,¶ Jacquelin,‡‡ and Gay-Lussac††).

3. Conversion of oxalate into oxide by ignition (Svanberg and Nordenfeldt‡‡).

4. Conversion of sulphate into oxide by ignition (Gay-Lussac§§).

5. Determination of chlorine in magnesium chloride (Dumas*).

6. Conversion of carbonate into oxide by ignition (Marchand and Scheerer†).

The results of these investigations are shown in the following table:—

Date.	Investigators.	At. wt. Mg. (O=16).	At. wt. Mg. (O=15.95).
1819	Gay-Lussac	22.89	22.812
1820	"	24.18	24.102
1826	Berzelius	25.20	25.122
1846	Scheerer	24.11	24.032
1847	{ Svanberg Nordenfeldt	24.63	24.562
1850	Jacquelin	24.11	24.032
1850	{ Marchand Scheerer	23.96	23.882
1852	Bahr	24.74	24.662
1859	Dumas	24.48	24.502
1884	Marignac	24.38	24.302

The method which we propose is essentially the same as that which was used in the determination of the atomic weight of zinc, and previously described in the *American Chemical Journal*.‡ Slight changes have been made in some details of the manipulation, and these will be noted in their appropriate places. The magnesium was purified by distillation in a vacuum. Weighed portions of the metal were converted into the nitrate, which was ignited to the oxide, first in a hot-air bath, and finally at the highest temperature obtainable in a muffle furnace. The simplicity and directness of the method are strong points in its favour, and we believe we have eliminated the two general difficulties by which the accurate determination of the atomic weight of magnesium has been beset, viz., first, presence of impurities in the materials used; second, the error involved in determining these impurities and correcting for them.

I. The Preparation of Pure Magnesium.

When an attempt was made to distil the magnesium in ordinary hard glass tubes, it was found that the vapours of the metal attacked the glass, forming a black voluminous substance which evolved a spontaneously inflammable gas when treated with an acid. The action of magnesium powder on silica and other oxides has been studied by Gattermann,§ and his results lead us to conclude that the black substance which we obtained was magnesium silicide of the formula Mg_2Si , and the explo-

sive gas was undoubtedly silicon tetrahydride. Further, when the silicide was dissolved in acid, there remained a yellow substance which probably was the suboxide of silicon described by Mabery.|| Repeated fractional distillation did not entirely separate this silicide of magnesium from the pure metal. In consideration of the fact that magnesium forms no alloys with iron, the idea suggested itself of using an iron tube inside the glass tube. Fig. 1 represents the method of arrangement. A is a tube of hardest potassa glass, fused together at one end. B is a tube made of thin sheet iron of the best quality obtainable. The iron tube was pushed into the glass tube as represented and then filled with small pieces of magnesium ribbon. The end of the iron tube at C is bent over in such a way as to prevent the carrying over of small pieces of magnesium during the distillation. About 10 grms. of the metal were used in each charge.

The glass tube was connected at f with a Sprengel air-pump and the apparatus thoroughly exhausted. The tube was heated in a combustion furnace throughout its whole length, but most strongly at B. When the iron tube showed a bright red heat the magnesium commenced to volatilise and sublime on the cooler portions of the tube at A, forming at first a black mirror of magnesium silicide.

Our first plan was to use an iron tube extending from C to D, so that the glass would be entirely protected from the vapours of magnesium, but numerous experiments showed that the first coating at A entirely protected the glass, so that subsequent portions of the metal were deposited without being contaminated with the silicide. Experiment also showed that the iron tube served to support the walls of the glass tube, as the latter would otherwise collapse when heated to the fusing point of magnesium. The tube at B was maintained at a bright red heat for about an hour, the gas was then turned down and the apparatus cooled very slowly. By taking proper precautions the cracking of the tube was prevented during the cooling process, thereby maintaining a vacuum in the apparatus until the end of the distillation. The portion of the metal remaining in B and that which had collected at D were rejected. The portion collected at A was three times redistilled; the magnesium which collected at A during the fourth distillation was employed for the atomic weight determination. It was deposited as a thin crystalline bar of pure white metal, which readily separated from the coating of magnesium silicide on the glass. In a few instances beautiful crystals of the metal were formed; these will be considered later in this paper. The magnesium deposited in the fourth distillation was carefully analysed, special pains being used in the tests for silicon, carbon, calcium, and iron, but we were unable to detect any impurity whatever. It was also spectroscopically examined, but the spectrum showed no lines of impurities, the characteristic green lines of magnesium being the only ones visible. We analysed the magnesium ribbon used in the distillation, and found small quantities of silicon, iron, and carbon.

II. Preparation of Pure Dilute Nitric Acid.

Pure strong nitric acid was prepared by the method already described in the *American Chemical Journal*.¶ In order that the magnesium might dissolve slowly, the nitric acid was diluted with an equal volume of water. The water was purified by distilling it first from acid permanganate of potassium, then from alkaline permanganate, and finally in the platinum apparatus which was used in preparing the nitric acid. The dilute acid was preserved in a platinum dish under a bell-jar, and a platinum spoon was used for transferring it as it was needed.

III. The Method of Procedure.

The conversion of the magnesium into its oxide was effected in porcelain crucible, the arrangement of the crucibles being the same as that described in the article on the atomic weight of zinc. A piece of magnesium weighing about 300 mgrms. was carefully broken off, and any clinging portions of dust removed by filing. A powerful lens was used in examining the metal, and it was not handled except by means of clean forceps. Having balanced a pair of crucibles with their appropriate tares, the difference in weight was noted. The piece of magnesium was then weighed into one of them, and treated with dilute nitric acid. When the metal had disappeared, the excess of acid and water was evaporated, and the nitrate of magnesium partially decomposed by heating in a sand-bath. Finally the crucibles were placed in a muffle furnace, and kept at a white heat for about two hours. After weighing, the oxide was again heated in the muffle, and as a rule one ignition was sufficient to insure constant weight. In some of the determinations,

* *Ann. ch. phys.* (3), 17, 1:9.

† *Four. f. pr. Chem.*, 1, 385.

‡ *Loc. cit.*

§ *Ber. d. Chem. Ges.*, xxii., 186.

|| *Amer. Chem. Jour.*, ix., 14.

however, two ignitions were necessary. The tares were treated with dilute nitric acid, and heated in every instance like the crucibles in which the determinations were made. The magnesium oxide was tested for oxides of nitrogen by the method described by Griess.* The magnesium oxide was dissolved in dilute sulphuric acid, and 2 c.c. each of sulphuric acid and naphthylamine hydrochlorate were added. Not a trace of the pink colour appeared. In another sample of the oxide which was not ignited to constant weight, the iodide of starch reaction for testing for nitrous acid failed to give a blue colour, while the sulphuric acid test showed a distinct pink colour.

IV. The Weighing.

The balance used was made by Becker Bros.; its capacity was 200 grms., and it was sensitive to $\frac{1}{10}$ milligramme with its full load. The balance case was enclosed in a tight-fitting wooden box furnished with appropriate doors, through which the weights and crucibles could be transferred. All observations were made with these doors closed. A gas lamp and mirror were so arranged that the ivory scale of the balance could be illuminated through a small aperture in the box; the excursions of the pointer were noted through a similar aperture situated just above the first. The methods of weighing by vibrations and of double weighing—that is, upon both pans—were employed throughout. The sensibility of the balance with the load furnished by the crucibles was determined at least once during each series of observations. Each weighing was made as rapidly as possible, allowing due time for noting observations accurately, as it is believed that an undue amount of time spent in weighing only increases the error due to changes in temperature and atmospheric conditions. Only the smaller platinum weights were used, since the magnesium oxide obtained in one experiment never weighed more than 700 m.grms. All weighings were made at night after the laboratory and streets in the vicinity had become quiet.

V. The Results.

The following table shows the result of ten successive experiments:—

Wt. of Mg.	Wt. of MgO.	At. wt. Mg. (O=16).	At. wt. Mg. (O=15.95).†
1. 0.33009	0.54766	24.278	24.202
2. 0.34512	0.57252	24.283	24.207
3. 0.26058	0.43221	24.292	24.216
4. 0.28600	0.47432	24.299	24.223
5. 0.30917	0.51273	24.301	24.225
6. 0.27636	0.45853	24.271	24.195
7. 0.36457	0.60475	24.286	24.210
8. 0.32411	0.53746	24.304	24.228
9. 0.32108	0.53263	24.284	24.208
10. 0.28323	0.46988	24.279	24.203
Mean		24.287	24.211
Highest		24.304	24.228
Lowest		24.271	24.195
Difference		0.033	0.033

If we calculate the atomic weight from the sums of the quantities of magnesium taken, and oxide obtained as recommended by Meyer and Seubert,‡ we have—

Wt. of Mg.	Wt. of MgO.	At. wt. Mg. (O=16).	At. wt. Mg. (O=15.95).
3.10031	5.14269	24.287	24.211

VI. Crystals of Magnesium.

Of the crystal form of magnesium very little is definitely known. The element is usually regarded as holohedral, hexagonal, and isomorphous with zinc and beryllium. The production of very perfect crystals during the dis-

tilation of our magnesium seemed of sufficient interest to warrant their study and description. Dr. G. H. Williams, of the Johns Hopkins University, undertook this work and kindly sent us his results for publication. The first account of magnesium crystals was given by Dumas* in 1880, who obtained them while experimenting with the gases absorbed by magnesium during distillation. Des Cloizeaux† measured these crystals and described them as hexagonal prisms with the unit pyramid and terminated by the basal plane. He obtained the axial ratio $a : c = 1 : 1.6391$.

The crystals which we obtained were about 1 m.m. in diameter, having very perfect planes, which furnished in most instances sharp and distinct reflections on the goniometer. No planes appeared except OP, P, and ∞ P. The following table shows the angles measured on four different crystals with a large Fuess goniometer. In each crystal one or more zones of 180° were observed; when more than one zone was measured the mean result is stated and the number of zones upon which this average is based is given in parenthesis.

Cryst.	OP : P.	P : ∞ P.	∞ P : P'.	P' : OP'.
I.	$61^\circ 47'$ (2)	$28^\circ 12'$ (2)	$28^\circ 17'$	$61^\circ 50'$
II.	$61^\circ 44'$	$28^\circ 15'$	$28^\circ 00'$	—
III.	$61^\circ 55'$	$28^\circ 5'$	$28^\circ 3'$	$61^\circ 57'$
IV.	$61^\circ 57'$ (3)	$28^\circ 5'$ (3)	$28^\circ 7'$ (3)	$61^\circ 52'$ (3)

The average of the twelve measurements of the angle OP : P is $61^\circ 52' 30''$; whose supplement is $118^\circ 7' 30''$. If we use this value for the axial ratio we have $a : c = 1 : 1.6202$, which is almost identical with the value obtained by Des Cloizeaux. It appears from these figures that magnesium is more closely related to beryllium, in its crystal form, than to zinc, as will be seen in the following statement:—

Beryllium $a : c = 1 : 1.5802$ Brögger.

Zinc $a : c = 1 : 1.35642$ Williams and Burton
(*Amer. Chem. Jour.*, xi, 219).

Magnesium $a : c = 1 : 1.6202$ Wilson.

Experiments were made to test the cohesive properties and slipping planes of the magnesium, but no results were obtained like those described in the investigation of zinc crystals.

It is with pleasure that we acknowledge our indebtedness to Professor Morley and Professor Mabery, who placed their laboratories at our disposal during this investigation. With such adequate facilities we were enabled to work much more rapidly and satisfactorily than we otherwise could have done.

THE DRY ASSAY OF TIN ORES.‡

PART II.

By HEINRICH O. HOFFMANN,
Assistant Professor of Mining and Metallurgy.

(Continued from p. 170).

Class A (b).

This class embraces the bronze assays of Winkler, and the different iron assays.

4. Winkler's method§ is as follows:—5 grms. of ore are mixed with 5 grms. of cupric oxide, and charged in a clay crucible; on top are placed 15 grms. of black flux with 1.25 grms. of borax glass, then a salt cover, and finally a large piece of charcoal. The crucible is heated in a muffle or a pot-furnace, after boiling has ceased, for

* *Comptes rendus*, xc., 1027.

† Value found by Keiser, *American Chemical Journal*, x., 249.

‡ "Die Atomgewichte der Elemente," p. 13.

three-quarters of an hour to an hour at a bright red heat, finishing the assay at almost a white heat. The result is a white brittle tin-copper alloy. With every tin assay, an assay of 5 grms. of cupric oxide with the same charge is made, and the weight of the resulting button of copper, subtracted from the bronze button, gives the weight of the tin contained in the ore.

This assay is really a modification of the German method. Its advantage is that no prills of tin (or, rather, particles of bronze) are found suspended in the slag. All the metallic oxides that have been reduced are found collected in one button. It is claimed that more tin is recovered by this method than by the regular German method, and that the buttons do not differ more than from 0.4 to 0.5 per cent. If this could be substantiated, the method would be a serious rival to the cyanide assay.

In the experiments carried out, the directions given (*ante*) were closely followed, only the black flux substitute (2 potassium carbonate and 1 flour) was used, as in the regular German method, instead of the black flux proper.

The charges were readily fusible, liquid, and showed a smooth surface when cool. The crucibles were not attacked, and no particles of bronze were discernible in the slags. As in the German assay, the upper salt slag and the lower borax slag have to be distinguished. The salt slag separates readily from the lower slag, has a crystalline structure, is brittle, has a pearly lustre, and is opaque. In the centre of every salt slag is a small cavity, into which white fern-like crystals protrude. The white base of the crystals is encircled by a green-tinged shell, and this by the bulk of the slag, which is of a lighter purple colour than that of the German assay. The reason is probably that less carbon is present in the charge, no charcoal having been added. The vitreous borax slag is hard, opaque, and greenish black. The oval bronze button is smooth, crystalline, brittle, white, and the more rounded copper button has thread-like lines of crystals on the surface, and is of a beautiful rose colour. Both separate well from their slags.

TABLE XVIII.

No. of assay.	Resulting bronze. Grms.	Resulting copper. Grms.	Resulting tin.	
			Grms.	Per cent.
95.	7.200	3.825	3.375	67.50
96.	7.170	3.805	3.305	67.30
97.	7.110	3.785	3.325	66.50
98.	7.105	3.785	3.320	66.40
99.	7.040	3.820	3.220	54.40
100.	7.020	3.770	3.250	65.00
101.	7.000	3.770	3.230	64.60
Average ..	7.092	3.794	3.298	65.96
102.	7.185	3.920	3.265	65.30
103.	7.140	3.920	3.220	64.40
Average ..	7.162	3.920	2.2425	64.85

Table XVIII. shows that too much has been claimed for this method, both as to output of tin and accuracy of results. The total average, Nos. 95 to 101 (65.96 per cent tin), is 1.88 per cent too low, and while in some cases excellent results are obtained (Nos. 95 and 96), in others, under the same conditions, an assay can be 3.24 per cent too low. It was thought that perhaps, by increasing the amount of reducing agent, better results could be obtained. Thus, 1 gm. of charcoal was mixed with the 5 grms. of ore and 5 grms. of cupric oxide, and then the usual charge given. The results (Nos. 102 and 103) show only an increase of weight in the copper recovered. Chalk lined crucibles were tried, as in the German method, but, while no essential particular could be observed in which the assay differed from that in the naked crucible, the results given in Table XIX. show that the discrepancy in the resulting weights of tin is enormous, while the output of copper is higher, and very even.

TABLE XIX.

No. of assay.	Resulting bronze. Grms.	Resulting copper. Grms.	Resulting tin.	
			Grms.	Per cent.
104.	6.850	3.815	3.035	60.70
105.	6.660	3.815	2.845	56.90
106.	6.760	3.810	2.950	59.00
107.	6.250	3.810	2.440	48.80

As a modification, therefore, the chalk lined crucible must here also be left out of consideration.

The reason that the results with the Winkler method vary so much is that the presence of copper adds a new difficulty to the assay. This can be seen from the tabulated results obtained in reducing cupric oxide for the tin assays carried out above.

In all the assays, precipitated chemically pure cupric oxide was used. If reduced completely, 5 grms. of cupric oxide ought to give 3.993 grms. of copper. In the naked crucible we obtain as an average 3.801 grms. and a discrepancy of 0.055 gm. between the highest and lowest results, which, if expressed in percentage, gives 1.1 per cent difference. In the chalk-lined crucible there is a better output in copper; if extra reducing agents be added, a still better result is obtained, even in the naked crucible, but not a correspondingly better reduction of stannic oxide. It would seem, therefore, that the amount of tin reduced will vary according to the amount of copper carried off in the slag.

TABLE XX.

Grms. of copper resulting in naked crucible with regular charge.	Grms. of copper resulting in naked crucible with regular charge and 1 gm. charcoal.	Grms. of copper resulting in chalk- lined crucible with regular charge.
3.825	3.920	3.815
3.820	—	3.810
3.805	—	—
3.785	—	—
3.770	—	—
Aver. 3.801	3.920	3.8125

In the assays with potassium cyanide it was seen that the presence of sulphates had a very bad effect on the result. As copper has a very great affinity for sulphur, the results of this bronze assay may also have been influenced by it. Several assays were made, omitting the salt and increasing the amount of potassium carbonate. The weight of the copper buttons was slightly higher, e.g., 3.850 grms.; but the reduction of the tin was very imperfect, as it did not all alloy with the copper and collected in one button of bronze; prills of bright malleable tin were found in the slag, showing that, to obtain a slag of sufficient fluidity for all reduced metal to collect in one button, the addition of salt is necessary. By reference to the German assay it will be seen that the presence of salt containing sulphates does not produce the same bad effect on tin as in the cyanide assay.

The Winkler method is given in a modified way by Ricketts:—"ore, 10 grms.; cupric oxide, 10 grms.; black flux substitute, 30 grms.; argol, 2 grms.; borax glass, 5 grms.—are well mixed, charged in a chalk-lined crucible, a salt cover and charcoal are added, and the charge heated gradually to a white heat for an hour. He advises separating tin and copper in the wet way. In this modified method, it will be seen that an additional reducing agent, argol, has been added, and that flux and ore are intimately mixed. Winkler makes a point of not mixing ore and flux, as he wishes to avoid the strong boiling of the charge, whereby particles of alloy might adhere to the sides of the crucible and escape being collected in the button.

* "Notes on Assaying," 1886, p. 89; quoting from Mitchell, "Manual of Assaying," p. 411 (probably fourth edition, as it has been omitted in the fifth edition of 1891).

Three bronze assays were carried out, and one copper assay, giving the following results:—

TABLE XXI.

No. of assay.	Resulting bronze. Grms.	Resulting copper. Grms.	Resulting tin.	
			Grms.	Per cent.
108.	13.685	7.360	6.325	63.25
109.	13.660	7.360	6.300	63.00
110.	13.630	7.360	6.270	62.70
Average ..	13.658	7.360	6.293	62.98

They show no advantage over Winkler's original method. Less tin is recovered, and more copper is scorified, and a treatment of the alloy in the wet way would be apparently a loss of time.

(To be continued).

CORRESPONDENCE.

THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—We shall be obliged if you will allow us to make the following statements in reference to the innuendoes contained in a letter in your last issue.

Our circular is, in both type and paper, totally unlike any document sent out by the Chemical Society to the Fellows, and the statement to the contrary is utterly without foundation, even though it comes from a former member of the council.

Of the hundreds of Fellows who have signed our circular thirty-eight returned them to the Chemical Society. These copies have been handed to us, and we have no reason to believe that any have been withheld.

We regret that anyone, more especially a former member of the council, should have such a poor opinion of the intellectual and moral status of the Fellows of the Society as to assume they would give their written assent to views, when promulgated by the council, which they could not assent to when promulgated by others.

Were it not that we must treat this assumption on the same basis as the rest of the letter, we think it would have been the strongest possible argument in defence of our present policy, which is to keep out of the Society those who are intellectually, or morally, unworthy of the Fellowship.—We are, &c.,

FREDERICK J. LLOYD.
FRANK L. TEED.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 18, November 3, 1890.

Action of Borax in Alkaline Developing Baths.—P. Mercier.—Sodium borate is generally considered as retarding the development, yet, as it presents an alkaline reaction, it ought to act solely as an accelerator. The explanation of this apparent anomaly may be found in a research by M. Aug. Lambert, published in the *Comptes Rendus*, and on the action of borax upon the polyatomic alcohols and phenols, and especially upon pyrogallol, hydroquinone, and pyrocatechin. It appears that boric acid combines with the primary polyatomic alcohols and

certain polyatomic phenols to give rise to certain boron-conjugated acids. Thus, borax added in small quantities to pyrogallol converts it into a true acid which reddens litmus. It is the same with tannin and pyrocatechin, so that with these substances the addition of an alkaline borate is equivalent to the addition of an acid, the salt in this case causing retardation. But this reaction is not produced with the isomers of pyrocatechin, i.e., hydroquinone and resorcin. Neither is it produced with the ether developing agents now in use. Here borax does not give rise to any acid, and acts merely by its alkalinity.

On the Affinities of Iodine in the Dissolved State.—Henri Gautier and G. Charpy.—Solutions of iodine in different liquids present a continuous series of colours from violet to brown, and to these different colours there seem to correspond different molecular condensations. The question arose if these different conditions did not introduce a modification in the chemical action of iodine. After various trials, the authors have succeeded in finding a reaction which shows a decided difference between the solutions. On agitating pure mercury with any solution of iodine, there is always formed a green precipitate of mercurous iodide; but if the mercury contains small quantities of another metal, the iodine combines with this latter in variable proportions, according to the nature of the solvent. The phenomenon is particularly distinct with lead amalgam, the yellow colour of lead iodide enabling us to follow the course of the reaction. A brown solution of iodine (in alcohol, ether, or acetone), if agitated with lead amalgam gives a yellow precipitate of lead iodide as long as traces of this metal exist in the mercury. When the precipitate takes a green tint, the mercury which remains is completely pure. On the contrary, a violet solution (in carbon disulphide, chloroform) gives, under the same conditions, a green precipitate analogous to that yielded by pure mercury. On operating with a great number of solvents, we may obtain a series of colours ranging continuously from yellow to green. The order in which we arrange the solvents is the same as that obtained by classing them according to the colour of the solutions of iodine. It appears thus that the violet solutions of iodine, which contain this body in a more simple molecular state, tend to form mercurous iodide at first.

On the γ -Cyanacetoacetic Ethers, and the Corresponding Chloroimide Ethers.—A. Haller and A. Held.—This memoir does not admit of useful abstraction.

Researches on the Conditions of the Progression of the Isopropylamines. Limit to the Progression and Development of Propylene.—H. and A. Malbot.—It is found that isopropyl chloride deviates from isopropyl iodide and approximates the orthopropyl, isobutyl, and isoamyl chlorides, which furnish free amines. There is this essential difference, that we easily obtain triorthopropylamine, tri-isobutylamine, tri-isoamylamine, but we cannot go beyond di-isopropylamine.

The Moulds of Copper and Bronze.—Raphael Dubois.—Many phenomena formerly attributed to chemical, physical, and mechanical agencies are now, thanks to the more profound study of the lower organisms, referred to the domain of biology. Numerous observations have proved that the lower beings may be developed in media formerly considered absolutely unfit for any vital manifestation. The author has recently observed in concentrated solutions of copper sulphate, neutralised with ammonia, and serving for the immersion of the gelatinous plates used in photographic engraving, whitish flocks of mycelium, presenting great analogies with those of *Penicillium* and *Aspergillus*. These mycelia are rapidly developed and fructify in Raulin's liquid, whilst in cupric solutions they remain in the mycelial state. If we pour upon a bronze coin, previously cleaned with nitric acid and well washed, a neutral solution of copper sulphate containing such mycelia, and place the coin under a moist

bell, the solution quickly changes colour at the points where the *mycelia* are collected. When the cupric liquid has completely evaporated, the surface of the coin is scattered over with spots of a characteristic malachite green resembling the patina of the most beautiful antique bronze. To be certain that the transformation of the copper sulphate into malachite is due to the vital action of the mould, the author sterilised the bronze coins in an autoclave, as well as a part of the liquid containing the *mycelia*. The copper sulphate then underwent no alteration, and the green tint of antique bronze was not produced at all. These facts show with what energy living beings can act upon inorganic matter, and how important it is to take account of their activity, especially among the causes of alteration of metals and in the formation of certain mineral bodies.

Moniteur Scientifique, Quasneville.

Series 4, Vol. iv., Part 1.

Action of Mineral Acids in Saccharification by Means of Malt, and in the Fermentation of Starchy Matters.—Dr. J. Effront.—This bulky treatise is quite incapable of useful abstraction.

Researches on the Condensation of the Carburetted Gases under the Influence of the Electric Effluve.—P. Schützenberger.—In this memoir, which is not completed, the author examines the condensation of carbon monoxide and the composition of the supposed carbon suboxide, C_4O_3 .

The Specific Gravity of Resin Oils and of Oils of Turpentine.—Adolphe Renard.—These oils are generally sold with a statement of their spec. gravity at +15. The author determines the correction to be made for higher or lower temperatures.

Detection of Olive Kernels in Pepper.—M. Pabst.—The author recommends for the detection of this fraud a test paper which has been saturated with dimethylparaphenylenediamine, as proposed by Wurster for detecting mechanical wood paste in paper, or thalline which is used in vegetable histology for colouring woody tissues. The paper is laid on a watch-glass, moistened with water, and dusted over with the suspected pepper; particles of the olive kernels are instantly coloured red, whilst pepper retains its ordinary colour. For preparing this reagent, the author mixes 10 grms. of commercial dimethylaniline with 20 grms. pure concentrated hydrochloric acid. He then adds 100 grms. of powdered ice, and then by degrees, whilst stirring, a solution of 7 grms. sodium nitrite in 100 c.c. of water. The reaction is let go on for half an hour. He adds, then, 30 to 40 grms. of hydrochloric acid and 20 grms. of tin-foil and allows the reduction to continue for an hour, and then precipitates the tin by means of granulated zinc. The liquid is decanted through a filter, then neutralised with potassium or sodium carbonate until a permanent turbidity is produced, which is re-dissolved by means of a few drops of acetic acid. Ten grms. of concentrated sodium bisulphite are added, and the whole is made up to 12 litres with water. The same reagent shows the presence of ground wood, nut-shells, &c. Thalline sulphate dissolved in 200 parts of water colours the olive kernels a very fine orange, which is produced more slowly than the red of the former test; and, further, this solution does not keep well.

Action of Carbon Disulphide upon certain Azocompounds and upon the Hydrazones.—P. Jacobson and V. Schene.—From the *Berichte Deutsch. Chem. Gesell.*

Green Ultramarine.—Dr. J. Szilasi (*Hungarian Academy of Sciences*).—The author considers it proved that green ultramarine is a definite chemical compound having a constant composition. This does not imply that all the green ultramarines answer to the same formula. It is known that there are several blue ultramarines having different compositions; some, e.g., poorer and

others richer in silica. Green ultramarine may also present different compositions, which are constant for each kind.

Researches on Narcotine.—W. Roser.—From *Liebigs Annalen*.

New Process for Preparing Phenacetine.—J. Riedel (*Archiv der Pharmacie*).—The author's process permits of the complete conversion of phenol into phenacetine. Paramidophenetol, under the influence of sodium nitrite and hydrochloric acid, is first transformed into ethoxyparadiazobenzol chloride. The solution of the latter, treated with phenol and an aqueous solution of sodium carbonate, yields a yellow amorphous precipitate of monoethylated diparadioxyazobenzene. This is purified by solution in a weak solution of sodium carbonate, from which it is precipitated with dilute hydrochloric acid. After purification it is dissolved in alcohol, caustic soda is added, and then ethyl bromide, and the whole is heated at 150° under pressure. The group OH of the second phenolic residue is transformed into the group OC_2H_5 . After having distilled off the alcohol and removed the sodium bromide formed with cold water, it is washed with dilute soda. The insoluble residue, consisting of diparadiethoxyazobenzol, is reduced by nascent hydrogen, which splits it up into two mols. of paramidophenetol, which when boiled with glacial acetic acid yields phenacetine.

Reaction of Sulphonal.—H. Wefers-Bettenk (*Chem. Repertorium*).—If 1 gm. of sulphonal is mixed with 4 gm. iron-filings, and the mixture is heated strongly in a test-tube, we perceive a smell of garlic. When cold, the contents of the tube are moistened with dilute hydrochloric acid, sulphuretted hydrogen is given off and may be recognised by means of a slip of lead-paper.

New Compounds obtained with the Alkaloids of the Cinchonas.—O. Hesse.—Prof. Hesse adds to a hot solution of the acid quinine sulphate an equivalent quantity of phenol. On cooling, there separates out an oily mass, above which there are formed fine white needles, $C_{20}H_{24}N_2O_2 \cdot SO_3 \cdot C_6H_5O + 3H_2O$. By simple re-crystallisation, a basic salt is obtained. All the compounds obtained from the phenols and the acid sulphates of quinine, hydroquinine, cinchonidine, and hydrocinchonidine behave in the same manner.

Analysis of Metallic Tungsten, of Ferro-Tungstens, and Tungsten-Steels; Ferro-Chromes and Chrome-Steels; with New Methods for Opening up these Metals.—Alfred Ziegler (*Dingler's Journal*).—The bulk of this paper will be inserted at the first opportunity.

Industrial Analysis of Wolframite.—B. Selik (*Chemiker Zeitung*).—The substance of this paper has been already inserted.

Observations on the Determination of Phosphoric Acid in Thomas Slags, and on certain Varieties of Tetrahydrated Ferric Phosphates.—G. Arth.—Already inserted.

Zeitschrift für Analytische Chemie.
Vol. xxix., No. 2.

On a New Catalytic Phenomenon and on the Dimorphism of Baryta.—Dr. G. Brugelmann.—If BaO is prepared from the hydrate in vessels of clay or of graphite, the oxide is left in needles, probably hexagonal, of the specific gravity 5.32. If BaO is obtained from the hydrate, but in a platinum vessel, the resulting oxide is regular and has the specific gravity 5.74, apparently in consequence of the catalytic action of the metal. BaO is obtained by the ignition of the nitrate in regular cubes of specific gravity 5.72. Hence the oxide is dimorphous. The assumption that pure BaO is of a greyish-white does not agree with facts. The author has obtained it in a state of purity absolutely white.

Contributions to the Characteristics of the Alkaline Earths and of Zinc Oxide.—Dr. G. Brügelmann.—This paper will be inserted in full.

On the Detection of Small Quantities of Arsenic with the Aid of the Induction Spark-Current.—Nix von Klobulow.—This paper requires the three accompanying illustrations.

The Distinction of the Jute Fibre from Flax and Hemp.—Dr. W. Lenz.—The recognition of the jute fibre by means of its known morphological characteristics, (especially the unequal thickening of the single bast fibres) is not difficult, but it requires practice and close attention. On the contrary, the different behaviour of the above-named fibres in polarised light presents distinctions which are more readily perceptible. For executing such an examination the author heats the threads of the tissue in question according to Schulze's well-known maceration process with officinal nitric acid (?), with the addition of a trace of potassium chlorate, washes with water, heats with water containing potassa to supersaturate any acid remaining in the fibre, decants off the alkaline solution, and shakes up the residual fibres strongly with pure water. The fibres are distributed very uniformly in the water, and in this state they are placed upon a microscope slide. The liquid accompanying them is let carefully to evaporate in a horizontal position, a drop of glycerin is added, a covering-glass is put on, and the object is examined after the glycerin has thoroughly penetrated the fibre. The fibre thus prepared not merely shows the characteristic thickenings of the sides, but is suitable for examination in polarised light. If the fibres are placed under the microscope with crossed nicols (dark field), almost every fibre of flax or hemp shows an exceedingly splendid play of colour. The jute fibres, on the contrary, appear more self-coloured—bluish and yellowish—and but few fibres show colours like those of hemp, but much less splendid. It is essential that the several fibres must be really separate from each other. If they lie over or close alongside each other, bright colours will appear at the points of contact even in the case of jute.

Determinations of Starch Granules in Corn.—Z. von Milkowski.—(See p.).

Chemical Examination of Combustion Gases.—Dr. Otto Schmidt.—The author's apparatus cannot be intelligibly described without the accompanying figure.

Determination of Sulphur in Iron.—L. Blum.—The author points out two objections to the process communicated by Marcel Lucien (*Chemiker Zeitung*, xii., p. 427).

An Impurity in Commercial Barium Chloride.—L. Blum.—A sample obtained by the author reduced permanganate strongly containing apparently traces of barium peroxide or of hydrogen peroxide; impurities which falsify the results in determining manganese in presence of iron by the Volhard-Meinecke method. In examining a sample of barium chloride it will be prudent to ascertain its indifference to solution of permanganate.

Simple and Rapid Development of Pure Gases.—H. Borntrage.—The author uses a mixture of acid sodium sulphate with the acid or neutral salts containing the corresponding acid. If it is desired to obtain the gas as dry as possible without a desiccating tube, &c., the author uses a carbonic acid apparatus, fills the globe usually containing marble with solid sodium disulphate in fragments, places the corresponding salt in the lowest vessel of the apparatus, and after making the connections moistens the sodium disulphate with water. The gas liberated is dried by contact with the sodium disulphate. The process is used in chemico-legal investigation.

Cutting Thick Glass Tubing.—Dr. F. Muck.—The author calls attention to an instrument, which is here figured.

Oil of Turpentine for "Denaturing" Alcoholic Liquors.—Dr. E. Meissl.—The Neustaät oil from Vienna is recommended, as it has the specific gravity 0.861—

0.865. The Russian, French, and American oils are much too heavy.

The Separation of Barium from Strontium.—Prof. R. Fresenius.—This memoir will be inserted at the earliest opportunity.

The Removal of Melts from Platinum Crucibles.—L. L. de Koninck.—Already inserted.

The Obviation of Weighed Filters in Weighing Precipitates which have not been Ignited.—L. L. de Koninck.—The author has extended the method first proposed by Professor R. Fresenius for determining potassium as double platinum-potassium chloride. He considers the process with especial reference to the determination of ammonium, arsenic, phosphorus, and magnesium, as well as zinc and cadmium. In determining ammonium as double platinum chloride the directions of Fresenius are to be exactly followed (*Zeitschrift*, vol. xv., p. 224, and vol. xvi., p. 63), i.e., the chief portion of the precipitate is to be removed from the filter, and the latter is to be replaced in the funnel. The residue is dissolved in hot water, the solution evaporated in a weighed platinum capsule, dried, and weighed after adding the bulk of the precipitate. The determination of arsenic as magnesium pyroarsenate can be effected by separating the ammonium magnesium arseniate from the filter, and placing it in a weighed crucible. The residue adhering to the filter is dissolved in a little dilute nitric acid, washed out with a minimum of water, and this liquid evaporated down in the crucible, which is then gradually heated to redness. In this manner, magnesium pyroarsenate is obtained snow-white, as the reduction of the arsenic acid is prevented by the ammonium nitrate. In a similar manner the precipitate of ammonium-magnesium phosphate may be treated in determining phosphorus or magnesium, and is always obtained white at once. The author is of opinion that the frequent blackening of magnesium pyrophosphate is due not to particles of carbon derived from the filter, but to organic bases present in commercial ammonia and in its salts. In determining cadmium and zinc by igniting the carbonates, Koninck separates the precipitate from the filter, extracts the latter with a few drops of nitric acid, washes out with water, evaporates down the solution in the crucible, and then adds the precipitate and ignites.

Quantitative Separation of Arsenic and Antimony.—O. Koehler.—H. Rose, in his *Handbuch der Analyt. Chemie* (6th edition, ii., p. 423), mentions a separation of antimony from arsenic by converting both into sulphides by precipitation with sulphuretted hydrogen, and treating the sulphides with strong hydrochloric acid, when antimony trisulphide is dissolved whilst arsenic trisulphide remains undissolved. Rose mentions that the separation is not quantitative, as a little of the arsenic trisulphide passes into solution along with the corresponding antimony compound. O. Koehler (*Archiv. d. Pharmacie*) confirms Rose's statements, but finds that a quantitative separation may be effected as follows:—20 c.c. of solution of antimony trichloride were mixed with 45 c.c. concentrated hydrochloric acid, and 5 c.c. of a solution of arsenious acid. The mixture was then heated almost to boiling, and sulphuretted hydrogen was passed in until its smell predominated after shaking. The arsenic trisulphide, clotted together in small pellets, was then filtered through a filter moistened with hydrochloric acid and washed with dilute hydrochloric acid (1:3). The precipitate, after the removal of the antimony, was oxidised with bromine-water, filtered off from residue, well washed with ammonia, and mixed with ammonia until it was decolourised. The arsenic was finally determined as ammonium magnesium arseniate.

The Use of Calcium Saccharate in place of Potassa for Absorbing Carbonic Acid.—Boner.—(*Chemiker Zeitung*). The saccharate has the defects of frothing strongly, and obstructing the narrow parts of the absorption apparatus.

On Drying the Hydracids with Phosphoric Anhydride.—G. H. Bailly and G. J. Fowler.—From the *Journal of the Chemical Society*.

Determination of Carbon in Graphite.—J. Widmer.—According to Cross and Bevan the carbon of cellulose and other organic matter is not completely oxidised to carbon dioxide by the treatment with chromic and sulphuric acids proposed by Rogers and Brunner, but is in part converted only into carbon monoxide. The author finds that this objection is not unfounded. If an acid is used made up of 2 parts by volume of sulphuric acid, and 1 part water, by weight, there was obtained only 89.18 per cent carbon instead of 94.06. Even with the most concentrated sulphuric acid carbon monoxide is still formed.

Glass for Drying and Weighing Filters.—C. Reinhardt (*Zeitschrift Angewandte Chemie*).—This note is useless without the accompanying figure.

Arrangement for Drawing off Vapours.—Cl. Winckler (*Berichte Deutsch. Chem. Gesell.*).—Requires the three accompanying figures.

Apparatus for Fractionated Distillation under reduced Pressure.—A number of devices taken from the *Berichte*, the *Chemiker Zeitung*, the *Journal of the Chemical Society*, and the *American Chemical Journal*, and accompanied by figures.

Several Laboratory Apparatus.—P. N. Raikow (*Chemiker Zeitung*).—These comprise (1) an apparatus for filtering liquids and washing precipitates *in vacuo*, or in a specific atmosphere. E. Loew (*Chemiker Zeitung*) proposes an apparatus for the same purpose. (2) An arrangement for rapid filtration, especially for amorphous precipitates. (3) A syphon for the continuous removal of an upper stratum of liquid.

An Acid-proof Exsiccator.—E. von Boyen (*Chemiker Zeitung*).—The author uses a cylindrical vaseline bath into which is introduced from above a support for the objects to be dried along with the cover.

An Apparatus for Determining the Specific Gravity of Platinum at 100°.—L. Weinstein (*Chemiker Zeitung*).—For an account of the arrangement we must refer to the original.

Safety Arrangements to Prevent Gas-Flames from Striking Back.—G. Spitz and P. N. Raikow (*Chemiker Zeitung*).

Titration of Hot Liquids.—L. L. de Koninck (*Zeit. Angewandte Chemie*).—The author uses an exit tube of the shape , so that the burette is not over, but at one side, of the hot liquid. This obviates the heating and expansion of the standard solution and the clouding of the burette.

Apparatus for Titration.—Modified burettes have been proposed by O. Kröfner (*Chemiker Zeitung*), V. Höbbling (*Zeitschrift*), Oppermann (*Chemische Industrie*).

Burette Float.—N. Wolff (*Chemiker Zeitung*) proposes small discs of paraffin of slightly less diameter than the burette and about 2 m.m. in thickness. A layer of paraffin of the required thickness is made by melting in hot water. When the cake is nearly cold it is laid upon paste board and discs of the proper diameter are cut out with the cork-borers.

Polar Contacts in Eudiometers.—C. E. Munroe (from the *Journal of Analytical Chemistry*).

Development of Chlorine for Analytical Purposes.—L. L. de Koninck (*Zeit. Angew. Chemie*).—The author recommends the action of gaseous hydrochloric acid upon granulated pyrolusite. The latter is placed in a cylinder, through which a current of hydrochloric acid streams, and the gas given off is then passed through a layer of calcium chloride and a sulphuric acid washing-bottle.

The Use of Normal Ammonia.—R. Rempel (*Zeit. Angew. Chemie*).—The author recommends that ammoniacal solutions for volumetry should never be stronger

than semi-normal. The ammoniacal solution should be let drop from a burette into the acid contained in a suitable flask. The ammoniacal liquid should be well shaken up before use. It should be kept in well-stoppered bottles and should be introduced into the burette without the use of long flexible tubes. If these regulations are carefully followed the semi-normal ammoniacal solutions will be found equal in accuracy to potassa and soda-lyes, and at the same time easier to prepare and manage.

On Sodium Carbonate.—R. Kissling.—The author has studied the behaviour of sodium carbonate when heated. From these experiments it appears that all the "semi-combined" carbonic acid is expelled at 120–130°. At 400° the residue loses some carbonic acid, and on fusion there is a decided formation of sodium oxide. Hence it is recommended that sodium carbonate to be used for standardising acids should not be heated over a direct flame, but should be kept for some time in the drying-closet at 150°. Kissling has also examined Dobbin's process for detecting caustic soda in presence of sodium carbonate. Dobbin has shown that mercuric potassium iodide gives the well-known yellow colour only in presence of caustic alkali, whilst an alkaline carbonate has no effect. This reaction can be used for the quantitative determination of caustic soda in presence of sodium carbonate by comparing the intensity of the colour with known standards. Kissling states that a quantitative determination of caustic alkali may also be based upon the fact that a mercuric potassium iodide solution mixed with ammonium chloride gives a permanent precipitate only if there is present a quantity of caustic alkali equivalent to the ammonium chloride.

Preparing the Iron Solution for Standardising Permanganate.—R. Jahoda (*Zeit. Angew. Chemie*).—A modification of the process of R. Fresenius. The flask for dissolving the iron, after receiving iron, a granule of sodium bicarbonate, and the necessary acid, is closed with a stopper which admits a glass tube bent twice at a right angle. The other end of the tube dips into a solution of sodium bicarbonate. When the solution cools at the end of the process a little of the bicarbonate solution is sucked back, and on coming in contact with the acid it evolves carbonic acid and prevents any further re-flux.

NOTES AND QUERIES.

* Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertisement columns.

Liquorice.—Can anyone inform the writer where he can obtain any information on the adulterants and analysis of liquorice, or preparations of liquorice?—B. S. ROWNREE.

Artificial Musk.—I shall be greatly obliged to any of your readers who can inform me, through your columns, where I can obtain a sample of the artificial musk which is reported in the *CHEMICAL NEWS* (vol. lxi., p. 249) to have been discovered by A. Baur, and the patent of which has been sold to certain perfumers at Mulhouse.—M.

MEETINGS FOR THE WEEK.

MONDAY, Dec. 1st.—Society of Chemical Industry, 8. "The Electrical Treatment of Sewage," Mr. W. Webster.
— Royal Institution, 5. General Monthly Meeting.
— Society of Arts, 8 (Cantor Lectures), "Gaseous Illuminants," by Prof. Vivian B. Lewes.
— Medical, 8.30.
TUESDAY, 2nd.—Institute of Civil Engineers, 8.
— Pathological, 8.30.
WEDNESDAY, 3rd.—Society of Arts, 8. "The Chicago Exhibition, 1893," by James Dredge, Member of Council.
THURSDAY, 4th.—Chemical, 8. Ballot for the Election of Fellows.
— "On the Volumetric Estimation of Tellurium," by Dr. Brauner.
FRIDAY, 5th.—Geologists' Association, 8.

ERRATUM.—P. 259, col. 2, line 19, for "square" read "square roots."

ON THE LAW OF DIFFUSION OF LIQUIDS.

By H. M. VERNON.

THOUGH Graham (*Phil. Trans.*, 1850, 1 and 805) made a very large number of careful and exact experiments on the diffusion of aqueous solutions of various salts for various periods of time, at different temperatures and at varying concentrations, yet no general law as to the relations between the salts and the amounts of them diffused under similar conditions as to time, temperature, and concentration, was shown to exist. Graham found that several series of isomorphous salts diffused at approximately equal rates, and he endeavoured to show that the rates of diffusion of several of the different groups were to one another as the square roots of simple numbers, such as $\sqrt{2}$ to $\sqrt{3}$, for he argued that, as with gases the rate of diffusion varied inversely as the square roots of their densities, some similar kind of relation should also obtain for the diffusion of liquids. Though the experimental results correspond in a few instances with numbers obtained empirically as above, yet it was probably due to chance, as there is no apparent reason why such in reality complex relations should exist. The object of this paper is to show that in all probability there exists a general law for the diffusion of aqueous solutions of salts.

From the kinetic theory of molecular motion, it follows that solutions of the same density should have equal rates of diffusion, supposing no combination takes place between the solvent and the body dissolved in it. In a series of salts arranged regularly according to the densities of their solutions, we should therefore expect that the amounts of salts diffused varied regularly from one end of the series to the other.

Graham considers in his experiments it is a remarkable fact that the quantities of various isomorphous salts diffused should be equal, and should not be to one another in proportion to their molecular weight. There is really nothing remarkable in the fact, as it must be remembered that equal and not molecular weights of the salts were taken in the first case, and that the solutions therefore contained varying numbers of molecules, just as the amounts of salts diffused if expressed in molecular weights would be variable. In all the instances tried in moderately dilute solutions, Graham has shown that the amount of substance diffused is directly proportional to the concentration of the solution, so therefore the rule he gives that several groups of isomorphous salts diffuse in equal quantities, may be better expressed by saying that equal members of molecules of the salts of several groups of isomorphous bodies diffuse in the same time.

In Graham's experiments, the times during which diffusion took place were arranged so as to give as nearly as possible equal amounts of diffusate in all cases, he then endeavouring to find numerical relations between the times thus obtained. As, however, it was also found that the amount of salt diffused was proportional to the time of diffusion, it is possible to calculate all his results to a constant time. In his experiments the times varied from 4.04 days to 16.16 days. In the tables given below all the results are calculated out to a constant period of eight days.

Though the amount of any salt diffused should depend solely upon the density of the solution and the molecular weight of the salt, supposing no combination between it and the liquid took place, yet we could not expect such a relation to hold with water for a solvent, as in all prob-

ability some combination takes place between the molecules of salt and the molecules of water. It is probable, however, that the modifying action thus introduced is not very great.

We must now examine Graham's results and see if they bear out our theoretical deductions. The values given are all for 1 per cent solutions. Determinations were made in most cases for 2, 4, and 8 per cent solutions, but it appeared that the values for more concentrated solutions were not so regular as for dilute solutions, but were affected by internal molecular forces just as gases at pressures considerably removed from that of their condensation obey Mariotte's law more exactly than at pressures near to it.

In the following table all the diffusions were performed at a temperature of about 16° C. The rate of diffusion greatly increases with increase of temperature, but as the rate of increase is not known in most cases, the values have not been calculated to a constant temperature, but have been left unaltered.

Substance.	Temperature.	Density.	Diffused from 1 p.c. solution in 8 days.
Ammonium bicarbonate ..	20.1°C	1.0049	6.84
Potassium chloride ..	16.7	1.00697	9.37
Sodium chloride ..	17.4	1.0076	7.18
Potassium bromide ..	15.4	1.0077	8.77
Potassium thiosulphate ..	15.3	1.0078	6.14
Potassium chromate ..	15.5	1.0078	6.14
Sodium bromide ..	15.4	1.008	6.85
Sodium iodide ..	15.4	1.0081	6.97
Potassium sulphate ..	15.7	1.00839	6.09
Sodium thiosulphate ..	15.4	1.0084	4.73
Potassium sulphite ..	15.3	1.0084	5.61
Sodium sulphate ..	15.5	1.0094	5.01
Sodium chromate ..	15.5	1.00953	5.04
Potassium carbonate ..	17.6	1.00957	6.09
Sodium sulphite ..	15.3	1.0106	4.79
Magnesium sulphate ..	18.5	1.0108	3.67
Sodium carbonate ..	17.4	1.0112	4.88
Aluminium sulphate ..	18.5	1.0116	2.70
Zinc sulphate ..	18.5	1.0183	3.30

In this table the salts are arranged in order of the densities of their solutions. We see that the diffusion values decrease more or less regularly with increase of density of the solutions. There are, however, several marked exceptions. Graham found that if two salts were allowed to diffuse, the amount diffused was not so great as if each salt had been allowed to diffuse in a separate solution, but that each salt to a certain extent retarded the diffusion of the other. In this table the value for ammonium bicarbonate is less than the normal, and so probably the molecules of this salt when in solution have undergone dissociation. This view is strengthened in

Substance.	Temperature.	Density.	Diffused from 1 p.c. solution in 8 days.
Ammonium chloride ..	11.7°C	1.0036	8.38
Hydrogen sulphate ..	9.8	1.0065	6.95
Sodium nitrate ..	11.7	1.0070	6.30
Magnesium nitrate ..	10.4	1.0073	4.54
Potassium iodide ..	11.9	1.0075	7.87
Copper nitrate ..	10.4	1.0075	4.50
Strontium nitrate ..	10.8	1.0077	4.75
Magnesium chloride ..	10.3	1.0077	4.31
Calcium nitrate ..	10.8	1.0081	4.48
Barium nitrate ..	10.8	1.0083	4.71
Manganese chloride ..	10.4	1.0085	4.72
Silver nitrate ..	10.8	1.0089	6.31
Calcium chloride ..	10.5	1.0090	4.55
Zinc chloride ..	10.5	1.0091	4.40
Copper chloride ..	10.3	1.0093	4.24
Barium chloride ..	10.5	1.0095	5.25

that this salt is known to be exceedingly unstable. The same also applies to the salts potassium and sodium thio-sulphate, which also show abnormally low values. As we continue down the table there appear no other very great irregularities till we get to aluminium sulphate, the low value of which also seems to indicate partial dissociation when in solution.

In this table the diffusions were performed at a temperature of about 10°C. It will be noticed that the diffusion values are not so regular as before, and also that they do not exhibit much decrease as the density of the solutions increase. This is partly accounted for by the fact that the densities themselves do not exhibit so much variation, they varying from 1.0036—1.0095, while in the previous table they varied from 1.0049—1.0193.

The most marked exceptions in this table are magnesium nitrate with a value below the normal, and potassium iodide, silver nitrate, and barium chloride, the values of which are considerably above the average. Why these salts should have such high values it is impossible to say; it may be that some errors have been committed in the determinations of the densities of their solutions.

From the above diffusion experiments we see that several of the salts in solution have undergone partial dissociation. If, however, diffusion values had been taken at higher temperatures, we should expect the dissociation to be still greater, and so more marked deviations from the normal values would be obtained. Graham has determined the diffusion values for several salts at two different temperatures. The mean rates of increase of diffusion for each degree from about 10°C. to 16°C. are here given—

Barium nitrate .. 0.140	Hydrochloric acid .. 0.311
Calcium chloride 0.196	Sulphuric acid..... 0.367
Sodium nitrate .. 0.268	Silver nitrate 0.410

As in most cases the density increases regularly with increase of temperature, so we should expect the increased rates of diffusion to be much more similar than we find them here; hence these results strengthen the supposition of dissociation taking place. It might be said that if dissociation did take place, then one product would diffuse more rapidly than the other, and so the diffuseate would contain some free acid, acids being known to diffuse faster than bases. It is possible that such was the case, but as Graham estimated the diffused salts by evaporating the solutions to dryness and weighing, the free acids would volatilise and so would not appear in the result. If extremely dilute solutions were used, the method of diffusion might be considered to afford a very good proof as to whether all salts in solution undergo dissociation, as has been recently affirmed by Van't Hoff from theoretical deductions.

In the above tables the diffusion values for HCl, HNO₃, NaOH, and KOH have been left out. They were very much greater than the normal, and appeared to follow some quite different rule than the rest of the substances experimented on.

We may therefore conclude that Graham's experiments show that solutions of the same density have equal rates of diffusion, or that with solutions of varying density the rate of diffusion decreases regularly with increase in the density of the solutions. If the diffusion of salts in solutions be looked upon as quite analogous to the diffusion of gases, it is difficult to understand why the densities of the salt solutions should have any effect at all on the diffusion values. It is therefore probable that the cases are not strictly analogous, but that in liquid diffusion the molecules move in much larger masses or aggregations, and so the actual question of mass comes in. In fact, we may consider the diffusion of salt solutions to be more analogous to the diffusion of gases at temperatures and pressures near to their condensation points than to the diffusion of "perfect" gases.

THE DRY ASSAY OF TIN ORES.*

PART II.

By HEINRICH O. HOFFMANN,
Assistant Professor of Mining and Metallurgy.

(Continued from p. 271).

5. *Iron Assays.*—Two sets of assays were made, the one recommended by Ricketts,† for tin ores containing silica only, the other by Mitchell,‡ for ores containing silica, and for tin slags.

The method is based on the fact discovered by Berthier,§ and already alluded to, namely, that iron completely precipitates tin from its combination with silica as metal, if added in sufficient quantity; if not, the stannic oxide is reduced only to stannous oxide, the iron itself being at the same time oxidised to ferrous oxide. Any excess of iron will alloy with the resulting metallic tin.

(1.) Ricketts gives the formula:—Ore, 10 grms.; hæmatite, 3 to 8 grms.; potassium cyanide, 40 grms.; and says:—"Mix and charge in a charcoal-lined crucible, cover with cyanide, and then with charcoal, lute and heat strongly from one half to one hour, remove, tap carefully, cool, and break. If the tin be in small buttons, collect by washing with water to separate the charcoal, dry, and weigh. Treat the button as an alloy of tin and iron."

The result of the experiment was a porous, greyish-black slag, through which small buttons of alloy were finely disseminated, and in the bottom of the crucible a button. Button and larger prills were picked out, the crucible lining crushed, the pulp screened, the scales and the siftings obtained from panning the pulp weighed with button and larger prills. The weights of the alloys were 8.355 and 8.320 grms., which shows a close agreement, if the amount of iron is the same in both cases. This assay was not further pursued, as there are more simple methods for obtaining accurate results. The silica of ores "containing silica only" can be treated in a much more simple way. It can be removed by washing, and the pure black tin assayed with potassium cyanide, or, if too great a loss of cassiterite is feared, the silica can be removed by hydrofluoric acid, and the resulting pure black tin then assayed. This method of assay has therefore little value for the assayer, except that it substantiates an interesting fact, namely, that iron carries down all the tin.

(2.) Mitchell|| mixes 400 grains of ore with 200 grains of ferric oxide, 100 grains of fluor-spar, and 100 grains of charcoal powder, charges the mixture in a covered crucible, keeps it at a dull red heat for half an hour, and then at a white heat for another half-hour.

In the experiments the above quantities were reduced to a basis of 10 grms. of ore. These resulted in a hard, rough, bluish-black shell, with bronze coloured stains. The inside was filled with fine charcoal, no button or any prills being visible. Apparently the ore and the hæmatite had united to form a slag. The method was not further investigated. If tin slags are to be assayed, it is a simple matter to decompose the finely pulverised slag with sodium or potassium disulphate, and then treat with acidulated water, when stannic oxide and silica will be left. The tin in this mixture can then be readily determined.

(3.) One more experiment remains to be mentioned here, i.e., the fusing of black tin with potassium ferrocyanide and potassium cyanide. Bloxam¶ states that by using this reagent all the tin can be obtained as an alloy. The idea that led to the experiments was, that if a weighed amount of dried ferrocyanide were fused with the

§ "Traité des Essais," 1847, vol. ii., pp. 459, 460, 484.

|| "Manual of Assaying," 1881, p. 484.

¶ *Journal of the Chemical Society*, New Series, vol. iii., 1865.

ore, the buttons obtained from a number of assays would all have the same weight. If all the iron set free by the decomposition of the ferrocyanide alloyed with the tin, the percentage of tin could be readily calculated.

In the experiments, 5 grms. of ore were mixed with 5 grms. of dried potassium ferrocyanide and 5 grms. of potassium cyanide. For the bottom of the crucible, and for the cover, 5 grms. of potassium cyanide were reserved. The results of the experiments were negative. The alloy was partly disseminated through the lower grey slag, which was porous and tough, and had partly collected in a button. The weights of several 5-grm. assays did not agree within 1 grm., showing that all the iron of the ferrocyanide had not united with the tin, but that part had remained suspended in the lower slag.

Class B.

The second group of assays comprises the Cornish methods, which are only for determining the tin obtained by treating the ores on a large scale. That the results of such assays must be wrong is conceded. How closely they may agree when repeated in the same way by the same person is not stated.

6. Mitchell* and Ricketts† give the following method "for pure tin oxide":—400 grains (Mitchell), or 10 grms. (Ricketts) are placed in a charcoal-lined crucible, to which a cover is luted. The crucible is heated gradually for twenty-five minutes, finishing the operation at a white heat.

For the experiments, 25 grms. of ore were treated as described. There resulted, in the bottom of the crucible, a dull button of tin, while on the walls and bottom were numberless bright prills of tin. Button and prills were free from iron. The charcoal lining was pulverised and made to pass a 60-mesh sieve. The button, the scales on the sieve, and the siftings resulting from the pulp that had been panned were weighed together. The weights of two assays were:—

18.120 grms. = 72.5 per cent tin.
16.150 " = 64.6 " "

The chemical analysis shows only 67.84 per cent of tin. The reason for this strange result is to be sought in the panning of the fine pulp. When all the charcoal has been washed off there remains in the pan a heavy, black residue. It is almost impossible to see what part of this is fine tin and what heavy slag, as they scarcely differ in appearance. It is certain that with the result 72.5 per cent slag still remained with the tin, and it is not at all sure that it was all removed with the result 64.7 per cent. Perhaps after long acquaintance with uniform ores some approximately reliable estimates might be obtained, but as far as exact results go the method appears to the writer a very doubtful one.

7. Another method is given by Mitchell‡:—2 ounces of ore are mixed with a small quantity of culm and projected into a red-hot, naked crucible; some fluor-spar is added if necessary, and after a quarter of an hour's fusion the tin is poured. The prills in the slag are recovered by pounding and vanning.

In the experiments, 50 grms. of ore were mixed with 12 grms. of finely pulverised anthracite, shot into the red-hot crucible and heated for half an hour, a little fluor-spar having been added. No fusion was apparent. The crucible was removed, and broken when cold. It contained a black, porous, fritted mass, full of prills of tin, and on the bottom a button. The entire lower part of the crucible was crushed, screened, and panned, and all the recovered tin weighed together. The weights were:—

34.10 grms. = 68.20 per cent tin.
27.38 " = 54.70 " "

The same difficulty as above in separating the heavy, black slag from the fine tin causes the irregularity.

8. In connection with the Cornish methods it may be mentioned here that it has been the writer's custom, in melting out metallic tin from different grades of black tin, to mix the black tin with 5 per cent of lime, 5 per cent of fluor-spar, and 12 to 15 per cent of charcoal or anthracite, the latter requiring a higher temperature, but giving cleaner slags. With pure concentrates obtained from ore occurring in quartz no special difficulties have been encountered, so that the entire contents of a plumbago crucible weighing about 10 pounds can be readily poured. With impure concentrates the results of such fusions have always been somewhat pasty slags, and additions of lime or fluor-spar were never of much avail. The only remedy has been to add salt, which makes the slags less pasty. The main point in all these fusions is always to have the crucible nearly filled. If the first charge has begun to fuse, a second one is added. Such a fusion takes from one to two hours. Unfortunately, no records have been kept of the amount of white tin contained in the black, which would give the amounts saved.

In reviewing the preceding experiments, it is striking that so many different methods and modifications should still be recommended when a few simple ones are quite sufficient. The experiments made show clearly that there are only two methods giving entirely satisfactory results. These are the German method, as exemplified by assays Nos. 1 to 6, and the method of fusion with potassium cyanide, as from assays Nos. 35 to 38; or, still better, if sufficient material is available, Nos. 39 to 42.

In the following investigations concerning the influence the different minerals associated with the black tin have on the results of these assays, we shall see to which of the two methods the final preference is to be awarded.

(To be continued).

ON THE REMOVAL OF GOLD FROM SUSPENSION AND SOLUTION BY FUNGOID GROWTHS.*

By A. LIVERSIDGE, M.A., F.R.S., Professor of Chemistry
in the University of Sydney.

SOME examples of gold removed from solution and suspension by fungoid growths were first exhibited by the author at a meeting of the Royal Society of New South Wales in September, 1889. Since then several additional experiments have been made under known conditions and with a gold solution of known strength.

On the occasion referred to, the fungoid growths exhibited had formed in bottles of distilled water, containing very finely divided gold in suspension, which had been prepared at different times to show a class of students that, under ordinary circumstances, gold reduced from a weak solution of the chloride by means of phosphorus dissolved in ether, usually takes several years to completely precipitate and yield a clear solution.

On examining the bottles, some of which had been settling since 1881, it was found that those containing a colourless liquid were also characterised by the presence of fungoid growths, usually at the bottom of the bottles; those without fungoid growths still possessed either the ruby red or the purple colour characteristic of gold reduced by phosphorus in ether; i.e., the gold still remained in suspension.

In the case of a bottle put up on 28th November, 1884, a purple-blue growth had formed, and the solution was practically colourless; the bottle had not been opened since 1884, and had been kept in the dark for six years. On removing the stopper the odour of ether was still present.

* *Op. cit.*, p. 480.

† *Op. cit.*, p. 88.

‡ *Op. cit.*, pp. 480 and 481.

* From the *Transactions of the Australasian Association for the Advancement of Science*, Melbourne Meeting, 1890, Section B.

Under the microscope, with a low power, the growth had the appearance of a mass of matted purple-blue filaments; when dried over a spirit lamp the filaments retained their form, but lost their purple colour and acquired the metallic lustre and colour of gold.

When the growth was rubbed in a mortar it also immediately acquired the colour and lustre of gold.

Although none of the solutions free from fungoid growths were colourless, many of those with fungoid growths still possessed tints of ruby or purple, even after standing for five or six years, e.g., a solution in a bottle put up on 1st December, 1884, was, in September, 1889, still of a deep purple-red colour, with a large, purple-red, muffin-like mould at the bottom of the bottle some $3\frac{1}{4}$ inches across and $\frac{1}{2}$ of an inch thick; but by 29th May, 1890, the whole of the colour had disappeared from the liquid. The disappearance of the tint between September, 1889, and 29th May, 1890, may have been hastened by the exposure of the bottle to daylight.*

In the case of a quart bottle put up on 30th April, 1885, the solution was, in October, 1889, perfectly colourless, and the fungoid growths were of a different character, some being white and others blue-black; the white ones were floating oval bodies, about $\frac{1}{4}$ of an inch in length, with a blue-black nucleus.

(Specimens of these growths, together with microphotographs and drawings of the same, enlarged 1000 diameters, were exhibited).

The gold in the foregoing experiments was, of course, merely in suspension, having been reduced by the phosphorus in ether prior to the formation of the growth. The growth seems to have been in most instances merely instrumental in removing the gold from suspension, although such growths will reduce or precipitate the gold as well as remove it from suspension.

The growths seem to have formed much more readily in those cases where phosphorus in ether or alcohol was used, and this may have been due to the oxidation of the phosphorus to phosphoric acid, the presence of which is, of course, favourable to such growths, and the ether and alcohol may have, in part, served as food for the moulds, since there was no growth, or but very little, when other solvents for the phosphorus, such as carbon disulphide, chloroform, turpentine, and benzene were used.

On 11th October, 1889, ten confirmatory experiments under known conditions were started. Several pint bottles of distilled water were put up, and a definite quantity of the ordinary crystallised gold chloride was added to each. The gold chloride solution was made by dissolving a fifteen-grain tube of the $\text{AuCl}_3 \cdot \text{NaCl} \cdot 2\text{H}_2\text{O}$ salt in 500 c.c. of water, and 5 c.c. of this solution were added to each pint (20 fluid ozs.) of distilled water, and a small quantity of the reducing solution or agent added at the same time. The bottle was then filled up to the stopper with distilled water, and not re-opened until the time arrived for examining the growth, if any, which had formed. These bottles are not placed in the dark as in the first experiments.

Roughly speaking each bottle contained 0.01 grm. of the crystallised gold salt.

In addition to chemical reducing agents various organic ones were made use of, and as I was not in a position to obtain named fungi, I made use of certain fungoid growths, which can always be obtained in a chemical laboratory, so that the experiments can be easily repeated, and the growths used can, if necessary, be identified and named.

Amongst those used, which are all likely to be more or less pure growths, were the moulds which form spontaneously in solutions of the following:—

1. Potassium acetate.
2. Citric acid.
3. Oxalic acid.
4. Magnesium sulphate.
5. Potassium tartrate.

The mould (*Penicillium*?) from cheese and banana skins was also used. Bread and other organic bodies were also employed. All of these were found to remove the gold more or less completely from both solution and suspension, and to become stained with the ordinary blue-purple colour characteristic of gold absorbed or taken up by organic matter.

All the bottles put up prior to October, 1889, had been kept in a cool, dark room, without a window, and the door of which was seldom opened, hence the change may in these cases have gone on more slowly.

Although the fungoid growth had been observed in some of the bottles prior to October, 1889, no special attention was paid to the matter until that date, hence in the table which follows no remarks are appended before that date.

The amount of gold chloride in bottles from one to eight is unknown, but from number nine to the end of the series it is 0.01 grm. (roughly) of the crystallised double gold and sodium chloride.

Since the note was communicated to the Australian Association and pending the printing of the paper, I have been able to add observations upon the solutions up to the 28th May, 1890.

The following table shows the changes which took place in the solutions of gold chloride on the addition of various reducing substances; the first date indicates when the solution was put up and the other dates when the observations were made.

REAGENT AND RESULTS.	
Date.	No. 1.
1 12 84.	Phosphorus in Ether.
1 1 90.	Blue-purple colour. Heavy blue-black growth.
22 5 90.	Blue-purple solution. Heavy blue-black growth, one mass of which $2\frac{1}{2}$ inches long and 1 inch wide.
28 5 90.	No further change.
No. 2.	
1 12 84.	Phosphorus in Ether.
1 1 90.	Perfectly colourless solution. Blue-black growth. Photographs and sketches were made of this.
22 5 90.	Colourless solution. Blue-black voluminous growth, with some light-coloured growth.
28 5 90.	No further change.
No. 3.	
30 4 85.	Phosphorus in Ether.
1 1 90.	Quart bottle. Solution colourless. Both white and blue-black fungoid growths had formed. The white were fluffy, about $\frac{1}{4}$ of an inch through, quite different from the other growths, and possessing a blue-black nucleus or centre.
No. 4.	
30 4 85.	Phosphorus in Ether.
1 1 90.	Colourless solution. Blue-black growth.
22 5 90.	Very pale slate coloured solution. Blue-black growth, and a downy white growth streaked in places with blue-black.
28 5 90.	Solution colourless. Blue-black flocculent voluminous growth, also amoeba-like growth of very pale-blue tint.
No. 5.	
23 11 85.	Phosphorus in Ether.
1 1 90.	Deep blue solution. Voluminous blue-black growth.
22 5 90.	Purple solution. Large black growth.
28 5 90.	Purple solution. Voluminous blue-black growth.

* This observation is now added to the paper as originally read.

No. 6.

- 23 5 88. *Phosphorus in Ether.*
1 1 90.—Water tinted with dark blue. Precipitate blue-black, rather denser and not so much fungoid growth as in the others.

No. 7.

- 23 5 80. *Phosphorus in Ether.*
1 1 90.—Greenish solution. Blue-black growth.
22 5 90.—Nearly colourless solution, but of a light purple-slate colour.
28 5 90.—Pale blue solution. Blue-black growth, in loose pieces about $\frac{1}{4}$ of an inch through.

No. 8.

- 15 8 89. *Phosphorus in Ether.*
Liquid of a red-purple colour. Only a slight amount of mould, also of a purple-red colour.
28 5 90.—No further change.

No. 9.

- 11 10 89. *Phosphorus in Ether.*
14 10 89.—Nearly colourless. Slight bluish-green precipitate.
1 1 90.—Red solution. Voluminous purple-red growth.
22 5 90.—Red solution. Voluminous purple-red growth, and a few minute portions of whitish growth.
28 5 90.—Red solution. Floating voluminous purple-red growth and a compact adherent growth at bottom of bottle.

No. 10.

- 21 11 89. *Phosphorus in Ether.*
1 1 90.—Deep purple-red solution. No growth, and little sediment.
22 5 90.—Solution almost colourless, but pale slate-colour. A considerable quantity of almost black sediment.
28 5 90.—Solution practically colourless. Dense blue-black growth at bottom of bottle.

No. 11.

- 15 8 89. *Phosphorus in Ether.*
1 1 90.—Dark purple-red solution. Dark purple-red growth.
22 5 90.—No apparent alteration.
28 5 90.—Fairly deep purple solution. Bluish-black voluminous growth.

No. 12.

- Potassium Acetate Mould.*
11 10 89.—Gold reduced immediately, and the solution became of a pale blue colour in ninety minutes.
14 10 89.—Dense blue-purple precipitate. Clear colourless solution. Mould stained blue-purple.
1 1 90.—Dense thin adherent dark purple deposit in addition to mould.
22 5 90.—Deposit very deep black.
28 5 90.—Deposit very deep black. Solution very pale slate colour.

No. 13.

- Phosphorus in Benzene (C₆H₆).*
11 10 89.—Purple-blue colour. No precipitate. No growth.
1 1 90.—Purple-blue solution. No growth and no deposit.
22 5 90.—Slight deposit of a dark purple colour.
28 5 90.—Solution of a fairly deep purple colour, apparently turbid. No further deposit, and no mould or growth.

No. 14.

- Citric Acid Mould.*
11 10 89.—Pale blue colour in ninety minutes.
14 10 89.—Red purple solution. No precipitate and no growth.
1 1 90.—Pale blue solution. Indigo-blue fungoid growth.
22 5 90.—Mould almost black, one piece $\frac{1}{8}$ in. $\times$ $\frac{1}{8}$ in.
28 5 90.—Solution colourless. Deep blue-black deposit, and free lump of similar-coloured growth.

No. 15.

- Phosphorus in Alcohol.*
11 10 89.—Dirty brown colour at once.
14 10 89.—Blue-purple solution. No precipitate or growth.
1 1 90.—Pale purple-blue solution. Small quantities of bluish growth.
22 5 90.—Considerable quantity of blue-black growth.
28 5 90.—Pale tint of blue left in liquid. Thick blue-black deposit evenly covering all the bottom of the bottle.

(To be continued).

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, November 20th, 1890.

Dr. W. J. RUSSELL, F.R.S., President, in the Chair.

CERTIFICATES were read for the first time in favour of Messrs. Arthur Colefax, B.A., Ph.D., Ashgrove, Bradford, Yorkshire; Ernest F. Hooper, Elmley, Beckenham; Moses William Jones, 343, Aspen Terrace, Church, Lancashire; Stephen Newcombe Wellington, Riverdale House, Brundall, Norfolk; Thomas M. Wyatt, 20, Queen Square, W.C.; David Wilkinson, Dunedin, Otago, New Zealand.

The following were elected Fellows of the Society:—Messrs. Charles F. Branson; D. G. Clark; Charles Edwin Day; Robert Frost; Colin Gordon; Arthur R. Haslam, Ph.D.; Wallis Jenkins; John McKillop; Thomas Rhymer Marshall; William Alexander McCubbin; Thomas Parkes; Richard James Redding; Edward Cox Seaton; Frederick Smith; John Brooks Thornley; and James Mitchell Wilson.

The following papers were read:—

90. "A New Method of Determining the Specific Volumes of Liquids, and of their Saturated Vapours." By SYDNEY YOUNG, D.Sc., Professor of Chemistry, University College, Bristol.

When a tube closed at both ends and partly filled with a liquid is raised in temperature, the liquid expands, but the apparent expansion is less than the real, for a certain amount of the substance separates and occupies the space above the liquid in the form of saturated vapour. If the density of the vapour were known, it would be possible to apply the necessary correction; but at high temperatures and pressures this is not the case. If, on the other hand, the upper part of the tube (enclosing the vapour and a portion of the liquid) be heated to a high temperature, the lower part being kept at a constant low temperature, and if, subsequently, a greater length of the tube be heated to the high temperature, there will again be expansion; but in this case the observed expansion will be greater than the real; for, in consequence of the diminution in volume of the saturated vapour, a portion of it must have condensed.

In both cases we have the same two unknown values the true volume of the liquid and the specific volume of the vapour, and from the two equations involving the experimental data, it is, therefore, possible to calculate both values.

The experimental method, based on the principles just described, is described in full in the paper. It possesses the following advantages:—It is applicable to substances such as nitrogen peroxide or bromine, which attack mercury; it is available for a very wide range of temperature and pressure, even to the critical points of many substances, the data obtained serve to determine not only the specific volume of the liquid but also that of its saturated vapour.

91. "The Molecular Condition of Metals when Alloyed with each other." By C. T. HEYCOCK and F. H. NEVILLE.

In the *Journal of the Chemical Society* for May, 1890, we showed that 1 atomic proportion of a metal when dissolved in tin produces the fall in the freezing-point that, on the theory of osmotic pressure, should be produced by one molecular proportion: we therefore concluded that when metals are dissolved in tin their molecules are monatomic. During the past summer, we have succeeded in carrying out similar experiments, using bismuth, cadmium, and lead as solvents. The method of experimenting was practically the same as for tin. We now give a brief abstract of our results. The molecular falls predicted by the theory of osmotic pressure, that is, the falls that one molecular proportion of any substance ought to produce when dissolved in 100 atomic proportions of the solvent metal, are as follows:—

Solvent bismuth, mol. fall is 2.08° C.

Solvent cadmium " " 4.5° C.

Solvent lead " " 6.5° C.

Hence, the following tables show that the atom is identical with the molecule in many cases:—

Bismuth.

	No. of experiments.	No. of atoms per 100 atoms Bi.	Mean atomic fall.
Lead ..	20	1.1—1.75	2.1
Thallium ..	2	0.3—0.9	2.07 M.
Mercury ..	4	0.3—4.3	2.04
Tin ..	4	0.16—2.2	2.03 Steady.
Palladium ..	4	0.9—2.2	2.03
Platinum ..	6	0.2—1.2	2.02 Steady.
Cadmium ..	4	1.0—4.0	2.01
Gold ..	4	0.4—1.8	1.97
Sodium ..	3	0.8—4.0	1.94 Steady.
Silver ..	3	0.7—2.5	1.91
Zinc ..	4	1.3—4.8	1.6
Copper ..	5	0.23—0.6	1.23
Arsenic ..	5	0.25—2.3	0.68 Very steady.
It is noticeable that arsenic both in bismuth and cadmium gives $\frac{1}{2}$ fall.			
Antimony ..	3	0.23—1.0	2.79 Rise.

Cadmium as a Solvent.

	No. of experiments.	No. of atoms per 100 atoms Cd.	Mean atomic fall.
Antimony ..	2	0.3—0.5	4.71 M.
Platinum ..	2	0.08—0.13	4.55
Bismuth ..	4	0.05—0.5	4.58
Tin ..	3	2.2—3.6	4.09
Tin ..	2	0.66—2.6	4.48
Sodium ..	3	0.6—1.3	4.44
Lead ..	2	0.84—1.4	4.4
Thallium ..	3	0.24—1.28	4.34 M.
Copper ..	8	0.2—2.0	3.5 No falling off.
Mercury ..	3	0.23—0.68	2.77
Zinc ..	3	0.06—1.6	2.72 No falling off.
Palladium ..	3	0.13—0.26	2.35
Potassium ..	2	0.5—0.6	2.26 M.
Gold ..	3	0.14—0.7	1.48
Arsenic ..	1	0.2	1.6

Seven out of fourteen metals appear to have monatomic molecules, the osmotic pressures ranging from 2 to more than 40 atmospheres. In the case of zinc, palladium, and mercury, there is a smaller fall even at the low pressure of 2–8 atmospheres.

Arsenic gave a fall of $\frac{1}{2}$.

Silver 1 0.05 9.33 Rise.

The dissolved substance separates from the solution as temperature falls.

	No. of experiments.	No. of atoms per 100 atoms of Sn.	Mean atomic fall.
Gold ..	4	0.33—2.7	6.45 Steady.
Palladium ..	3	0.32—1.8	6.45
Silver ..	6	0.2—1.4	6.45
Platinum ..	4	0.15—0.6	6.42
Copper ..	3	0.1—0.195	6.15
Arsenic ..	4	0.38—4.9	5.33
Magnesium ..	2	1.5	4.56
Zinc ..	3	0.2—1.2	4.43
Antimony ..	4	0.6—4.7	3.9 Steady.
Cadmium ..	2	0.6—6.1	3.62 Steady.
Mercury ..	3	0.73—6.7	3.31 $\frac{1}{2}$
Bismuth ..	6	0.23—4.6	3.02 Steady.
Tin ..	3	0.4—1.8	1.8
Sodium ..	2	6.0—9.0	1.6 $\frac{1}{2}$ Sn ₄ .

Theoretical fall = 6.5.

Of the fourteen metals dissolved in lead, it would appear that five have monatomic molecules; while mercury, bismuth, and cadmium are diatomic; the molecule of tin would seem over a long range to be tetraatomic.

92. "The Estimation of Cane-sugar." By C. O'SULLIVAN, F.R.S., and FREDERIC W. TOMPSON.

The authors describe a new method of estimating sucrose, which they claim is applicable to all solutions containing cane-sugar, including natural juices and other preparations in which the use of acids is not possible. The process is a very simple one, and it is shown, by comparing it with estimations in which invertase is used, that it is very accurate. It is based on the one used by Kjeldahl in 1881, and is as follows:—

The neutral solution containing cane-sugar is placed in a constant temperature bath at 55°. A little pressed brewer's yeast is added, and complete admixture secured by gentle stirring. At the end of four hours inversion is nearly always finished. The solution is cooled, made up to double its original bulk and filtered. During the process there is a decrease in the optical activity of the solution, and an increase in the cupric reducing power. Each of these factors is an accurate measure of the amount of cane-sugar originally present. The authors quote experiments showing that good results are thus obtained in solutions which would not admit of the use of acids.

93. "The Spectra of Blue and Yellow Chlorophyll, with some Observations on Leaf green." By W. N. HARTLEY, F.R.S.

The author refers to the numerous memoirs on chlorophyll of Stokes, Sorby, Chautard, Timiriaseff, Pringsheim, Reinke, and of Russell and Lapraik and Schunck. Having been occupied at various times during the last seven years in an investigation of the different colouring-matters described under the name of chlorophyll, he has deemed it advisable to present his results to the Society without awaiting the further development of the research. The subject-matter may be conveniently arranged under the following heads:—

- Observations on the spectrum of chlorophyll contained in living tissues.
- The spectrum of chlorophyll as seen in dried leaves.
- Mode of extracting leaf-green unchanged and separating the blue from the yellow chlorophyll.
- Measurements of the spectra of the chlorophylls.

1. Living tissues which are fresh and young, and which therefore contain the leaf-green unaltered, exhibit no trace of a band in the yellow close to D, such as is usually attributed to chlorophyll, and there is no indication of one in the green. Complete absorption, just beyond δ , extends through the ultra-violet.

2. Yellow chlorophyll has a distinct absorption-band in the red differing from that of blue chlorophyll. It has likewise a distinct fluorescence.

3. When light is concentrated on living tissues the

absorption spectrum of the green colouring-matter is soon altered.

4. Separation of blue from yellow chlorophyll. The blue chlorophyll may be extracted from minced leaves by cold absolute alcohol, and may be precipitated by addition of baryta. The yellow chlorophyll is not so precipitated, or not precipitated so readily.

A warm solution of boracic acid in glycerin, mixed with a little alcohol, liberates the unchanged blue chlorophyll from the dried barium compound.

5. The blue chlorophyll exhibits two absorption bands in the red, close together; in the less refrangible region of rays one overlies B and the other overlies C. There is a feeble band near D.

6. Concentrated solutions of yellow chlorophyll in benzene are brownish in colour, and exhibit a magnificent red fluorescence.

When blue and yellow chlorophyll are separately treated with formic acid and ether, there are produced two new substances showing absorption-bands in the green. It is believed that when these bands have been observed, either in preparations of chlorophyll or in living tissues, that the chlorophyll has been altered by oxidation of formic aldehyd in the plant. The oxidation could be caused in living tissues by an excessive degree of illumination, which causes the destruction of the tissues, and otherwise by exposure of the contents of the plant cells to air or oxygen. An excessive illumination causes an exceedingly great activity in decomposing carbonic acid, and probably oxygen cannot be respired sufficiently rapidly; hence there may be a reverse action, or an oxidation of formic aldehyd to formic acid.

The leading characteristics of unaltered leaf-green are those of blue chlorophyll, namely, an intense absorption in the red, stronger even than in the violet or ultra-violet.

94. "Note on Dibenzanilide." By J. B. COHEN, Ph.D. In consequence of the appearance of the papers of Paal and others, and of Piçet (*Berichte*, 1890, 2587 and 3011), the author describes the results of experiments made some time ago. He comes to the conclusion that up to the present dibenzanilide has not been prepared; at any rate, not in the pure state. He finds that on heating benzanilide with acetic anhydride and a small quantity of fused sodium acetate, it is converted into acetanilide.

A meeting of the Research Fund Committee will be held in December. Fellows desiring grants are requested to forward their applications to the Secretaries before December 13th.

ROYAL INSTITUTION OF GREAT BRITAIN.
General Monthly Meeting, December 1, 1890.

SIR JAMES CRICHTON-BROWNE, M.D., LL.D., F.R.S.,
Treasurer and Vice-President, in the Chair.

THE following gentlemen were elected Members of the Royal Institution:—Messrs. Charles Arthur Aikin, F.R.C.S., Louis Brennan, A. M. Dunlop, Henry Gourlay, John Rose Innes, B.Sc., B.A., Maurice Marcus, Charles Gibson Millar, and George Danford P. Thomas, M.D., M.R.C.S.

The Presents received since the last Meeting were laid on the table, and the thanks of the Members returned for the same.

Shortcomings of Denaturised Spirits for Burning.—C. Reinhardt (*Zeit. Angew. Chemie*).—Such spirit often attacks metals, e.g., brass lamps, fills the wicks with the salts of zinc and copper, and rapidly destroys platinum crucibles. According to Schenkel (in the same journal), this mischief is not due to the presence of pyridine bases and wood spirit, but to the fact that many dealers add an acid to the denaturised spirit to diminish its odour. This addition has subsequently been interdicted.

NOTICES OF BOOKS.

Fuels; Solid, Liquid, and Gaseous. Their Analysis and Valuation. For the Use of Chemists and Engineers. By H. J. PHILLIPS, F.C.S., Analytical and Consulting Chemist to the Great Eastern Railway Company. London: Crosby Lockwood and Co.

THIS little book will, we feel sure, be welcomed by the class of persons to whom it is more especially addressed. In our days it is felt necessary to select for every purpose that kind of fuel which is found to be the most suitable and in addition to obtain from each kind the maximum duty which it is capable of performing. For this purpose both a correct analysis and a determination of calorific value become frequently necessary, and to this end the author gives in brief the most suitable methods.

For the analysis of gaseous fuels he recommends the apparatus of Elliot, which is here described and figured. He has found it suitable for "quick working and reasonable accuracy." Certain more delicate procedures are inapplicable where time is a great object. For the estimation of the small quantity of nitrogen usually found in fuel the Dumas process is recommended. The calorific value of solid and liquid fuels is directed to be effected by means of Thompson's calorimeter.

There is a valuable selection of tables giving practical results and analyses. Thus we find the average composition of coal from various localities, that of various anthracites, the progressive diminution of hydrogen and oxygen from wood to anthracite, the analysis of patent fuels, the composition of water-gas, the gases occluded in coal, composition of oil-gases, &c. In fine, the work ought to have its place in the laboratory of every metallurgical establishment, coke manufactory, and wherever else fuel is used on the large scale.

Manchester Technical School. *Introductory Addresses on Technical Teaching in its Application to Trades and Industries Delivered at the Opening of the Session 1889-91; Together with the Address Delivered by SIR PHILIP MAGNUS, on the Occasion of the Annual Distribution of Prizes, Saturday, October 4, 1890.*

THIS pamphlet contains addresses on the "Engineering Trades," by Alderman W. H. Bailey; on the "Building Trades," by Frederick Smith; on the "Textile Trades," by J. R. Barlow; on the "Printing Trades," by Alderman H. H. Bemrose; on the "Chemical Trades," by Ivan Levinstein, and on the "Plumbing Trade" by J. Smeaton, as well as the Address by Sir P. Magnus.

There is in these addresses very much which of necessity withdraws itself from the purview of the CHEMICAL NEWS. Most of the arts discussed in these addresses are mechanical, not chemical. Not only so, but the economical and semi-political point of view here taken, and that quite justifiably, is not open to us.

There are, indeed, many golden utterances which we can only hope will sink deeply into the minds of the hearers and of the public. One of the speakers quotes from Adam Smith the saying: "The art of seeing governs the whole conduct of human life." Precisely so, and yet we have made education, from the Board School up to the University, to turn on words and abstractions. We have cultivated what a recent writer terms the "vice of inobservance." We are here rightly told that the "all round man is of little value." Yet we still try to develop all-round men.

Says another speaker, wisely enough, of the British workman, "if he will only do himself justice by mastering the theory as well as the practice of his trade, and by avoiding the pitfalls of drink and betting, the fact of his higher wages and shorter hours of labour will not place him behind his foreign rivals." There is here an admission that in technical education "we have still much leq-

way to make up" and that "we have been spending our energies upon discussions as to the rival claims of Board and Denominational schools." Might it not have been said that we have lavished our means in forcing elementary literary education upon those who do not want it, instead of putting higher, scientific, and technical training within the reach of those who need it? It is greatly to be deplored that the authors of the addresses do not seem to admit that one of the chief shortcomings of English education is its examinal character, with the accompaniments of "standards" and "payments by results." Another defect is that the management of education so largely devolves upon the nominees of political factions and religious sects.

Mr. Levinstein's very able and interesting address on the Chemical Trades announces one of the greatest misfortunes to India, and consequently to Britain, which have happened for a long time. A Swiss chemist, Professor Hemmann of the Zurich Polytechnicum, has at last invented a method of making artificial indigo at a reasonable price. A compound known as phenylglycocine, obtained by the action of monochloroacetic acid upon aniline, can be converted into indigo by merely heating with caustic alkali. Unless some great improvement can be effected in the cultivation of the indigo-plant there is great reason to fear that the indigo-districts of India may share the fate of the madder-districts of France.

Mr. Smeaton remarked that working in lead is little understood on the Continent, and that all the best work in Berlin, Dresden, Vienna, and other cities is done by Englishmen. He mentioned, however, that in London and other great cities plumbing work is falling more and more "into the hands of builders and contractors who do not understand plumbing, and care nothing about it so long as the contract is executed at a profit." Of this sort of work the speaker gave some startling instances.

These addresses, as they stand, are of exceeding value. Had the speakers recognised the folly of the examinal system, and especially of competition in education, they would have been simply priceless.

Manual of Assaying Gold, Silver, Copper, and Lead Ores. By W. LEE BROWN, B.Sc., of Chicago. Revised, Corrected, and Considerably Enlarged, with a Chapter on the Assaying of Fuels. By A. B. GRIFFITHS, Ph.D., F.R.S.E., F.C.S., &c. London: Heinemann.

WITH the exception of the chapter on fuels this work is a re-issue of a manual which has given great satisfaction in the United States.

Certain matter has been retained which is of questionable use in England. Thus, in the chapter on apparatus we are repeatedly referred to "Troemner's list." This price list is not to be found in England unless specially ordered.

"Casseroles" is apparently the American name for a porcelain evaporating-basin fitted with a handle. Generally speaking, the account given of apparatus, reagents, and manipulation corresponds with that which we find in the most approved manuals of analytical chemistry.

Mr. Brown, in drawing a line between assaying and analysis, depends on the method employed. The discovery of the composition of any substance by means of dry reagents and heat is an assay. The same determination mainly by the use of wet reagents, with or without the aid of heat, is an analysis. We are not sure that this distinction can always be followed. What, for instance, is the determination of the ultimate composition of an organic compound? The ores and metals for which special directions are given are gold, silver, copper, and lead. The author admits that none of the furnace methods for the determination of copper and lead give very accurate results. For copper he gives as much more accurate the volumetric process, and above all, the electrolytic method of Luckow.

But in the appendix we find a passage which must be pronounced "rule of thumb in excelsis." The writer, Mr. G. Nixon, says that "in a certain sense no one cares to know the ultimate amount of metal that an ore contains. What is desired in practice is the yield under the most skilful treatment, and this information is approximately obtained by fire for copper." Surely the rational industrialist will need to know how far his "most skilful treatment" falls short of the truth, and is still capable of amendment. Time was when the Cornish assay was the only method available. But what excuse can there be in these days for retaining it and analogous methods?

In the chapter on the examination of fuels, instructions are given both for its analysis and for its calorimetric examination.

For the examining of furnace gases the author describes and figures Bunte's apparatus as made by P. Harris and Co.

We regret to find that the author in speaking of "parting" makes use of Baumé's hydrometer scale instead of Twaddell's, or of direct specific gravity.

Our opinion of this work, as a whole, is distinctly favourable.

Anleitung zur Darstellung Chemischer Präparate, ein Leit faden für den Praktischen Unterricht in der anorganischen Chemie. "Introduction to the Preparation of Chemical Products; A Clue for Practical Instruction in Inorganic Chemistry." Von Dr. HUGO ERDMANN, Privat Dozent an der Universität Halle. Frankfurt am Main: Bechhold.

IT has long been found necessary to devote special treatises to the analytical department of chemistry, and it is now perceived that the synthetical department also requires a more thorough treatment than it can receive in the general text-books.

As far as inorganic chemistry is concerned, Dr. Erdmann makes a very successful effort to meet this want. He has had the advantage of working for five years as assistant to Prof. Volhard, to whom he declares himself indebted for various trustworthy methods which so far are not generally known. As far as possible he sets out from cheap or worthless materials, from by-products and residues which are apt to accumulate in the laboratory. The finished products, on the other hand, are largely such as are in constant use, and are at the same time not always to be met with in trade of sufficient degree of purity. Methods are given for the production of 10 per cent sodium amalgam, of sodium nitrite, of pure silver, both crystalline (according to Stas) and molecular, from residues, mercuric chloride, and platinum chloride, both from residues, hydrogen peroxide, &c. A curious printing fault in the preface puzzled us for the moment. It reads, "The beginning (Anfang) of the book discusses briefly some of the most essential laboratory appliances, &c." It should be "The appendix (Anhang)" &c.

We must pronounce this little work an excellent guide for instruction in inorganic chemistry.

Bechhold's Handlexicon der Naturwissenschaften und Medizin. ("Bechhold's Manual Dictionary of the Natural Sciences and Medicine.") Bearbeitet von A. VELDE, Dr. W. SCHAUF, Dr. V. LOEWENTHAL, und Dr. J. BECHHOLD. Frankfurt am Main: Bechhold.

WE have here the first part of what promises to be a very useful work. It is not an encyclopædia, but a dictionary explaining the technical language of the sciences. It is calculated to be useful not only to the cultivated laymen, but even to the *savant* in subjects outside his own speciality. The work is to be completed in ten parts of 64 pp. each. The descriptions are concise, but clear. Great use has been made of abbreviations, which are duly explained in the beginning of the work and present no difficulty. After the term to be explained follows first the

branch of science to which it belongs, and at the end of each such paragraph there is given the derivation of the word. We observe only two typographical errors: *acidum chronicum* instead of *chromicum*, and *Almus viridis* instead of *Alnus*. Some readers may possibly be puzzled by finding the names of certain chemicals given in the peculiar Latin guise used by German physicians and pharmacists. Thus "*ammonium chloratum*" stands not for ammonium *chlorate*, but for the corresponding chloride. Thus, even the suggested re-introduction of Latin as the universal language of science (though vastly preferable to Volapük) would not give us uniformity of nomenclature. This hand-lexicon will be very useful to all who have occasion to consult German scientific works.

Report of the Committee on Spelling and Pronunciation of Chemical Terms Appointed at the Toronto Meeting of the American Association for the Advancement of Science, August, 1889.

THIS pamphlet, for which we are indebted to the courtesy of Dr. Carrington Bolton, is a reprint from the *Proceedings of the American Association for the Advancement of Science*, vol. xxxviii. This Association, at a previous meeting, appointed a committee on the spelling and pronunciation of chemical terms. The committee sent out in May, 1889, a provisional list of words based upon the list drawn up by Prof. J. H. Appleton, and requested critical replies. A report based upon these replies was considered by the Chemical Section at the Toronto Meeting, when a further report was sent out to all American chemists. The "general principles" laid down are in many cases conflicting. Thus, it is recommended that "the pronunciation should be, as far as possible, in accord with the analogy of the English language, yet Continental pronunciation should be approached and present usage should be retained as far as possible. Many of the pronunciations laid down are in close accordance with those customary in Britain. We find, however, the *e* in methyl and ethyl marked short, which would probably involve ðther. In the four halogens the *i* in the last syllable is marked short. Words ending in *ide* or *id* are to be shorn of the final *e* and be pronounced chlorid, exid, &c. In words ending in *yl* the *y* is also to be short. Some of the suggestions seem very appropriate; thus the word "titre," or as written in America *titer*, is to be avoided. "Benzol" is justly considered undesirable. The authors do not approve of the proposal of Watts to make the names of basic compounds end in *ine* and those which are neutral in *in*.

We do not see how the words benzine and benzene, which do not signify the same substance, are to be distinguished. The termination *meter* occasions the committee some trouble. To distinguish micrometer (the instrument) and micrometer (the measure) they rely only on accents. In England we escape the difficulty by writing "metre" where it terminates the name of a measure. The pronunciation "tallic" laid down for "phthallic" will doubtless surprise many readers. The authors, we see, propose to use "radical" instead of "radicle," and to write "gram" for "gramme." This we consider a most objectionable innovation. Some scientific men, especially when writing for the press, have a habit of omitting the dot over the *i*, and thus it would often be impossible, in hurriedly written M.S., to distinguish between the words "gram" and "grain."

Upon the whole we should fear that the innovations in pronunciation proposed would render terms liable to be confounded with others.

The Committee does not appear to have taken any steps towards an international nomenclature in chemistry—a weightier matter than pronunciation. The English speaking nations still retain their needless terminations in phosphorus, chlorine, &c.; whilst the French cling to azote, and add the appendage *ine* to certain basic oxides, such as "lithine." We have repeatedly mentioned the

peculiarities of the Latin nomenclature used by German pharmacists, such as ammonium *chloratum* for ammonium chloride. But this subject can only be dealt with by a joint committee of English, French, and German chemists.

CORRESPONDENCE.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—Although Messrs. Lloyd and Teed deny that their circular had any resemblance to the official notices of the Chemical Society, there appears to have been a likeness sufficiently close to cause thirty-eight out of the "hundreds" who answered it to assume it to be an official notice, notwithstanding the request made by the writers to return answers to them.

The writers still decline to specify the real number of answers they have received, and how many were qualified in various ways; and I am, therefore, justified, since "hundreds" are named, in assuming that about 200, or say 12 per cent of the Fellows, agree with the proposals. This is scarcely enough backing for a somewhat ambitious programme.

Our self constituted guardians regret that anyone should have so poor an opinion of the "intellectual and moral status" of the Fellows as to suppose that they would assent to views put forth by the Council, and withhold assent from the same views advanced by private members.

For my own part I should regret extremely to see anything like a respectable number of the Fellows do the contrary. There is all the difference in the world between the two actions, and it by no means implies either intellectual or moral defect when assent is gladly given to a policy pursued by a lawfully elected and responsible body, and withheld from an identical policy proposed by a self-elected and irresponsible clique.

The words "Our present policy, which is to keep out of the society those who are intellectually or morally unworthy of the Fellowship," constitute, I think, an outrageous and insulting usurpation of the prerogatives of the Fellows and the Council.

Surely these gentlemen do not realise the immense responsibility they assume when, with such views publicly expressed, they or their friends proceed to blackball a candidate. What esoteric knowledge do Messrs. Lloyd and Teed possess by virtue of which they pronounce a candidate unfit "intellectually or morally" (after hearing his profession or calling read out) when five of their fellow members, presumably just as anxious for the welfare of the Society, have signed a declaration that he is a fit and proper person for election? What right have they to assume that Fellows are so careless, incompetent, or evil minded as to propose such candidates?

I think, sir, that if our two censors will quietly think matters over they will see that they have made a mistake, and will have the courage to withdraw from an untenable position,—I am, &c.,

R. J. FRISWELL.

115, Darent Road, N.
December 1, 1890.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—Will you kindly allow me to say that when signing the circular received some time since I was under the impression that it had in some way the support of the Council, and in doing so desired more to express a general

agreement with the idea that something ought to be done than a specific endorsement of each detail of the proposal?

I think with Messrs. Bloxam and Blount, that the best solution of the difficulty is for the Society to publish that it is not a qualifying body for professional chemists, and would suggest that a simultaneous publication of the existence and main function of the Institute should be made.

In this part of the world the F.C.S. reigns supreme, and the F.I.C. is practically unknown,—I am, &c.,

THOMAS FARRINGTON, M.A.

Analytical Laboratory,
4, Waterloo Place, Cork, Nov. 25, 1890.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Zeitschrift für Analytische Chemie.
Vol. xxix., No. 2.

The Presence of Arsenic in Commercial Zinc Oxide.—W. Stromeyer (*Archiv. de Pharmacie*).—The sample should be dissolved in hydrochloric acid and mixed with hydrogen sulphide water.

The Recognition of the Conclusion in Titrating Iron Chloride with Stannous Chloride.—F. H. Morgan.—From the *Journal of Analytical Chemistry*.

The Recognition of Mercury as Oxydimercuri-ammonium Iodide.—Joseph Klein (*Archiv. de Pharmacie*).—The author uses the action of ammonium chloride upon an alkaline solution of mercuric potassium iodide—a reaction which is the inverse of Messler's reaction for the detection of small quantities of ammonium salts. For detecting mercury in a dilute aqueous solution the author adds to a portion of it a little solution of potassium iodide and adds some soda-lye (lye of specific gravity 1.34 diluted with an equal volume of water), and a solution of ammonium chloride (10 parts of the solid chloride in 50 of water). If the solution is very dilute the test solution is superstratified.

Determination of Arsenic.—R. C. Canby (*Journal of Analytical Chemistry*).

Determination of Arsenic in Iron.—F. G. Müller, C. Reinhardt, and M. A. von Reis.—This memoir will be inserted as early as possible.

Removal of Arsenic Present in Determinations of Phosphorus.—E. D. Campbell.—From the *Journal of Analytical Chemistry*.

Detection of Nitrous Acid.—Curtman (*Phar. Central-Halle*) utilises the reaction of antipyrine with nitrous acid, depending on the formation of iso-nitrosoantipyrine. The reaction consists in the appearance of an emerald green colour.

Determination of Nitrous Acid in Presence of Nitric Acid.—Kalmann.—The nitrous acid is converted into nitric oxide gas by means of hydriodic acid according to the equation: $\text{NaNO}_2 + 4\text{HI} = \text{NaI} + \text{NO} + \text{I}_2 + \text{H}_2\text{O}$, and the nitric oxide formed is measured. The solution of hydriodic acid is prepared by dissolving at least twice as much iodine as is necessary for the decomposition of the nitrous acid in a saturated solution of potassium iodide, and lets solution of sodium sulphite flow in until the mixture is decolourised.

Determination of Nitric Acid.—F. H. Morgan and Edes Bates.—From the *Journal of Analytical Chemistry*.

Volumetric Method for Determining Carbon in Iron.—J. Wiborgh (*Berg der. Hütten Zeitung*).—This paper requires the accompanying illustration.

Determination of Graphite in Minerals.—J. B. Mackintosh.—From the *School of Mines Quarterly*.

A New Reaction for Thymol.—L. van Itallie (*Archiv der Pharmacie*).—If a few drops of potassa-lye are added to a liquid containing thymol and then iodised potassium iodide until the liquid has a faint yellow colour, a fine red colour appears on gently heating. The colour increases at first in intensity, but disappears soon afterwards. The reaction is said not to occur with other phenols.

Detection of Hydrosulphocyanic Acid.—G. Colasanti.—A dilute solution of this acid or of its salts gives a fine emerald green colour on the addition of a solution of copper sulphate (*Gazzetta Chimica Italiana*).

A Reagent for the Mercaptanes.—G. Denigès.—Already noticed under *Comptes Rendus*.

Action of Borax upon Polyatomic Alcohols and Phenols.—A. Lambert.—Noticed under *Comptes Rendus*.

An Improvement in Organic Combustions.—F. Blan (*Monats-Hefte für Chemie*).—The back end of the combustion tube, which is 114 c.m. in length, projecting 10 c.m. out of the furnace behind, and 19 in front, is closed with a caoutchouc plug through which passes a glass tube 10 c.m. long. In this a glass rod, 40 c.m. long, carrying at its front a strong platinum wire, can slide air-tight backwards and forwards. An air-tight closing is effected by means of a piece of caoutchouc tubing drawn tightly over the glass rod and the glass tube. By means of the rod the platinum boat, with the substance to be analysed, is moved backwards or forwards. To effect a firm connection between the wire and the boat there is a small appendage to the latter, having a narrow slit in its upright part. By thus rendering the boat movable, the combustion can be more nicely and easily regulated than heretofore.

Sources of Error in Determining Nitrogen by the Will and Varrentrap Process.—W. O. Atwater (*Amer. Chemical Journal*).

Determination of Iodoform.—M. Greshoff (*Chemiker Zeitung*).—A small quantity of the substance (0.1–0.5 grm.), is heated in a wide test-tube with 10 grms. of a 10 per cent solution of silver nitrate in the water bath. When cold any fatty matter is withdrawn by means of ether.

Quantitative Separation of Strychnine and Brucine.—J. E. Gerock (*Archiv. der Pharmacie*).—These bases, and especially their picrates, behave differently if heated with nitric acid. Brucine is coloured red by nitric acid, and on heating gives a yellow solution, which when carefully neutralised is not precipitated by picric acid. Strychnine does not suffer any chemical change from the action of nitric acid of 1.056 specific gravity (or weaker).

Determination of Nicotine by Polarisation.—M. Poporici.—The author's method requires the use of a table, for which we refer to the original.

The Quantitative Determination of Aniline and Monomethylaniline.—F. Reverdin and Ch. de la Harpe (*Chemiker Zeitung*).

A New Method for Determining Paranitro-Toluol.—F. Reverdin and Ch. de la Harpe (*Chemiker Zeitung*).—These two memoirs will be inserted as early as possible.

Researches on the Carbonic Acid in the Air.—W. Spring and L. Roland.—The particulars are not given.

Examination of Beer.—H. Schwarz (*Dingler's Polytechn. Journal*).—This paper does not admit of useful abstraction.

Determination of Acidity in Food-fats and Oils.—Gantler.—This is generally effected by dissolving the fat in ether free from acidity and titrating, using phenolphthalein as indicator. Gantler has checked the results with sensitive litmus paper, and has met with a rape-oil which turned the litmus paper very distinctly blue after

the addition of 2 c.c. alcoholic potassa, whilst the red colouration of phenol-phthalein did not appear until after the addition of 6 c.c. potassa solution.

Valuation of Indigo.—Ch. Tennant.—From the *Journal of the American Chemical Society*.

Eucalyptol.—Remarks on the sophistication of this oil.

Testing Glue.—R. Kissling (*Chemiker Zeitung*). This paper requires the accompanying figures.

Presence of Amber in Lakes.—W. Sonne (*Zeit. Angew. Chemie*).—The author's method turns on the recognition of succinic acid.

Chemical Examination of Blacking.—J. Hölbling (*Zeit. Ange. Chemie*).—The author tests for fatty matter, carbon, phosphoric and sulphuric acids, glycerin, iron, and extractive matters.

Determination of Benzaldehyde in Bitter Almond Water.—C. Denner (*Pharm. Central Halle*).—The author's process depends on the behaviour of benzaldehyde with phenyl-hydrazine.

Examination of Pharmaceutical Extracts.—A series of processes for which we must refer to the originals.

Detection of Diamines in Urine.—L. von Udränsky and E. Baumann.—An examination of a urine containing cadaverine and putrescine (pentamethylenediamine and tetramethylenediamine).

Determination of Urea.—Fowler mixes 1 vol. urine, the specific gravity of which is exactly known, with 7 vols. of solution of sodium hypochlorite, also of known specific gravity. The mixture is let stand for 2–3 hours and its density is re-determined. The difference of the values depends on the decomposition of urea, and on multiplication with 770 it gives the percentage of urea.

Occurrence and Detection of Indigo-red in Urine.—O. Rosenbach (*Berlin Klin. Wochenschrift*).—Urines which contain the chromogen of indigo-red yield with Jaffe's indican test no pure blue, but a more or less decided violet colour to chloroform.

Two Unusual Urine Pigments.—B. J. Stokvis.—A colouring matter found in the urine of a patient who had been taking resorcine resembled that of litmus. In another urine there was found a colour resembling, but distinct from, hæmatoporphyrine.

Detection of Albumen in Urine.—G. Roch (*Pharm. Central Halle*) finds that salicylsulphonic acid throws down albumen as a flocculent precipitate, even when present in so small a proportion as 0.005 per cent. The test is not affected by solutions of urea, uric acid, glucose, or peptone, or by normal urine.

Heller's Blood Test.—According to Filehne (*Virchow's Archiv*) this test may give a red, phosphatic deposit in the absence of the colouring matter of blood.

Determination of Alkalinity and Carbonic Acid in Blood.—A series of observations by different authorities for which we refer to the originals.

Detection of Carbon Monoxide in Hæmoglobine.—A. Welzel.—To 10 c.c. of undiluted blood are added 15 c.c. of a 20 per cent solution of potassium ferrocyanide, and 2 c.c. of an acetic acid made up by mixing 1 vol. of glacial acid and 2 vols. of water, and the whole is gently shaken. The coagulum in normal blood is black-brown, in blood containing carbon monoxide an intense light red. Or, the blood diluted with 4 parts of water is mixed with about three times its quantity of a 4 per cent solution of tannin. Blood containing carbon monoxide gives a bright crimson precipitate, which retains its colour for months. Normal blood gives a red precipitate at first, which in 1–2 hours takes a brownish shade, and in 24–48 hours turns to a permanent grey.

Detection of Tin in Confectionery.—J. Mayrhofer.—The author first destroys the articles in question with

nitric acid. To this end 20 grms. of the substance are covered with 50 grms. nitric acid (specific gravity 1.45), in a flask containing 400 c.c., and gently heated on the sand-bath until copious red fumes escape. When the main reaction is over, 10–15 c.c. of nitric acid are added at intervals of half-an-hour, heating gently, by which means the oxalic acid formed is mostly consumed. The decomposition lasts for half a day and requires 70–100 grms. nitric acid. The residue is placed in a porcelain capsule, the flask is rinsed out with 10 c.c. hydrochloric acid, and the whole evaporated to dryness. The residue is taken up in water and hydrochloric acid (about 100 c.c.), sulphuretted hydrogen is passed into the solution at 60–70° for half-an-hour, filtered when cold, the filter burnt, the ash reduced by ignition in a porcelain boat in a current of hydrogen, and the product of the reduction is dissolved in hydrochloric acid.

On Prout's Hypothesis with Reference to the Atomic Weights of Oxygen and Carbon.—J. A. Groshans (*Rec. des Travaux Chim. des Pays-Bas*).—On comparing the formulæ of different compounds which only contain hydrogen, oxygen, and carbon, the author concludes that the figures 12 and 16 must be admitted for carbon and hydrogen.

The Atomic Weight of Palladium.—E. H. Keiser, —(*Report of Chemical Section of Journal of Franklin Institute and Chemical News*).

Journal für Praktische Chemie.
New Series, Vol. xli., No. 11.

Researches from the Chemical Laboratory of Prof. A. Saytzeff at Kasan.—This contains a paper by A. Reformatzky on the Investigation of Linoleic Acid. The formula hitherto assumed for the composition of linoleic acid, $C_{18}H_{28}O_2$, is erroneous. Its true composition is $C_{18}H_{32}O_2$.

Researches from the Laboratory of the University of Freiburg.—These comprise a memoir by Ad. Claus and H. Burstert on the products of the chlorising of metaxylyl, and a paper by C. Willgerodt on a method of obtaining azohydrazines and polyazo-compounds.

A New Method for the Determination of Sulphur in Inorganic Sulphides.—P. Jannasch.—This memoir requires the accompanying figure.

In Reply.—F. Stohmann.—An answer to certain polemical comments by Herr Ossipoff on the combustion heat of fumaric and maleic acids.

Royal Institution.—The following are the Lecture Arrangements before Easter:—Professor Dewar, Six Christmas Lectures to Juveniles, on Frost and Fire; Professor Victor Horsley, Nine Lectures on the Structure and Functions of the Nervous System (Part I. The Spinal Cord, and Ganglia); Mr. Hall Caine, Three Lectures on the Little Manx Nation; Professor C. Hubert H. Parry, Three Lectures on the Position of Lullu, Purcell, and Scarlatti in the History of the Opera; Professor C. Meymott Tidy, Three Lectures on Modern Chemistry in Relation to Sanitation; Mr. W. Martin Conway, Three Lectures on Pre-Greek Schools of Art; The Right Hon. Lord Rayleigh, Six Lectures on The Forces of Cohesion. The Friday Evening Meetings will begin on January 23rd, when a Discourse will be given by The Right Hon. Lord Rayleigh on Some Applications of Photography; succeeding Discourses will probably be given by the Right Hon. Lord Justice Sir Edward Fry, Professor J. W. Judd, Professor A. Schuster, Dr. E. E. Klein, Mr. Percy Fitzgerald, Dr. J. A. Fleming, Dr. Felix Semon, Professor W. E. Ayrton, and other gentlemen.

Sizing Paper According to New Practical Experiments.—(From *Dingler's Journal*).—This paper will be noticed at some length as early as possible.

MISCELLANEOUS.

Diaries for 1891.—We have received from Messrs. Cassell and Co., publishers to Letts's Diaries Co., a selection of these well-known and old-established Diaries. The foolscap sizes, Nos. 31 and 48, interleaved with blotting-paper, are not only useful as Diaries, but they will be found convenient for the laboratory desk as rough note-books for jotting down results of experiments in progress, pending their record in the regular note-book. The smaller Diaries, Nos. 18, 23, and 26, give, besides the usual space for notes and memoranda, much new information on many subjects of daily enquiry. The Ladies Diary and Pocket Book gives, in addition, a table of Christian names and their meanings, useful in families where a name, male or female, has occasionally to be selected; it also gives, each month, for the benefit of young housekeepers, a list of articles of food in season. The Medical Diary keeps up its character, and contains much new information bearing on fees, doses, antidotes, nursing, &c. The Office Diary, No. 8, will perhaps be found the most popular, owing to its convenient shape and the fulness of the information at the beginning. It contains a Colonial and Foreign Banking, Postal, and Telegraph Directory, which is a marvel of compactness, and would be valuable to all who have much foreign correspondence if it were a little fuller in names of places which are now coming into notice.

NOTES AND QUERIES.

* Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertisement columns.

Nickel Capsules.—(Reply to "C.")—Your correspondent will find some letters on the subject of nickel utensils in the *CHEMICAL NEWS*, about January, 1887.—T. F.

THE CHEMICAL NEWS.

VOL. LXII. No. 1620.

A RAPID METHOD FOR THE ESTIMATION OF UREA IN URINE.

By C. J. H. WARDEN,
Professor of Chemistry, Medical College, Calcutta.

As Mr. Sutton has remarked, the sodic-hypobromite method of estimating urea in urine has given rise to endless forms of apparatus, the principle of construction being in all cases similar. With the exception, I believe, of Lunge's nitrometer—when it is used for the estimation of urea—in all the instruments hitherto proposed the decomposition of the urea by the hypobromite has been accomplished in one apparatus, and the evolved gas measured in a separate tube. In the method now described, the evolved nitrogen is measured in the same tube used for the decomposition of the urea, and the procedure is consequently much simplified.

The apparatus employed for the decomposition of the urea and measurement of the liberated nitrogen consists of a slightly modified form of Crum's well-known nitrometer. Crum's tube, as usually constructed, has a total length of 210 m.m., an internal diameter of 15 m.m., and a capacity of about 25 c.c.; the cup at the top having a capacity of a little over 2.5 c.c. The modifications desirable in adapting the tube for the estimation of urea may be thus summarised:—

(a). Trebling the length of the tube, and thus making it 630 m.m. long; the capacity being increased to 75 c.c.; while the internal diameter is not altered.

(b). Grinding on to the lower open end of the tube a glass stopper, on which two narrow grooves have been filed.

(c). Increasing the capacity of the small cup at the top of the tube to 5 c.c., and having it accurately graduated to hold 2.5 c.c. when filled to a certain mark.

(d). Using somewhat thinner glass than that employed in the construction of Crum's tubes, as no mercury is used in the process.

The tube is graduated on the principle of Russell and West's apparatus. Russell and West's gas measuring tube was graduated to be used with 5 c.c. of urine. It was found that 5 c.c. of a 2 per cent solution of pure urea evolved 37.1 c.c. of nitrogen, and this volume was taken as the basis of graduation.

In the process now being described, only 2.5 c.c. of urine are used, and as 2.5 c.c. of a 2 per cent urea solution evolve 18.55 c.c. of nitrogen, this volume of gas will necessarily be equivalent to 2 per cent of urea; one per cent of urea is therefore equal to 9.27 c.c. of nitrogen, and the 9.27 c.c. volume is divided into ten equal parts, each part being equal to 0.1 per cent of urea; these divisions are further subdivided into two, each representing 0.05 per cent of urea.

The graduations should be continued so as to indicate up to 3 per cent of urea.

As in Russell and West's tube all calculations are avoided, the observed volume of gas at once indicating the percentage of urea in the specimen of urine under examination.

In using the apparatus the following solutions are required:—

1. A cold aqueous saturated solution of common salt-brine.
2. Hypobromite solution, made by dissolving 100 grms. of caustic soda in 750 c.c. of distilled water and adding 25 c.c. of bromine; this solution should be freshly prepared in small quantities as required for use.

To use the apparatus the stop-cock should be first slightly greased and closed, the tube inverted, and the grooved stopper removed.

The salt solution is poured into the tube to overflowing, the stop-cock opened to allow a drop or two to escape, and thus displace the small column of air in the bore of the stop-cock. The grooved stopper is then pressed home, the excess of brine escaping by the grooves in the side of the stopper, in the same manner as the superfluous fluid escapes through the capillary orifice in the stopper of a specific gravity bottle. In this way the tube is filled with the salt solution, all air being excluded.

The tube is now stood in a small trough of brine—a finger bowl answers very well—and supported by a filter-ring or clip, and the cup carefully dried.

The sample of urine to be examined is poured into the dry cup up to the 2.5 c.c. graduation, and any excess accidentally introduced removed by a fine fold of blotting-paper. The cup is then filled with water to the 2.5 c.c. mark, which is allowed to enter the tube, and this is repeated, the object being to free the cup from any traces of urine. The stopper is now removed, and the cup repeatedly filled with hypobromite solution, which is allowed to enter the tube until 40 c.c. of the solution or more have been used. When the addition of the hypobromite solution ceases to cause active effervescence, the tube is grasped by the right hand, the thumb being tightly pressed against the open end, and the contents thoroughly agitated.

The tube is again stood in the trough of brine, and when the temperature of the gas has reached that of the surrounding air, the volume is measured with the usual precautions; the volume of gas indicating the percentage of urea in the urine. Corrections for temperature and pressure can, of course, be applied if necessary.

In using the tube, if the evolved gas should exceed the volume yielded by 3 per cent of urea, the urine must first be diluted with an equal volume of water and 2.5 c.c. of the diluted urine used in the manner already described; the percentage of urea as indicated by the volume of gas being doubled. The froth which forms on the surface of the liquid in the tube can be dispersed by introducing a few drops of kerosene oil.

The points to which special attention may be drawn in connection with this method of estimating urea are—

1. Extreme simplicity of apparatus; all the various operations of measuring the urine, decomposing the urea, and measuring the volume of evolved gas, being performed with one instrument.

2. Ease and rapidity of manipulation.

3. Results as accurate as those afforded by any of the various modifications of Russell and West's original method.

Messrs. Cetti and Sons, of 36, Brook Street, Holborn, sole manufacturers, are prepared to supply these modified Crum tubes, and the well-known name of the

firm is a sufficient guarantee that the graduations will be accurate.

EXAMINATION OF OILS, FATS, AND ALLIED SUBSTANCES.

By THOMAS T. P. BRUCE WARREN.

IN examining oils, &c., no test should be considered as superfluous. There are some tests which are more important than others as regards their special significance, so that experience must decide the procedure to be followed in particular cases.

The specific gravity of an oil or mixture, if fluid, at 60° F., should always be noted at this temperature: fats, concrete oils, thick lubricating petroleum, should be taken at 100° F. The expansion of an oil is an important factor, the temperature at which it begins to show a divergence from the mathematical functions used in constructing a curve for constant or variable changes should also be noted. In this way we can frequently detect changes where chemical methods would be extremely troublesome even if possible.

A specific gravity bottle is constructed holding 25 c.c. to the neck, which is graduated and widened at the top into a funnel for the convenience of filling and retaining any oil beyond the capacity of the neck. The capacities of the bottle and the graduated neck are determined by pure mercury, so that the expansion due to the glass itself can be accurately measured and allowed for if required. It is preferable to distil the mercury direct into the bottle, otherwise the expulsion of air is very troublesome.

The difficulty of adapting different forms of Sprengel tube for this purpose led to the designing of this form of specific gravity tube. In using this it is immersed in water or oil to the upper mark of the neck. A platinum wire serves as a suspension for weighing or holding in an oil or water bath.

Knowing the capacity of the bottle, the specific gravity of an oil occupying the same bulk is easily determined.

The expansion of an oil is taken as being simply an arithmetical mean for the observed differences of temperature. This is certainly not correct; the first effect will be to expand A, the original bulk to $A + a$, a further increment of heat will expand A and a together, and so on for every successive increment of volume; consequently the expansion is in a geometrical ratio, and so long as no abnormal change takes place, we obtain a logarithmic curve in which the axes x and y follow a regular rate of variation. If on the axis x we represent the thermometrical increments, then y will show the corresponding volumes.

When something happens which makes the curve change with respect to its initial ordinates, it is a common thing to say that an interpolation formula must be introduced. Now whenever this occurs there must be some change to explain; either the capacity for heat has altered, so that an increased temperature no longer produces an uniformly corresponding mechanical effect, or some chemical change has crept in which upsets the previous mathematical relation of x and y .

We can discard for the present the examination of these points by polar co-ordinates and endeavour to find out by chemical methods what is really taking place. We know by the curve when a change has begun, and we can also tell between what points the change is uniformly constant; another interpolation or point in the curve indicates another change, and so on. At all these points an oil should be examined when cooled down to the original temperature. Some oils are more stable than others at the same temperature, and a mixture of two oils, such as olive and sesame oils, can be readily detected. The chemical change is due mainly to the loss of glycerin and to the partial oxidation of the fatty acids thus set free.

Oils which are easily oxidised are best heated in a flask with a bent neck dipping under mercury, or in connection with a vacuum pump.

The iodine absorption of an oil, if taken before and after heating, shows a diminished absorption which may be due to oxidation or other causes. Sulphur chloride shows that glycerin has been expelled.

In some cases it is useful to know the rate at which an oil absorbs oxygen, and how the same is expended; a measured volume of the gas contained in a graduated gas tube with an outlet at the top, standing over mercury is connected with a suitably constructed flask containing the oil, the air in which has been displaced by oxygen, the volume of which is noted. The residual gas in the tube is analysed; the CO_2 represents approximately the glycerin set free, and the deficiency of O beyond this shows what the oil and fatty acids have retained.

"The Oxidation of Lubricating Oils," by Dr. O. Bach, was given some time ago in the *Chemiker Zeitung*. This interesting paper will be referred to when dealing with machine oils.

THE VISCOSITY OF LUBRICATING OILS.

By H. JOSHUA PHILLIPS, F.C.S.

THE viscosity of an oil used for the lubrication of all kinds of machinery, cylinders, &c., being such an important factor in its specific selection, it becomes important that a recognised standard viscosimeter should be used by oil merchants and buyers, so that in drawing up a specification definite viscosities at definite temperatures (which would be decided according to what purpose the oil was proposed to be used), could thus be stated. It is well known that many cylinder mineral oils now in the market, although very viscous at the ordinary temperature, would be far too thin to be used at the working temperature of a cylinder.

Sacker's viscosimeter, an apparatus much in use for determining viscosities of oils, is practically useless to base any specification upon, since it is very rarely that any two of them will be found to give the same results with the same oil, owing to differences in bore and shape of constriction of the graduated tube and the length and bore of the protruding capillary tube; and moreover, the apparatus is not supposed to determine viscosities above the boiling-point of water. The apparatus which commands itself for uniformity and accuracy of results is that devised by Mr. Boverton Redwood, F.R.S.E., &c. (*vide Jour. Chem. Soc. Ind.*, v., 126). It is made of copper, the exit portion being agate, of definite bore and limited protuberance. Each apparatus is accurately standardised by Mr. Redwood himself, average rape-oil being taken as unity.

By using such an apparatus, there should be no difficulty with oil merchants and brokers in sending samples of oils of prescribed viscosity at stated temperatures, which would thus limit the shoals of specifically useless oils that one is often obliged to test and report upon.

G.B. Ry. Laboratory, Stratford, London, E.

ON THE SO-CALLED II., OR COMPOSITE HYDROGEN SPECTRUM OF DR. B. HASSELBERG.†

By Prof. A. GRÜNWALD.

BALMER has shown in the "Transactions of the Naturalists' Society" (*Wiedemann's Annalen*, xxvi., p. 80) that the wave-lengths of a part of the rays in the line-

* July 10th, 1889.

† Read before the Imperial Academy of Sciences, at Vienna, April 17th, 1890.

spectrum of hydrogen, $H\alpha$, $H\beta$, $H\gamma$, $H\delta$, have simple rhythmical relations to each other, so that any one of these wave-lengths may be represented by the formula—

$$\lambda = h \frac{m^2}{m^2 - 4}$$

($m=3, 4, 5, 6 \dots$) h being independent of m .

If we put $m=n+2$, we have then for the wave-lengths of the rays in question: $\lambda_1, \lambda_2, \lambda_3, \lambda_4 \dots$ the formula—

$$\frac{1}{\lambda_n} = \frac{1}{h} \left(1 - \frac{4}{(n+2)^2} \right),$$

($n=1$) ($1, 2, 3, 4 \dots$), and there exist the proportions—

$$\frac{1}{\lambda_1} : \frac{1}{\lambda_2} : \frac{1}{\lambda_3} : \frac{1}{\lambda_4} \dots : \frac{1}{\lambda_n} \dots = 1 - \frac{4}{3^2} : 1 - \frac{4}{4^2} : 1 - \frac{4}{5^2} : 1 - \frac{4}{6^2} \dots : 1 - \frac{4}{(n+2)^2}$$

The minute examination which the author undertook towards the end of last year on the II., or so-called compound hydrogen spectrum of Dr. B. Hasselberg, which he (Prof. Grünwald) is about to communicate to the Imperial Academy under the above title, led to the very remarkable result that a large part of it can be resolved into a finite number of groups of rays, whose corresponding wave-lengths, $\lambda_1, \lambda_2, \lambda_3 \dots \lambda_n$, have rhythmic relations to each other.

To each of the homologous wave-lengths of the different groups of this kind there corresponds a value of the independent factor h in the first formula.

From this discovery, the numerical demonstration of which admits of no doubt, the primary atoms of the hydrogen molecule in question, which emit the above mentioned series of groups of rays, consist of very numerous atomic particles forming a nucleus of maximum density, and form around this a series of separate strata or rings, the density of which decreases with the distances of the strata from the nucleus. If we give these strata from the outermost to the nucleus, the numbers $1, 2, 3, 4 \dots n$, these densities are as the rational numbers—

$$1 - \frac{4}{3^2} : 1 - \frac{4}{4^2} : 1 - \frac{4}{5^2} : 1 - \frac{4}{6^2} \dots : 1 - \frac{4}{(n+2)^2}$$

The atoms thus constituted are the primary atoms "a" of hydrogen $H = ba_4$.

If we assume, as it is most natural, that the agglomerations of the simplest chemical atoms consist of a great number of atomic particles (which, again, may be the simplest agglomerations of the ether) and take place according to the same laws as do the systems of stars according to the hypothesis of Kant and Laplace, *e.g.*, the group of stars in Andromeda, it follows at once that the primary atoms "a" of hydrogen must have approximately the stratified structure of the nebula in Andromeda, as shown photographically by Isaac Roberts, in December, 1888.

The primary element, "b," must have a much more complicated structure, on account of its higher valence.

ACTION OF THE GAS FROM As_2O_3 AND HNO_3 UPON *p*-OXYBENZOIC ACID.*

By EDGAR F. SMITH.

In vol. viii., p. 99, of the *American Chemical Journal*, I called attention to the fact that when methyl salicylate, in ethereal solution, was exposed to the gas arising from arsenic trioxide and nitric acid, ethers of α and β -meta-nitro-salicylic acids were produced. This procedure gave a ready method for the production, as well as an easy means of separating these two acids, the ether of the

α -acid being readily soluble, while that of the β -acid was practically insoluble in ether.

The ethyl ether of meta-oxybenzoic acid, in ether, gave when acted upon as above ethers of β -nitro-meta-oxybenzoic acid (m. p. $230^\circ C.$) and trinitro-meta-oxybenzoic acid (m. p. $171^\circ C.$). The details of this investigation may be found in the *Proceedings of the American Phil. Soc.*, September 7, 1888. I have recently experimented in the same line with *p*-oxybenzoic acid. The starting point was ethyl para-oxybenzoate, prepared according to the recommendation of Hartmann in the *Journal für Praktische Chemie* [II., xvi., 50. The ether thus obtained, after crystallisation from water, gave the constant melting point $112.5^\circ C.$, as stated by Graebe (*Annalen*, cxxix., 146), and not $116^\circ C.$, as given by Hartmann. The pure ether was next dissolved in ordinary ether, and the solution then acted upon for one and one-half hours, in the cold, by the vapours from nitric acid and arsenic trioxide. The flask containing the ethereal solution was corked and allowed to stand in a cool place for several days, after which the ether was distilled off. The residue was dark and oily, but after several hours became solid and crystalline. By solution in hot alcohol and re-crystallisation long, stout, red-coloured needles were obtained. These melted regularly at 69° – $70^\circ C.$ Barth (*Jour. f. Prakt. Chemie*, c., 369), speaking of the action of nitric acid upon ethyl *p*-oxybenzoate, mentions two products, ethyl nitro-para-oxybenzoate and ethyl dinitro-para-oxybenzoate. His description of the mononitro ether is so meagre that I was not able to determine at first whether I was dealing with a well-known compound or an entirely new product. The subsequent analysis of the free acid left no doubt as to the identity of my compound and that described by Barth. This chemist remarks that the melting-point of the nitro-ether lies below $-100^\circ C.$, I have found it as above -69° to $70^\circ C.$ On boiling the ether with caustic potash for some time and then acidulating the alkaline liquid a crystalline mass separates. It dissolves readily in hot water, crystallising from it, on cooling, in long needles with a faint yellow colour. At times the needles showed a flesh-red colour; this was removed by boiling the aqueous solution with animal charcoal. When pure the acid melted at 184° – $185^\circ C.$, the same as the acid obtained by Barth. A nitrogen determination, made by Mr. Seal of this laboratory gave 7.95 per cent N. The required N for a mononitro-*p*-oxybenzoic acid is 7.65 per cent.

An attempt to estimate the nitrogen in the ether by the Kjeldahl method failed.

Griess (*Berichte*, xx., 480) also obtained nitro-*p*-oxybenzoic acid of melting-point $185^\circ C.$, and showed that it was identical with the acid he had previously prepared from *p*-amidonitro-benzoic acid by boiling with KOH, so that its constitution and that of the acid prepared by me as above described is undoubtedly—

Hasse (*Berichte*, x., 2188) states that nitro-*p*-oxybenzoic acid contains water of crystallisation. The acids of Barth, Griess, and myself are anhydrous.

While *p*-nitro-oxybenzoic acid requires a large volume of hot water for its solution, its sodium salt is very soluble, and from its concentrated liquid separates in beautiful red coloured needles forming bundles.

The amide of the acid ($C_6H_3(NO_2)OH.CONH_2$) consists of beautiful orange-yellow coloured tufts. It melts at 160° – 161° , and dissolves easily in hot alcohol.

The above account concludes my study of the action of the vapours from nitric acid and arsenic trioxide upon the three hydroxy-benzoic acids. The results briefly summarised are these:—

* From the Chemical Section of the *Journal of the Franklin Institute*, December, 1889.

With ortho-oxy-benzoic acid two nitro acids were obtained; with meta-oxy-benzoic acid one nitro acid and a tri-nitro-meta product resulted; and with para-oxy-benzoic acid, one meta-nitro acid.

The course of the reaction in these three cases (the *m*-oxy-acid excepted) was not attended by any troublesome intermediate products, and for this reason the method may perhaps become serviceable in the nitration of other oxy-acids.

THE ACTION OF HYDROGEN SULPHIDE GAS UPON METALLIC AMINES.

By EDGAR F. SMITH and HARRY F. KELLER.

WHEN pure, dry hydrogen sulphide gas was conducted over palladammonium chloride, $\text{Pd}(\text{NH}_3\text{Cl})_2$, no change occurred in the appearance of the compound. However, on applying a gentle heat (70° – 80° C.) to the boat containing the metallic amine, the latter gradually assumed a black colour. This change extended throughout the entire mass. Upon increasing the heat ammonium chloride was volatilised. The residue was found to consist of palladium and sulphur. Single mineral acids were without effect upon it. Aqua regia attacked it very slowly.

I. 0.3790 grm. of $\text{Pd}(\text{NH}_3\text{Cl})_2$ gave 0.2498 grm. of the black sulphide. Assuming that the latter is represented by the formula PdS , the required monosulphide for the quantity of palladammonium chloride used would be 0.2484 grm.

II. 0.2795 grm. $\text{Pd}(\text{NH}_3\text{Cl})_2$ gave 0.1822 grm. sulphide, while the calculated amount should be 0.1831 grm.

This behaviour of the palladammonium chloride led us to expose the following metallic amines to the action of hydrogen sulphide gas:—

Purpureo-Cobaltic Chloride ($\text{Co}_2\text{Cl}_6, 10\text{NH}_3$).—0.5287 grm. of this substance, finely divided, were weighed out in a porcelain boat. The latter was placed in a combustion tube of hard glass. This was in connection, on the one side with a drying apparatus, on the other with a Peligot tube containing water. The latter served to produce a back-pressure of the gas, and in this manner the boat and its contents were constantly surrounded by an atmosphere of hydrogen sulphide. The gas was at first allowed to act in the cold. It produced an immediate change. The cobalt amine assumed an intense black colour. To all appearances the change was complete in a few minutes, and extended through the entire salt. On the application of a gentle heat (80°) ammonium chloride volatilised. Later the heat was raised, and a current of carbon dioxide substituted for the hydrogen sulphide. The boat was allowed to cool down in the gas. The final product was dense, and black in colour. Its weight was 0.2258 grm. Assuming the change of the amine was to sesquisulphide the amount of the latter, corresponding to 0.5287 grm. of the amine, would weigh 0.2253 grm. On examining the sulphide it was found to consist of sulphur and cobalt.

Roseo-Cobaltic Sulphate ($\text{Co}_2(\text{SO}_4)_3, 10\text{NH}_3 + 5\text{H}_2\text{O}$).—This salt, too, sustained an immediate change when acted upon in the cold by hydrogen sulphide. There was in addition a simultaneous evolution of moisture, and stellular, colourless crystals appeared on the walls of the combustion tube. These gradually dissolved in the water present, and imparted to it an intense yellow colour. The crystals were $(\text{NH}_4)_2\text{S}_2$. On gently heating roseo-cobaltic sulphate in a stream of hydrogen sulphide, it invariably happened that when a temperature of 70° C. was attained, the black mass, in the boat, swelled up considerably, and was projected into the tube. Some deep-seated change

occurred, which we are not prepared to explain at present.

Luteo-Cobaltic Chloride ($\text{Co}_2\text{Cl}_6, 12\text{NH}_3$).—This salt was affected by hydrogen sulphide in the cold, although heat was required to bring about a complete change. One quantitative determination gave the same result as was obtained with purpureo-cobaltic chloride, *i.e.*, that the product was evidently cobalt sesquisulphide.

Of the cobalt amines examined, the roseo-derivative was most rapidly changed by the gas. We have good reasons for believing that we can make this reaction serviceable in the determination of cobalt in these bases.

Purpureo-Chromic Chloride ($\text{Cr}_2\text{Cl}_6, 10\text{NH}_3$).—We exposed this salt for a long period, in the cold, to the influence of hydrogen sulphide, without its sustaining any alteration. On raising the temperature so that it was slightly lower than the dissociation temperature of hydrogen sulphide, the purple-coloured amine became quite black in colour. It had a velvety appearance and resembled the chromium sesquisulphide obtained by other methods.

I. 0.6390 grm. substance gave 0.2640 grm. sulphide. The theoretical amount should be 0.2629 grm.

When this sulphide is exposed to a high heat in a current of hydrogen gas, it parts very slowly with its sulphur.

It is our intention to apply this reaction to other metallic amines as soon as we can do so, though at present our work has been interrupted by unforeseen circumstances.

ON THE REMOVAL OF GOLD FROM SUSPENSION AND SOLUTION BY FUNGOID GROWTHS.*

By A. LIVERSIDGE, M.A., F.R.S., Professor of Chemistry
in the University of Sydney.

(Concluded from p. 279.)

Date.	No. 16.
11 10 89.	<i>Reduced by Ferrous Sulphate Solution.</i>
14 10 89.	Clear solution. Flocculent dirty bluish-green precipitate of gold.
1 1 90.	Pale green solution. Dirty green precipitate. No growth.
22 5 90.	Pale yellowish-green solution. Dirty green precipitate. No growth.
28 5 90.	Bottle coated with very thin film of gold. Bluish-black precipitate in powdery form, not coherent nor adherent to bottle. No growth. Solution colourless.
	No. 17.
11 10 89.	<i>Bread Crumbs.</i>
14 10 89.	Bread stained purple outside. Blue-purple solution. Neither growth nor precipitate.
1 1 90.	Pale blue solution. Bread stained blue-black. Slight fungoid growth on bread of a pale purple-blue colour.
22 5 90.	No further change.
28 5 90.	No further change.
	No. 18.
11 10 89.	<i>Potassium Tartrate Mould.</i>
14 10 89.	Purple-red solution. No precipitate. Mould stained purple.
1 1 90.	Thick, dark bluish growth. Pale blue solution.
22 5 90.	Thick, dark bluish growth. Purple slate-coloured solution.

* Read at the Chemical Section of the Franklin Institute, October 21, 1890.

* From the *Transactions of the Australasian Association for the Advancement of Science*, Melbourne Meeting, 1890, Section B.

28 5 90.—Solution colourless. Mould very voluminous, readily floating about, of a deep bluish colour. Growth $\frac{3}{4}$ of an inch across. Also a blue-black deposit.

No. 19.

Magnesium Sulphate Mould.

14 10 89.—Colourless solution. All gold precipitated. Mould stained dirty green.

1 1 90.—Slight dirty green precipitate. Mould dark green, but had not increased.

22 5 90.—No apparent alteration.

28 5 90.—Colourless solution. Slight blue-black precipitate. Mould blue-black also.

No. 20.

11 10 89. *Green Cheese Mould.*

14 10 89.—Purple-red solution. Cheese mould stained purple. No growth nor precipitate.

1 1 90.—Purple-blue solution and growth.

22 5 90.—Purple-blue solution and growth.

28 5 90.—Dark purple-blue solution. Blue-black growth on pieces of the cheese mould.

No. 21.

11 10 89. *Phosphorus in Turpentine.*

14 10 89.—Red-purple solution. No precipitate. No growth. Turpentine floating on top.

1 1 90.—Red (ruby) solution. Some whitish growth.

22 5 90.—Ruby solution. Some dark ruby-coloured mould in addition to the whitish growth.

28 5 90.—Solution red. Growth dark-red, mixed with some white.

No. 22.

11 10 89. *Phosphorus in Carbon Disulphide.*

14 10 89.—Pale purple solution, the carbon disulphide of a dirty colour.

1 1 90. Slate-purple solution. Adherent film of light slate-coloured deposit. No growth.

22 5 90.—No apparent alteration.

28 5 90.—Dark (slate) purple solution. No growth and no precipitate at bottom.

No. 23.

Oxalic Acid Mould.

11 10 89.—Deep purple in ninety minutes.

14 10 89.—Red purple solution. No precipitate, and mould had disappeared.

1 1 90.—Purple colour. No mould and no precipitate.

22 5 90.—Slight growth at bottom.

28 5 90.—Red-purple colour. No growth and no precipitate.

No. 24.

11 10 89. *Phosphorus in Chloroform.*

14 10 89.—Almost colourless solution. Chloroform at bottom of a pale purple-blue colour. No precipitate. No growth.

1 1 90.—Red-purple solution. No growth. A little black deposit.

22 5 90.—Pink-purple solution. A whitish growth. A little black precipitate.

28 5 90.—Pale ruby-red colour. Turbid (metallic) looking. Small quantity of purple-red growth in small heavy pieces. Also small pieces of a waxy-looking material, probably separated phosphorus.

No. 25.

Banana Skin Scrapings (Mouldy).

11 10 89.—Pale-purple in ninety minutes.

14 10 89.—Dark-purple solution. Skin stained. Slight precipitate.

1 1 90.—Dark purple-red solution. Growth on skin almost black.

22 5 90.—Dark blue purple solution. Growth on skin black. Dark growth at bottom of solution.

28 5 90.—Dark blue purple solution. Growth on skin purple-black. Also purple-black loose precipitate.

The details of the experiments are given since they show the first appearance of the mould and the time, taken for the change in colour according to the removal of the gold.

It is noticeable that no growth was produced where chloroform, turpentine, or carbon disulphide was used as the solvent for phosphorus, but alcohol favoured such growth. The development of the mould may be in part due to the presence of the alcohol radical (C_2H_5) ethyl existing in both ether and alcohol; the presence of phosphoric acid, we know, is as essential to penicillium as it is to man.

It is remarkable that the oxalic acid mould did not increase but disappeared (confirmatory experiments are required on this and other points). The organic substances, like bread, &c., behaved as might have been expected.

It was found by Roulin that the salts of iron and zinc promoted the growth of moulds; and Hamlet ("Australasian Association for the Advancement of Science," Sydney, 1888, p. 326), found zinc in the mould of mouldy bread, and it may be that many other metallic substances, including gold, are favourable to the growth of moulds.

There is no doubt that gold in natural waters could be removed by any moulds with which it might come in contact; but then any other organic matter, living or dead, does the same. Hence at this stage of the experiments I do not wish to draw any inferences as to the possible part which fungoid growths may have had in the separation and accumulation of gold in natural deposits, alluvial or otherwise.

THE DRY ASSAY OF TIN ORES.* PART II.

By HEINRICH O. HOFFMANN,
Assistant Professor of Mining and Metallurgy.
(Continued from p. 277).

V. Influence of Associated Minerals on the Assay.

THE minerals that are liable to remain with the black tin after the ore has been washed, roasted, and treated with nitro-hydrochloric acid, are quartz, felspar, mica, tourmaline, garnet, and columbite (tantalite). To test their influence, the minerals were ground fine enough to pass through a 60-mesh sieve, and any particles of iron coming from the implements used in grinding were removed by the magnet. The minerals were mixed with the black tin in the different proportions shown in the subjoined tables, and the effects studied which they have on the two best methods of assay,—the German method and the method of fusing with potassium cyanide. The charges were so regulated that the flux in the German assay was always equal to three times the quantity of the ore plus the mineral, and in the cyanide assay to six times the quantity. Four parts of cyanide were mixed with the ore; one part served as bottom for the crucible and one part as cover. In the German assay, the amount of borax glass was increased in proportion to the percentage of mineral added and that of salt decreased. The fusions were made in the usual way; the time for the cyanide assay had to be increased to not less than fifteen minutes before a tranquil fusion was obtained.

* Read at the Colorado Meeting of the American Institute of Mining Engineers, June, 1889. From the *Technology Quarterly*, Vol. iii., No. 3.

(1). The quartz used was the ordinary compact colourless variety.

The amount of soft slag found on top of the borax slag decreased in proportion to the percentage of quartz added, showing that a part of it had entered into combination with the borax slag. In assay No. 111 it was $\frac{1}{2}$ inch thick, in No. 115 only $\frac{1}{4}$ inch. Its structure was not so coarsely crystalline as usual. It grew finer, and the brittle slag became harder with increase of silica; the lustre remained the same; the colour varied from grey to bluish black. The borax slags increased in quantity as quartz was added, their vitreous character being somewhat impaired by the silica, and also their brittleness; the lustre remained uniform; the usual olive-green colour changed somewhat and became brownish. The buttons separated well from their slags, had the usual appearance, and were free from iron. The results obtained in Nos. 111 to 115 (see Table XXII.) showed a gradual decrease in the amount of tin recovered. This is, however, less than has been generally supposed from the figures of Berthier, Nos. 116 to 120, which are usually quoted.* Berthier,† as the writer understands it, mixes his siliceous ore with four times the amount of black flux. With the German method of charging the black tin with 67.84 per cent of tin mixed with 50 per cent of silica gave 51.30 per cent of metallic tin; Berthier's black tin containing 70 per cent of tin, with the same addition of silica, but mixed with the flux, gave only 28 per cent of tin, or 24.8 per cent less than is charged as in the German method. This shows the disadvantage of mixing ore with basic flux.

In the cyanide assays, Nos. 121 to 123, the slags showed uniformly a very coarsely crystalline structure and had a strong lustre. They were as opaque as usual, and became harder with the increase of silica. In No. 121 only the upper rim was parrot-green. This spreads in No. 122 so as to cover the entire surface; it is $\frac{1}{4}$ inch thick at the

circumference and $\frac{1}{4}$ inch in the centre; in No. 123, the thickness is uniformly $\frac{1}{4}$ inch. The appearance of the buttons is the same as if no silica had been added. The results show a decrease in the amount of tin recovered, but the loss is not so great as with the German assay.

(2). The felspar used was the compact albite that occurs so generally in the tin lodes; it has a very perfect cleavage, shows a pearly to a silky lustre, and is white with a tinge of grey.

Salt and borax slags of the German method, Nos. 124 to 128 (see Table XXIII.), are similar to those obtained when quartz was added to the ore. The buttons, however, are surrounded by a slag that is more stony than the borax slag above, and almost black. It adheres strongly to the buttons, and is liable to retain particles of metal. All the buttons were dark and dull; they were brittle, hard to cut, and contained iron, its presence being caused by the infusible character of the albite; the reduction was prolonged, and the ferric oxide of the cassiterite reduced before fusion took place, and alloyed with the metallic tin resulting from the more readily reducible stannic oxide. By examining the results, Nos. 124 to 128, it will be seen that, although all the buttons are ferruginous, the weight of the last four buttons is too low, showing that tin had also entered the slag, not enough iron being present to precipitate all the tin. The slagging is assisted by the intimate contact of the refractory felspar and the cassiterite. Owing to the character of the charge, stannic oxide, or even metallic tin, is liable to be slagged by the alkali carbonate, and stannous oxide by the silica.

The influence on potassium cyanide is seen by Nos. 129 to 131 (Table XXIII.). The upper white slag of pure cyanide with cyanate adheres to a lower porous slag of greenish grey colour, which encloses the buttons. These are white, bright, malleable, easily cut, and free from iron. The amount of tin lost, even if 37.50 per cent of albite is added to the ore, is only a little over 2 per cent. It is strange there should be so little difference between

* Mitchell, *op. cit.*, p. 483; Ricketts, *op. cit.*, p. 87.
† "Traité des Essais," 1847, vol. ii., p. 485.

the three assays which contain such varying amounts of albite. The only explanation seems to be that, at the low temperature at which the assay is carried out, the felspar is not decomposed, but remains suspended in the lower slag, which receives its greenish tinge from the iron of the cassiterite, and its grey from the felspar mixed with it. If the lower slag is boiled in water, it falls to pieces, leaving a residue that looks very much like the original pulverised albite after it has been moistened, except that it has a slight tinge of green, resulting from the iron.

(To be continued).

PROCEEDINGS OF SOCIETIES.

PHYSICAL SOCIETY.

November 28, 1890.

Prof. W. E. AYRTON, F.R.S., President, in the chair.

THE following communications were made:—

“Additional Note on Secondary Batteries.” By Dr. J. H. GLADSTONE, F.R.S., and W. HIBBERT, F.I.C.

After referring to the debateable points as to what compounds are formed and decomposed in the working of such batteries, the authors give the results of their examination of the red substance formed by the action of dilute sulphuric acid or minium, and which Dr. Frankland believes to be a compound having the formula $Pb_3S_2O_{10}$. The ultimate analysis showed 72 per cent of lead. A portion of the substance was treated with a 3 per cent solution of ammonium acetate, to dissolve out any normal sulphate that might be present; this left a residue much darker in colour than the original substance, and containing 82 per cent of lead. PbO_2 contains 86.6 per cent of lead. The colourless solution yielded a ratio of Pb to SO_4 varying from 2.0 to 2.15; pure $PbSO_4$ requires a ratio of 2.16, and Dr. Frankland's compound 3.23. From these results the authors conclude that the portion dissolved was not a basic sulphate, and that the evidence tells against the original substance being a chemical compound.

The authors have also continued their comparative experiments on the action of spongy lead on dilute sulphuric acid, either pure or containing a small quantity of sulphate of soda. After the experiments had gone on for five months, the residues were analysed. That from the pure acid showed 82 per cent of lead sulphate and 18 per cent of metallic lead; whilst that mixed with sodium sulphate gave 89 per cent of lead sulphate and 11 per cent of lead. They therefore conclude that although the action of acid on lead is initially diminished by the presence of sodium sulphate, the final result is rather the other way.

Mr. G. H. ROBERTSON, who had used ammonium acetate to analyse plugs from storage cells, said he had arrived at results much the same as those stated by the authors.

Mr. SWINBURNE said Dr. Frankland was absent, but without agreeing with him, he would suggest that Dr. Frankland might say that ammonium acetate decomposed the sub-salt $Pb_3S_2O_{10}$, and then dissolved the sulphate $PbSO_4$. The question might be attacked by acting on equal quantities of the substance and the mixture $PbO_2, 2PbSO_4$, in a calorimeter with ammonium acetate, to see if the same heat is produced; this would show whether the substance is a mixture or a compound.

Dr. S. P. THOMPSON was glad that the authors allowed a possibility of basic sulphate being formed, for it was well known that an almost irreducible sulphate resulted from leaving a cell nearly discharged; this, he thought, would point to a possible formation of a basic sulphate from PbO and $PbSO_4$. Mr. Swinburne did not see where the PbO came from, except in newly pasted negatives

he knew of no evidence of an intermediate stage of oxide on the plates. They appear to change directly to sulphate.

Dr. THOMPSON said that a rapid discharge was known to produce basic salts.

This Mr. SWINBURNE thought due to deficiency of acid near the plates. Peroxide, he said, could not be formed on the negative without the acid was heterogeneous and gave rise to local currents.

Mr. W. HIBBERT, referring to Mr. Swinburne's statement, said he had put one plate of spongy lead into strong acid, and another into weak, and from this arrangement obtained a fairly large current. As regards the basic sulphate spoken of by Dr. Thompson, he did not think there was much probability of its being formed. Time, he said, had an important influence on a discharged cell, and he would not expect to easily reduce the $PbSO_4$ formed by the long-continued action of lead on sulphuric acid.

The PRESIDENT enquired whether Mr. Hibbert's argument would apply to a fully charged cell.

Mr. HIBBERT in reply, said that in this case the time required to produce sufficient sulphate to be irreducible would be very much longer, for in a partially discharged cell much sulphate was already formed.

Dr. GLADSTONE said he had anticipated that Dr. Frankland would raise the objection referred to by Mr. Swinburne. As far as he was aware, there was no direct evidence either way, but he thought that the suggested decomposition was improbable. If he acted on a mixture of PbO_2 and $PbSO_4$, he would expect to get the results actually obtained. Mixtures, however, were difficult to deal with and the results not conclusive, for the physical condition of the mixture was not the same as that of the actual products. Referring to Dr. Thompson's remarks, he understood that it was the basic sulphate which he (Dr. Thompson) considered irreducible. Dr. Frankland, however, believed this sulphate more easily reduced than $PbSO_4$.

The PRESIDENT remarked that he thought Dr. Frankland had two reasons for his belief in the existence of the basic sulphates. One of these was the difficulty in reducing normal sulphate, whilst the other was based on the rapid fall of E.M.F. at a certain part of the discharge. It was at this point that Dr. Frankland thought the new sulphate formed, and to meet this argument it was necessary to find some other explanation of the rapid fall. In this connection he (the President) enquired whether there was sufficient peroxide formed on the negative plate to account for the drop.

On this point Dr. Gladstone could not speak decisively.

“An Illustration of Ewing's Theory of Magnetism.” By Prof. S. P. THOMPSON, D.Sc.

A number of small “charm” compasses were placed together on a glass plate of an ordinary vertical-attachment to a lantern. A large magnet at a distance served to neutralise the earth's field, and a coil enabled a magnetising force to be applied in the plane of the needles. By this apparatus all the various phenomena exhibited by Ewing's model were beautifully shown on a screen. In the course of his experiments Dr. Thompson had found that when small magnets placed at moderate distances apart were used, it was much more necessary to neutralise the earth's field, in order that they might set themselves according to their mutual attractions, than when larger magnets were employed. A weak field directed the small openly spaced magnets, whereas with larger ones their mutual actions were much more powerful. This fact, he thought, throw some light on the molecular grouping in magnetite (loadstone). This substance exists in two forms, viz., one crystalline and the other of a heterogeneous structure. The former variety exhibits no magnetic retentiveness, whilst the latter is decidedly magnetic. As far as he was aware no sufficient explanation had been given of the non-retentiveness of the crystalline variety. A difference in the molecular distances or groupings might account for the peculiarity.

Mr. BOYS said it was rather curious that Prof. Rücker had just devised a somewhat similar illustration of Ewing's theory, and he exhibited it at the meeting. It consists of little magnets made of long U-shaped pieces of watch-spring pivoted by glass caps on needle points; the needle points are fixed in little discs of lead stuck on a sheet of glass which forms the base of a glass box. An open helix surrounding the box serves to apply magnetic force.

Mr. SWINBURNE called attention to two theoretical points. First as regards susceptibility (which he regarded as a mere ratio and not a property), he said that if particles of iron at a high temperature rotate, as has been supposed, the susceptibility should be negative, and Prof. Ewing, he believed, had some reason to think that this was the case. The next point concerned the loss of energy when an armature rotates in a strong magnetic field; this, he said, was known to be considerable, whereas if Ewing's theory is correct he would expect little or no loss, for all the little magnets would always put themselves in the direction of the field and would never pass through positions of unstable equilibrium.

The PRESIDENT said he had discussed the question of negative susceptibility some years ago with Dr. Lodge with reference to the drop in the characteristics of dynamos, but he was not aware that any direct evidence had been obtained.

Prof. PERRY thought negative susceptibility might be possible in strong fields, but not in weak ones.

Mr. SWINBURNE, on the contrary, considered its existence would be more marked in weak fields.

Mr. H. TOMLINSON said he had tried experimentally whether the susceptibility of nickel, when heated above its critical temperature, was negative, but he had not been able to detect it, although his apparatus was very sensitive.

"The Solution of a Geometrical Problem in Magnetism."
By THOMAS H. BLAKESLEY, M.A.

The problem referred to was the following:—Given the two poles of a magnet and a straight line intersecting at right angles, its axis produced, to determine at what point this line is parallel to the field. The question is of scientific interest, because if the point be found experimentally, the distance between the virtual poles of the magnet can be determined, whilst it is important practically from its bearing on the deviation of ships' compasses in certain cases.

The instances in which it would apply are pointed out in the paper.

Assuming the points m and n (see figure) to be the

positions of the virtual poles, and P the required point it is shown that—

$$\frac{m}{(d^2 + m^2)^{\frac{3}{2}}} = \frac{n}{(d^2 + n^2)^{\frac{3}{2}}}$$

where $om = m$, $on = n$, and $oP = d$. From this the expression—

$$\left(\frac{d^2}{2mn}\right)^3 - \frac{d^2}{2mn} - \frac{1}{2} \frac{m^2 + n^2}{2mn} = 0$$

is deduced.

Now in hyperbolic trigonometry we have a formula—

$$\cosh^2 \theta - \frac{1}{2} \cosh \theta - \frac{1}{2} \cosh 3\theta = 0;$$

hence, making $\frac{m^2 + n^2}{2mn} = \cosh 3\theta$ we have also $\frac{d^2}{2mn} = \cosh \theta$

The value of θ can be then found by aid of the tables of hyperbolic sines and cosines, compiled by the author, and published recently by the Society. The distance d can thus be determined in terms of m and n .

A method of finding the point experimentally is then described, and the distance between the poles ($2a$) shown to be given by the expression $\frac{a}{l} = \tanh \frac{3\theta}{2}$; where

$$\frac{l}{d} = \sqrt{\frac{\cosh 3\theta + 1}{4 \cosh \theta}}, l \text{ being the distance } oc. \text{ The}$$

latter function can be deduced from the tables already referred to.

Experiment shows that the distance between the virtual poles soon approaches the length of the magnet as d increases.

The strength of the field at P is given by the expression $\frac{4M}{d^3} \frac{\cosh^3 \theta}{4 \cosh^3 \theta - 1}$; where M is the moment of the magnet.

This can be simplified by arranging d and l so that $\cosh^2 \theta = \frac{5}{4}$, and then becomes $\frac{5M}{8d^3}$. Under these con-

ditions, $\frac{l}{d} = 0.85065$, and therefore the angle $oCP = 40^\circ 23' 10''$.

NOTICES OF BOOKS.

Decimal Coinage; Weights and Measures Popularly Explained. By Sir GUILFORD MOLESWORTH, K.C.I.B. and J. EMERSON DOWSON, M.Inst.C.E. Revised and issued by the Decimal Association, Eastcheap, E.C. Kenric B. Murray, Secretary.

It is, in these days, scarcely possible that any serious objection can be urged to the principle of decimal weights, measures, and coins. The object of the present pamphlet is to combat some of the objections to its introduction which are popularly entertained. Others, however, they overlook, and it might not be time lost were the Decimal Association to consider how these difficulties could be met or avoided. One of these points is the loss to be incurred by reducing all existing measures and weights to the condition of waste material, and by throwing aside all tables used by engineers, surveyors, &c. For this we can see no remedy: the loss must be faced sooner or later, and perhaps the sooner the better.

A second point concerns the law courts. It would be very easy for Parliament to legalise the metric system. But unless it is made universal and compulsory, it will merely increase the existing complication. Now, attempts at uniformity of weights and measures have hitherto been made with but slender success. The pound and the ounce are, indeed, the same throughout England, but the stone and the peck vary within distances of twenty miles. It will be necessary when we introduce the metric system to make it penal to sell, quote, or buy, by any of the old standards. Out of this, we fear, a popular election catchword would be manufactured against the Government which proposed the change.

A more tangible difficulty, but one capable of being

removed, lies in the names which the French and their followers have thought proper to give to the different metric denominations. These names are all polysyllabic, whilst the names of the majority of our customary weights and measures are monosyllables. Here, an improvement on the present guise of the metric system is possible. We might call, *e.g.*, the metre, *yard*, and the demi-kilogramme, *pound*; both, of course, being a little larger than the present weight and measure.

Another practical difficulty is the somewhat pedantic refusal of the friends of the metric system to make up their weights in any form other than in multiples and sub-multiples of 10. If we open a box of weights as used in the laboratory, we find the following pieces:—0.1, 0.2, 0.5, and 1.0. In an English set of grain weights the pieces are 1, 2, 3, 6, 10. Now on trial it will be found that the English arrangement allows us to make up any desired weight, on an average, with fewer pieces than does the French. Many persons also object to the flat pieces of metal with the value stamped upon them as being more open to mistakes than the bent wires used in English chemical weights. To prevent any confusion between, *e.g.*, 6 grains and 0.6 gm. the latter might be made of flattened wire.

These two latter points, of course, are mere matters of detail which fall within the competence of the makers of balances and weights. The nomenclature of the denominations seems certainly to merit the attention of the Association.

CORRESPONDENCE.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—The penultimate paragraph of Mr. Friswell's letter in your last issue emphasises the urgency for the settlement of the controversy as to admission of persons to the Fellowship of the Chemical Society, for it is obvious that pending settlement either *all* or *no* candidates must be admitted.

It is therefore to be regretted that those taking part in the debate are discussing details rather than principles and imputing motives instead of ascertaining facts.

The issue is of the plainest:—

If the title F.C.S. be permitted to continue to confer, as it undoubtedly does, a distinct advantage on its possessor, causing him to be considered a chemist by the outside public, it is absolutely essential that none but perfectly qualified persons shall be allowed to hold it, and the most drastic employment of the ballot must be resorted to in order to check the admission of unqualified candidates, and means must be adopted to eject those who have already been admitted without due qualification.

If, on the other hand, the Chemical Society be merely a convenient common centre for all interested in chemistry, whether professional chemists or the veriest *dilettanti*, it is of the most urgent necessity that the pretensions of those using their membership for trade purposes shall forthwith be demolished by the wide and persistent advertisement of the fact that they have no qualification whatever, and that the letters F.C.S. are absolutely devoid of significance when used as a diploma. There appears to be no possible middle course.

Those responsible for the present agitation have adopted the first supposition as their working hypothesis, and are bestirring themselves to prevent future admission of those whom they consider unqualified, regardless of their illogical position in not crusading against those already admitted.

Those who do not agree with their views must needs

be anxious for the prompt execution of the alternative policy. Those upholding the present system (if any there be), accepting the public estimate of the high value of the title F.C.S., while bestowing it upon those who neither desire nor deserve to be considered chemists, convict themselves of being either illogical or dishonest.—We are, &c.,

A. G. BLOXAM.
BERTRAM BLOUNT.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—It is greatly to be regretted that Mr. Friswell should see fit to adopt the tone which he does in writing to you upon the above subject, and that in his no doubt well-meant anxiety for the welfare of the Society, he should be led into, what appears to me to be, an inaccuracy of statement. In your issue of 21st November, Mr. Friswell says that a circular recently issued by Messrs. Lloyd and Teed had "a remarkable resemblance in type and paper to Chemical Society's notices." This statement amongst others was denied by those gentlemen in your issue of 28th November, and with their opinion I concur.

Mr. Friswell now advances a fresh assumption with reference to the probable number of supporters of Messrs. Lloyd and Teed in so definite a manner that he must surely be in a position to prove the truth of this statement. Moreover, as his word is questioned, it becomes his duty, both to himself and the Society, to substantiate his facts and figures. If, on the other hand, Mr. Friswell should find that he has been misled into making an erroneous statement it would surely be in better taste to publicly withdraw his accusation, than to make a second statement which he asks your readers to believe without furnishing the least evidence in support.

It is clearly manifest that reform in the method of admission to the Chemical Society is needed in the interests of the profession, and equally obvious that a subject of such real importance should be calmly debated on its merits without the semblance of acrimonious insinuations or unpleasant personalities. These have no bearing on the issue.—I am, &c.,

W. J. LIVINGSTON.

18, Arbour Street, East Stepney.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 18, November 10, 1890.

New Researches on the Synthesis of Rubies.—E. Fremy and A. Verneuil.—The authors believed that they have solved the problem of "feeding" crystals of ruby in the dry way, just as other crystals are fed in the wet way. The crucibles are now heated by gas fires in place of coke. They often find amongst their red crystals others of a violet or a blue colour. They submitted to the Academy crystals red on one side and blue on the other. Hence, it appears probable that the colour of the ruby and the sapphire is due to one and the same metal—perhaps chrome in different stages of oxidation.

Compounds of Mercury Cyanide with Cadmium Salts.—Raoul Varet.—An account of cadmium-mercury iodide, bromide, and chloride.

The Fluor-Spar of Quincié.—H. Becquerel and H. Moissan.—Certain varieties of fluor-spar, if pounded, emit a peculiar odour. The spar from Quincié gives off gas of a penetrating scent, which recalls that of ozone and also that of fluorine. It decomposes water, forming hydrofluoric acid and ozonised oxygen. The authors conclude from their experiments that the fluor-spar of Quincié contains an occluded gas, which is observed escaping when the mineral is broken up under the lens. All the reactions of this fluor-spar may be simply explained by the presence of a small quantity of free fluorine among the occluded gases.

On the Analysis of the Hypophosphorous, Phosphorous, and Hypophosphoric Acids.—L. Amat.—The oxygen compounds of phosphorus may be distinguished from each other by their reductive power, *i.e.*, by the quantity of oxygen which they take up on their conversion into phosphoric acid. For this determination, there may be employed either mercuric chloride, as proposed and employed by H. Rose, or potassium permanganate. The former method is the more precise, but the more tedious.

Preparation and Properties of Benzoyl Fluoride.—E. Guenez.—Benzoyl fluoride is a colourless liquid, with an odour more irritating than that of benzoyl chloride. It boils at 145°, and burns easily, with a smoky flame edged with blue. It attacks glass with very great rapidity. The results of its analysis correspond with the theoretical composition of benzoyl fluoride.

Synthesis of Citric Acid.—A. Haller and M. Held.—The authors set out with the preparation of acetone-dicarboxylic ether, which they convert into cyanhydrin; this, again, is made to yield citric acid. The crystals obtained gave the form, the taste, and the general properties of the natural acid.

No. 20, November 17, 1890.

On the Name Bronze: New Indications.—M. Berthelot.—The author, in his *Introduction à la Chimie des Anciens*, expressed the opinion that the name "bronze" took its name from the town of Brundisium, the seat of certain manufactures in this alloy: *as Brundisium*. But in a manuscript three centuries older, discovered in the library of the canons of Lucca, and reprinted by Muratori in his *Antiquitates Italicae* we read: "De compositis brandisii: eramen partes II., plumbi parte I., stagni parte I." Another formula in the same work prescribes: "eramen partes II., plumbi partem I.; vitri dimidium et stagni dimidium. Commisceat at conflas; fundis; secundum mensuram vasorum facit et agluten eramenti cum asinitru." It is remarkable that the word *vitridum* in the exact meaning of vitriol is repeatedly found in this M.S., which shows that the word is much more ancient than the epoch of *Albertus Magnus*.

On the β -Pyrazol Dicarboxylic Acids.—M. Maquenne.—The author has formerly shown that dinitrotartaric acid reacts upon the methylic or ethylic aldehyds in presence of ammonia, giving rise to monobasic acids which heat splits up into carbonic acid and β -pyrazol (glyoxaline). The same reaction occurs with many other aldehyds, and nitrotartaric acid is a special reagent for these bodies.

On a Phenol-Acid Derived from Camphor.—P. Cazeneuve.—The author has obtained an acid, the amethylcamphophenol sulphuric, which precipitates quinine, chinchonine, brucine, and strychnine, but not morphine, from their saline solutions. When boiling it reduces gold and platinum chlorides and ammoniacal silver nitrate, the last more slowly. It precipitates gelatin, but not starch water. It precipitates baryta water, but not lime water. The tannins which are phenol acids behave in a similar manner.

On the Saponification of Halogenous Organic Compounds.—C. Chabré.—The author concluded that the alcohols of higher atomicity might be obtained by saponifying their fluorhydrines. He has applied this reaction successfully to ethylene fluoride.

On the Active Starchy Derivatives.—M. Philippe, A. Guye.—The author gives a table of forty amylic derivatives, which are all dextro-rotatory.

The Fixation of Gaseous Nitrogen by Leguminous Plants.—Th. Schloesing, Jun., and Em. Laurent.—The authors show by an indirect method of experimenting that nitrogen is really gained in the course of the vegetation of the legumens, and they prove by direct methods that this gain is really due to the fixation of gaseous nitrogen. M. Berthelot observed that this memoir seems to close the controversy relative to the fixation of free nitrogen by the joint action of the soil, and of plants under the influence of microbia.

On the Microbian of the Nodosities of Leguminous Plants.—Em. Laurent.—The organisms in question form a distinct group intermediate between the bacteria and the lower filamentous fungi. The author proposes to call them *Pasturiacae*.

No. 21, November 24, 1890.

Facts Relative to the History of Carbon.—Paul and Léon Schützenberger.—If a slow, regular current of pure, dry cyanogen is passed through a porcelain tube heated to cherry-redness, it is very imperfectly decomposed into carbon and nitrogen, the bulk of the cyanogen issuing from the tube unaltered. At a white red heat the decomposition is more active, and the inner surface of the tube becomes lined with a thin, bright, blackish grey layer, with a lustre resembling that of graphite. But if a long boat of retort-coke, dusted over with powdered cyclite, is placed in the hottest part of the tube, the decomposition of the cyanogen is complete, and the tube becomes ultimately stopped up with a deposit of blackish-grey elastic filaments matted together. If a fragment of aluminium is placed in the boat the carbon deposited in its neighbourhood is also filamentous, but devoid of elasticity, and assuming, after compression, the appearance of graphite. The filiform carbon formed by the pyrogenous decomposition of cyanogen in presence of vapours of cryolite is a peculiar variety of carbon, approximating to, but not identical with, electric graphite. The property of forming oxyhydrated derivatives capable of being suddenly destroyed by heat does not belong exclusively to graphites and is met with in certain varieties of amorphous carbon, such as retort-coke. It will therefore be suitable to abandon the too exclusive names of *graphitic acids* or *oxides*, and give these bodies the general name of carbon hydroxides.

On the Artificial Production of a Chrome Blue.—Jules Garnier.—The author melts together, in a lined crucible—Potassium chromate 48.64 grms.; fluor-spar 65.0 grms.; silica 157.0 grms. The product is a glass of a fine blue, surrounded with a thin layer of metallic chromium, which is capable of being detached. This process, it appears, had been deposited in a "sealed paper" on June 13, 1887.

Researches on the Application of Measurements of Rotary Power to the Determination of the Compounds Formed by Aqueous Solutions of Malic Acid, with Double Potassium, and Sodium Molybdate, and Acid Sodium Molybdate.—D. Gernez.—The author's results are given in the form of a table, which does not admit of abridgment.

Bulletin de la Société Chimique de Paris.
Series 3, Vol. iv., No. 2.

Applications of the Oleorefractometer of E. H. Amagat and F. Jean to the Detection of Sophistications.—Ferdinand Jean.—This instrument enables us to ascertain the purity of an oil by a simple reading. If the oil is falsified the deviation will be more or less removed from the special degree of the pure oil, and according as this deviation is increased or lessened, we have a datum bearing on the nature of the oil fraudulently added. The indications of the oleorefractometer should

always be controlled by determining the specific gravity and the thermic degree as shown in the thermoleometer. In this manner it is easy to detect margarine or similar matters to butter, and to distinguish pure butter from sophisticated butters. For the examination of butter and solid fats, such as tallow and lard, the oleorefractometer is regulated always with the same standard oil to the zero B of the scale, the adjustment and the observations being made at 45°. Under these conditions pure butters deviate -35°, whilst the margarine Mège-Mouries deviates only -15°. All the vegetable oils deviate strongly to the right, hence oleomargarines containing oils of sesame or cotton deviate still more strongly from pure butter. Pure lard gives a deflection of -12.5, and cotton oil +20°. Hence an addition of 5 per cent cotton oil is revealed by a decrease of 2.5° in the deviation of the lard. If the oleorefractometer is adjusted to a suitable standard it may be used for the examination of benzenes, petroleum, turpentine, methylenes, and essential oils.

Apparatus for Checking the Results in Sugar Works.—P. Horsin-Déon.—This paper requires the accompanying figure.

Action of Camphoric Anhydride upon Benzene in Presence of Aluminium Chloride. Formation of an Acid and Acetonic Compound.—E. Burcker.—By causing the above bodies to react under conditions very similar to those which give rise to benzoyl-propionic acids the author obtains a substance agreeing with the formula $C_{16}H_{20}O_3$, and possessing acid and acetonic properties. If separated from its sodium compound it forms very light crystalline laminae, soluble in absolute alcohol, ether, chloroform, and acetic acid, very sparingly soluble in benzene, and nearly absolutely insoluble in water. This substance melts at 125–126°, and does not resume the crystalline state if the melting point has been slightly exceeded.

New Apparatus for the Manufacture of Pure Yeast.—A. Feuerbach.—This paper requires the accompanying cut.

Separation and Determination of Zinc in Presence of Iron and Manganese.—J. Riban.—This paper will be inserted in full.

New Method for Measuring the Sugar to be used in Wines intended to become Effervescent with a Pressure of n Atmospheres without fear of Breakage.—E. J. Maumené.—The weight of normal sugar candy necessary to produce a given weight of carbonic acid is exactly known. It is therefore sufficient to weigh exactly the carbonic acid absorbed by the wine in question to produce a force of 5 or 6 atmospheres perfectly constant. When the equilibrium is obtained it is easy to weigh the carbonic acid if the wine has been weighed previously, and weighed again after the absorption. The difference gives the weight of the carbonic acid if this gas is perfectly pure and anhydrous.

Vol. iv., No. 3.

On the Dissociation of Selenium Tetrachloride.—C. Chabré.—The author, in opposition to W. Ramsay, maintains his former view that selenium tetrachloride is dissociated into chlorine and subchloride, which recombine in the cooler parts of the receiver.

Means of Obtaining Nitrogen Hydride, NH_3 .—E. J. Maumené.—The author heats the double chloride of platinum and ammonium in a glass retort fitted with a tubulure drawn out to a point and melted. The vapours are first directed into a small bottle, where they traverse the surface of a known weight of water, then through a tube containing a little potassa, and lastly into a trough of water. The properties of the compound will be described in a future communication.

Remarks on the Phenomenon of Coagulation.—A. Béchamp.—The author summarises the various meanings which chemists have given to the word "coagulation,"

and traces the history of the albumenoids of white of egg. Passing to the study of the albumenoids of milk he concludes that the isolation of caseine by acetic acid is a phenomenon of displacement and not a true coagulation.

Chemical Industry at the Paris Exhibition of 1889. J. Krutwig.—A general review of the articles displayed at this exposition, which, of course, was the less interesting as one country exceptionally eminent in some departments of chemical industry declined to recognise the demonstration. The author still hopes for the success of artificial indigo, which he considers would be a great benefit.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale. Series 4, Vol. v., No. 56.

Report Presented by M. H. Le Chatelier on Behalf of the Committee of Chemical Arts on a Memoir by M. Deval, Relating to the Assay of Cement and Hydraulic Lime with Hot Water.—Trials of resistance in cold throw no light on the quality of a cement, since cements with an excess of lime, which is certainly detestable, resist the ordinary trials perfectly. Portland cements of good quality made up into mortar with one-third of normal sand, resist hot water at 80°. They give, after 2 and 7 days of hardening in hot water, resistances equal to what they give with cold water at the end of 7 and 28 days. Cements which contain too great an excess of free lime, whether from defective burning or from wrong proportions, do not resist immersion in hot water after setting for 24 hours. When the excess of lime is less the briquettes may resist hot water after setting for a longer or shorter time. But in this case the resistances in heat at the end of 2 and 7 days are much greater than those obtained in the cold after 7 and 28 days. A comparison of the resistances in heat and cold enables us to recognise the presence of free lime in cements. The author recommends that the trials should be made by immersing the briquettes in water at 80°, twenty-four hours after they have been made.

Journal de Pharmacie et de Chimie.
Series 5, Vol. xxi., No. 12.

Recognition and Determination of Starch.—A. Leclerc.—Starch may be dissolved out from other proximate vegetable principles, such as cellulose, fatty and nitrogenous principles, by means of neutral zinc chloride.

Detection of Olive-Kernels in Pepper.—M. Pabst.—Already noticed.

Determination of Urea.—D. B. Dott.—From the *Pharmaceutical Journal*.

The Colorimetric Determination of Nitric Acid by Means of a Sulphuric Solution of Diphenylamine.—J. A. Müller (From the *Bulletin de la Société Chimique*).

On the Attack of Certain Sulphides, such as Bournonite, Red Silver, &c., with a Current of Air charged with Vapours of Bromine.—P. Jannasch (*Journal für Praktische Chemie*).—Already inserted.

The Attack of Pyrites by a Current of Oxygen.—P. Jannasch (*Journal für Praktische Chemie*).—Already noticed.

Analysis of Wax.—H. Rättger.—The author concludes that in the analysis of bleached wax there is no need to adapt other normal numbers than for the analysis of yellow wax.

New Process for Utilising the Oxygen of the Air.—M. Georges Kassner.—The author has sought to substitute for barium manganate a body whose oxidising action may be as energetic as that of the manganate, which may be exerted under all circumstances, and which may be of an easy preparation. He has fixed upon calcium plumbate.

Use of Glycerin for Preserving Solutions of Sulphuretted Hydrogen.—From the *CHEMICAL NEWS*.

Improved Method of Obtaining Fine Crystallisations.—H. N. Warren.—From the *CHEMICAL NEWS*.

Preparation of Chlorine and Oxygen in the Cold in the State of a Continuous Current by means of Kipp's Apparatus.—Some time ago C. Winkler recommended for preparing chlorine in the cold a mixture of calcium hypochlorite and gypsum cast in sticks; these sticks when solidified are introduced into a Kipp's apparatus and treated with dilute hydrochloric acid, which produces a regular escape of chlorine at the common temperature. This process has been improved by R. J. Thiele, who simply submits the chloride of lime to energetic compression by means of a screw press so as to form a flat cake which is broken into fragments which are sufficiently resistant not to be liquefied in Kipp's apparatus. The only inconvenience of this method is that the chlorine may contain a little carbon dioxide, but in most cases this impurity has but slight importance. According to Volhard oxygen may be obtained with the same apparatus by causing oxygenated water to act upon the hypochlorite prepared as above described.

Rules for the Preservation of Antiquities.—From *Dingler's Journal*.

Conditions of the Reaction between Copper and Nitric Acid.—H. V. Riley.—From the *Journal of the Society of Chemical Industry*.

MISCELLANEOUS.

Royal Institution of Great Britain.—The following are the probable arrangements for the Friday Evening Meetings before Easter, 1891:—

Jan. 23rd. The Right Hon. Lord Rayleigh, M.A., D.C.L., LL.D., F.R.S. "Some Applications of Photography."

Jan. 30th. The Right Hon. Sir Edward Fry, Lord Justice, F.R.S., F.S.A., F.L.S. "British Mosses."

Feb. 6th. Professor J. W. Judd, F.R.S., F.G.S. "The Rejuvenescence of Crystals."

Feb. 13th. Professor A. Schuster, Ph.D., F.R.S., F.R.A.S. "Some Results of Recent Electric Experiments."

Feb. 20. The Right Hon. Lord Kelvin, M.D., F.R.S. "Infectious Diseases, their Nature, Cause, and Mode of Spread."

Feb. 27th. Percy Fitzgerald, Esq., M.A., F.S.A. "The Art of Acting."

March 6th. Professor J. A. Fleming, M.A., D.Sc. "Electromagnetic Repulsion."

March 13th. Felix Semon, M.D., F.R.C.P. "The Culture of the Singing Voice."

March 20th. Professor W. E. Ayrton, F.R.S. "Electric Meters, Motors, and Money Matters."

The Smoke Nuisance.—Meeting at St. James's Hall.—A well attended meeting was held at St. James's Hall on December 5th under the auspices of the Balloon Society of England. A well thought out and interesting paper was read by Mr. I. MacIntyre, B.A., upon the "Smoke Nuisance and its Solution." This was followed by a very vigorous discussion, the claims of many inventions being advocated. A resolution was ultimately put to the meeting and carried. "That the latest inventions for dealing with the difficulty, viz., Elliott's Smoke Annihilator, now being exhibited on the Thames Embankment, is worthy of the greatest consideration, and that the Government and the County Council be earnestly solicited to give a trial to the same."

MEETINGS FOR THE WEEK.

MONDAY, 15th.—Society of Arts, 8. (Cantor Lectures). "Gaseous Illuminants," by Prof. Vivian B. Lewes.

Medical, 8.30.
TUESDAY, 16th.—Institute of Civil Engineers, 8.
Pathological, 8.30.

WEDNESDAY, 17th.—Society of Arts, 8. "Impressionism in Photography," by George Davison.

Metereological, 7.
Geological, 8.

THURSDAY, 18th.—Chemical, 8. "The Constitution of Hydracetic Acid," by Dr. N. Collie. "The Theory of Dissociation into Ions, and its Consequences," by S. U. Pickering. "Phennoic Acid," by Dr. A. Colefax.

Royal, 4.30.
Royal Society Club, 6.30.
FRIDAY, 19th.—Quekett Club, 8.

PATENTS.

Provisional Protection, from £2 2s.

Lowest cost of complete English and Foreign on application. Also, Designs and Trade Marks. Inventions financed.

WALLACE, WEATHERDON, & CO.

REGISTERED PATENT AGENTS,

57 & 58, Chancery Lane, and 11, Southampton Buildings, W.C.

Established 1849.

LATEST RESEARCHES ON THE PHOTOGRAPHY OF METALLIC SPECTRA.*

By Prof. V. SCHUMANN.

I HAVE succeeded in photographing the ultra-violet spectrum beyond 1820 for a considerable extent. I thus obtain photographs which, if measured from Al No. 32, λ 1852 (Cornu), are two or three times as long as the entire spectral region between H (λ 4861) and Al No. 32. Hydrogen possesses the greatest photographic energy and the most refrangible rays; no other spectrum is so rich as this in lines in the extreme ultra-violet. These photographs can be taken only in a vacuum, and with plates sensitive for the ultra-violet. All known photographic plates, even the gelatin emulsion plates, are not sensitive for waves of very small wave lengths; hence they could, hitherto, not be photographed. I have invented a new sensitive plate the photographic maximum of which lies in the most refrangible spectral region. I propose, subsequently, to publish my process of preparing these plates.

During the last six weeks I have been perfecting my vacuum spectrograph, and have fitted it with a sliding slit which is within the apparatus, and consequently in a vacuum, but capable of being manipulated from without. For this purpose the slide is provided with two micrometers, one for the width of the slit and the other for its length. The edges of the slit are absolute edges, and the jaws are ground optically plane. These jaws are made of hard steel. I thus obtain a very even slit for the light, and consequently very well-defined spectrograms. When I use a magnifying power of 100^x the photographs taken are still fit for measurement. This is scarcely possible with other spectrograms on gelatin plates if strong magnifying powers are used.

I will shortly send you a sketch of the newly discovered lines of thallium, which lie beyond the lines shown in the spectrogram which I have already sent you. The taking of the photographs of these new lines involved especial difficulties, as the vapours of thallium oxide arising from the passage of the spark between the metallic electrodes coated the window of the vacuum spectrograph, and rendered it opaque, thus keeping back the effective rays. The air is so impervious to the most refrangible rays that I had to let the spark strike across quite close to the window. Hydrogen is very pervious, but the photographic energy of the spark striking in this gas is so faint that less can be done in this manner than in atmospheric air. Had the photographic action of the light been greater I should have allowed the spark to pass in hydrogen gas.

THE ANALYSIS OF WATER TO DETERMINE SCALE-FORMING INGREDIENTS.†

By Prof. THOMAS B. STILLMAN.

THE scale-forming ingredients of a water are usually composed of calcium and magnesium carbonates and calcium sulphate, and though an analysis of a water for boiler purposes usually states the number of grains per gallon of the above constituents, the analysis should also comprise the determination of many other ingredients, not

scale forming, that are necessary to a proper estimation of the former.

This is especially true of the alkalis, which are not always determined in a commercial analysis for boiler purposes, the amount of lime, magnesia, chlorine, carbonic and sulphuric acids being considered a sufficient index of the character of the water.

The alkalis and their salts rarely form scale in boilers,* and so cannot be classed as scale forming, yet they play fully as important a part in the relation they sustain to the sulphuric acid and chlorine.

If all the sulphuric acid in a water were combined with the alkalis there would be no sulphate of lime present, and the latter would be eliminated as part of the scale ingredients. This is a condition rarely occurring, however, since in most waters a portion of the sulphuric acid is united with the alkaline earths and the alkalis. The indirect estimation of the carbonic acid would be changed also. That is to say, where the CO_2 is estimated by uniting all the CaO and MgO (left uncombined with the SO_3 and Cl) with CO_2 , it is evident that if all the SO_3 is united with CaO , when a large portion belonged to the alkalis, the amount of carbonate of lime would be too small, and also that the proportion of the CO_2 would be deficient by the amount required to saturate the CaO incorrectly united with the SO_3 .

There is nothing in the usual commercial analysis to indicate whether the sulphuric acid, as determined in the water, is all united with the lime to form calcium sulphate or not; but the custom has been so to unite it; with the result that calcium sulphate may be represented as a large component of the scale-forming material, when in reality none whatever may be present. The converse is also true. In a partial analysis of the Monongahela River water (*Transactions American Institute of Mining Engineers*, vol. xvii., page 353), the amounts of objectionable substances, for boiler use, are given as follows:—

	Parts per 100,000.	Grains per gallon.
Total lime	161	= 94
„ magnesia	33	= 19
Sulphuric acid	210	= 122
Chlorine	38	= 22

It states further the amounts of carbonates of lime and magnesia precipitated upon boiling to be:—

	Parts per 100,000.	Grains per gallon.
Carbonate of lime	130	= 76
„ magnesia	21	= 12.2

The alkalis not having been determined, the proportion of sulphuric acid combined with lime becomes problematical; in fact, the inference is that there is none present, when, in all probability, it amounts to a large percentage.

Another example ("Report State Geologist," New Jersey, 1885, page 121), is as follows:—

Analysis of Water from Well No. 1.

	Grains per gallon.
Chlorine, as chlorides	2.2422
Sulphuric acid, as sulphates ..	0.3666
Silica	0.9098
Iron and alumina	0.0233
Lime	2.1461
Magnesia	0.3965

Alkalies and undetermined matter ..	6.0845
	6.7155

Total solids 12.800

* A sample of scale, analysed by the author in 1887, had the following composition:—Carbon, 1.01; SiO_2 , 1.38; Al_2O_3 , 0.43; NaCl , 7.12; KCl , 1.01; MgCl , 1.71; CaCl_2 , 10.32; CaSO_4 , 11.20; Undetermined, 0.68; Total, 100.00.

* Extracts from letters to the Editor.

† The *Stevens Indicator*, vol. vii., No. 4, Oct., 1890.

Analysis of Water from Well No. 2.

	Grains per gallon.
Chlorine, as chlorides	1'1955
Sulphuric acid, as sulphates ..	0'3091
Silica	0'5948

Lime	3'7907
Magnesia	0'6531
	6'5665
Alkalies and undetermined matter ..	5'5519
Total solids	12'1184

Numerous instances are constantly being cited in the literature of technical water analyses of similar incomplete analyses, and having thus indicated the necessity of including the alkalies, the accompanying scheme has been arranged to show the method of making a water analysis for boiler purposes.

To show in detail the method of using the scheme, the following water analysis is given. (Preliminary tests having shown the water to contain but little residue, 8 litres of it were evaporated).

	Grms.
Pt capsule and residue (8 litres)	147'460
" without residue	146'620
Total residue	0'840
Before ignition, capsule and residue	147'460
After " " " "	147'197
Organic, volatile (CO ₂ , &c.)	0'263
SiO ₂ + crucible	15'970
Crucible	15'904
SiO ₂	0'066
Solution made to 100 c.c.—75 c.c. for bases, 25 c.c. for SO ₃ .	
75 c.c.	
Fe ₂ O ₃ (Al ₂ O ₃) + crucible	15'9338
Crucible	15'903
	0'0308
CaO + crucible	16'0197
Crucible	15'903
CaO	0'1167
MgO + crucible	15'928
Crucible	15'903
MgO	0'025
SO ₃ .	
Crucible and BaSO ₄	16'023
Crucible	15'903
BaSO ₄	0'120

The chloride found by titration amounted to 0'0055 grms. per litre, or 0'32 grain per gallon.

	Grms.
Pt dish and alkaline sulphates and (MgSO ₄)	53'370
Pt dish	53'197
Sulphates	0'173

Dissolved in H₂O, made solution up to 50 c.c.—25 c.c. for magnesia determination, and 25 c.c. for potash determination.

	Grms.
Mg ₂ P ₂ O ₇ + crucible	15'942
Crucible	15'904
Mg ₂ P ₂ O ₇	0'038
0'038 × 2 = 0'076 Mg ₂ P ₂ O ₇	
Mg ₂ P ₂ O ₇ : (MgSO ₄) ₂ :: 0'076 : × MgSO ₄ = 0'082 gm.	
K ₂ Cl ₃ Pt Cl ₄ , on tared filters = 0'023 gm. corresponds to 0'0046 K ₂ SO ₄ in the 50 c.c.	

Having determined the amounts of sulphates of magnesium and potassium, the residue remaining is sulphate of sodium, as follows:—

	Grm.
Total sulphates	0'173
Magnesium sulphate	0'082
Sulphates of sodium and potassium ..	0'091
Sulphate of potassium	0'0046
Sulphate of sodium	0'0864

And calculated to their oxides would be as follows:—

	Grm. for 75 c.c.	Grm. for 8 litres.
MgO	0'027	0'036
Na ₂ O	0'0377	0'0502
K ₂ O	0'0025	0'0034

The weights above obtained are calculated in terms of the total residue, 8 litres, and then converted into values corresponding to 1 litre, the result being as follows:—

	Grm. per litre.
Silica	0'0082
SO ₃	0'0206
Cl	0'0055
K ₂ O	0'0005
Na ₂ O	0'0062
MgO	0'0077
CaO	0'0194
Fe ₂ O ₃ (Al ₂ O ₃)	0'0051
Organic, &c.	0'0193
Carbonic acid	0'0137
Oxygen in excess of Cl.	0'0016
Total residue	0'1046
(To be continued).	

THE DRY ASSAY OF TIN ORES.*

PART II.

By HEINRICH O. HOFFMANN,
Assistant Professor of Mining and Metallurgy.
(Continued from p. 293).

(3). THE mica used was a pure white muscovite.

The general behaviour of the assays, according to the German method, Nos. 132 to 136 (see Table XXIV.), is the same as those with felspar, the exception being that with 50 per cent of mica only an incomplete fusion could be obtained. In the bottom of the crucible was a porous fritted dark mass, no tin being visible; it was covered by a semi-fused scoriaceous spongy mass of a brown colour. The buttons had the same appearance and properties as those from the felspar mixture. The results show a greater loss of tin and a stronger reduction of iron than above, the reason being that muscovite is more refractory in the assay than albite.

* Read at the Colorado Meeting of the American Institute of Mining Engineers, June, 1889. From the *Technology Quarterly*, Vol. III., No. 3.

In the assays with potassium cyanide, Nos. 137 to 139, the behaviour of mica is similar to that of felspar, the mica appearing also here more refractory.

(4). The tourmaline pulverised for the experiments was the large black crystal which occurs so often with the tin ore.

In the German method, Nos. 140 to 144 (Table XXV.), the upper slag is parrot-green, the lower slag is slightly vitreous, but quickly becomes stoney with the increase of tourmaline. The buttons have all a grey surface; they dull, brittle, hard to cut, and ferruginous. These properties increase with the addition of tourmaline. In assay No. 124 no complete fusion could be obtained, and no button or particles of alloy were visible in the porous fritted dark mass. The results show a loss of tin increasing

with the addition of tourmaline, and an increased amount of iron is taken up by the tin.

With potassium cyanide, tourmaline has no effect that is essentially different from that of previous assays, as the slags show about the same appearance, and the buttons the same properties and nearly the same weight.

(5). The garnet occurring in the tin deposits is the iron garnet (almandite). It has a brownish red to fine deep red colour, and is very rich in iron. This appears in its high specific gravity, 4.149, and from the fact that, after being heated by itself in a crucible to a bright red heat, it shows magnetic properties. For the experiments, transparent crystals of a fine deep red colour were pulverised.

From Table XXVI. it will be seen that no borax was added to the charges of the German assay, Nos. 148 to 152,

as the garnet with the addition of a small amount of base (lime or alkali) forms a liquid slag. The salt slags were less crystalline than usual, but otherwise the same with the exception of the colour, which varied from light to dark red. The borax slags lost their vitreous and brittle character by the addition of garnet, became stony and tough, and changed from subtranslucent to opaque. The colour, a dull olive-green, became lighter, the last slag, No. 152, being peacock-green. The buttons were all a dull dark grey, hard to cut, brittle, and rich in iron. The weights obtained in the first four assays, Nos. 148 to 151, are strikingly close. This would seem to show that about the same amount of iron had been present in all of them, forming an alloy of nearly the same composition, the rest of the iron having remained in the slag. The uniformly well melted charges, and the beautiful manner in which the one-button separates from the slag above, show that, if tin is to be recovered from siliceous ore as an alloy, a basic silicate of iron is the best, because it gives up the necessary iron for the tin and also retains sufficient in combination to form with the alkali of the charge a readily fusible brittle slag.

In the cyanide assays the compact white upper slag decreases, and the porous bluish green lower slag increases as garnet is added to the charge. In No. 153 (Table XXVI.) the proportions were half and half, in No. 155 one quarter white and three quarters grey. The buttons are all ferruginous and show the usual characteristics. The figures prove that, although iron has been taken up, tin has gone into the slag.

(6). The columbite found with the tin ores has an iron-black colour and a streak that varies from a very dark brown to a pure black. The pure mineral has the following composition:—

	Per cent.
Ta ₂ O ₅	18.20
Nb ₂ O ₅	64.09
FeO	11.21
MnO	7.07
SnO ₂	0.10
CaO	0.21
Total	100.88

The specific gravity varies between 5.89 and 6.12. The columbite used for the experiments contained a small proportion of albite.

In the German assays, Nos. 156 to 160 (Table XXVII.), the salt slags were stony and dull; their colour, at first, a brownish green, gradually lost the brown, and became finally parrot-green. The borax slags were vitreous, brittle, and had a resinous lustre, the colour changing from a light to a dark olive-green. The buttons were all ferruginous; their colour, at first a dark grey, became black. The results show that the amount of iron reduced increased with the percentage of columbite added to the charge. Also, that if tin ore containing columbite be treated on a large scale, the columbite will probably behave in a way similar to the wolframite of Cornwall ores, where the iron that alloys with the tin is the principal cause of trouble, and not the tungsten of the mineral which, according to Berthier,† may be present in considerable quantities.

In the experiments with potassium cyanide the upper slags showed the usual properties, the lower slags were very porous, slightly glassy, and had a dark blue-grey colour. The porosity increased with the percentage of columbite added. The buttons were white, bright, malleable, easily cut, and contained very little iron; from their appearance they might have been supposed to be free from iron, until especially examined for this metal. If pure cassiterite and pure columbite are ground together and fused, thus intimately mixed, with potassium cyanide, the iron and manganese of the columbite combine with

the tin, leaving a yellowish slag which contains the columbic and tantallic acids.*

By comparing the effect produced by the associated minerals in the two methods of assay, we see that the cyanide assay must be accorded the preference, although, if the amount of associated mineral be small, the German method will give entirely satisfactory results.

In concentration works, where several assays have to be made daily, the question of cost must be considered, and the cheap German assay will probably be preferred to the more expensive one, especially if the assay is only made in order that the manager may know how pure his concentrates are. In questions connected with the buying and selling of ores or concentrates, the assay with potassium cyanide is better, because the associated minerals have comparatively little influence on it.

(To be continued).

THE COEFFICIENT OF MINERAL CONDENSATION IN CHEMISTRY.†

By T. STERRY HUNT.

1. THAT the solid and liquid mineral species known to us (including under the designation of minerals all distinct forms of unorganised matter) are formed by a process of intrinsic condensation or so-called polymerisation from simpler chemical species, which are themselves often gaseous, and, moreover, that this condensation is very considerable, is a conclusion to which chemists have been naturally led. The problem of fixing its amount, or, in other words, of determining the coefficient of the condensation which results in the production of such mineral species, is one which must present itself to every earnest student of chemical physics, but has nevertheless hitherto been generally disregarded. A reason for this neglect of the problem is to be found in the belief that it does not admit of solution, as may be shown by citations from the writings of many eminent chemists.

2. Thus Wolcott Gibbs in 1877, after reviewing the researches of his predecessors, Marignac, Scheibler, H. Deville, and Debray, on the various polytungstates and polymolybdates, and his own important contributions to the subject, describes these various bodies as salts of "complex inorganic acids," and proceeds to illustrate by formulae, the results of their chemical analysis. Of a certain hydrated phosphovanadotungstate of barium examined by him he declares that "it has the highest molecular weight yet observed, 20,058." By this we are to understand no more than that this number corresponds to the simplest chemical formula admissible, for he further says, "We have no positive knowledge of the composition of these salts, their molecular weights being, as in the case of most inorganic compounds, entirely unknown," adding that research "tends constantly to show that the structure of inorganic bodies is more complex than was formerly supposed."‡ The language of Roscoe in 1884 embodies the same thought when he speaks of looking forward to "the establishment of a systematic inorganic chemistry which need not fear comparison with the organic branch of our science"; and adds, referring to the complex inorganic acids of Gibbs: "It is well to be reminded that complexity of constitution is not the sole prerogative of the carbon compounds, and that before this systematisation of inorganic chemistry can be effected we shall have to come to terms with many compounds concerning whose composition we are as yet wholly in ignorance."§ It may be remarked, in passing, that the

retention by these writers of the old antithesis between organic and inorganic chemistry, as distinguishing carbonaceous compounds from other species, can only serve to hinder the systematisation and the unification of the facts of the science.

Still more recently, in 1889, Victor Meyer, in his address before the Association of German Naturalists and Physicians at Heidelberg on "The Chemical Problems of To-day," says with regard to the question of intrinsic condensation: "We know to-day very well that the silicon oxide cannot have the formula SiO_2 , and that this must be multiplied by a very large factor, but of the numerical value of this last we have no indication." Further he adds: "We lack the least knowledge in regard to the true molecular weight of minerals."*

3. The direct and concise language of Louis Henry of Louvain, in 1879, may be taken as a fuller expression of the opinions generally entertained by chemists on this subject up to the present time. Having shown that for most oxides of the elements the normal forms corresponding with the chlorides, as in the case of iron, aluminium, titanium, silicon, &c., are unknown, and that we possess only greatly condensed polymers of these oxides $(\text{RO}_x)_n$, he proceeds to inquire: "What is the true value of n , the coefficient of polymerisation, or, in other words, what is the real molecular formula of these polymeric oxides? These questions are, doubtless, of great interest, but it should be stated at once that it is absolutely impossible to give a direct answer. I do not know of any fact which would allow us to assign an absolute value to the coefficient of polymerisation, n So far as facts will permit a conclusion, we may affirm that in most cases this number is very high, though different for different oxides."†

4. The same important questions had been propounded by the present writer in 1853, when, after noting that the equivalent weights for volatile bodies are known from the densities of their vapour, but in the case of non-volatile bodies are assumed, it was said that "having determined the true equivalent of a species from the density of its vapour, the inquiry arises whether a definite and constant relation may not be discovered between its vapour-density and the specific gravity of a species in its solid state. Such a relation being established, and the value of the condensation in passing from a gaseous to a solid state being known, the equivalents of solids, like those of vapours, might be determined from their specific gravities." The question was then asked, "What is the value of the condensation which takes place in the change from the gaseous to the solid state? or, in other words, what equivalent corresponds to a given specific gravity in any crystalline solid?" It was further said: "The equivalent of a crystallised species may often be a multiple of that deduced from those chemical changes which commence only with the destruction of its crystalline individuality." This point was then illustrated by examples in the history of various soluble crystalline species.‡

5. The question thus proposed by the writer in 1853, and repeated by Louis Henry in 1879, was persistently kept in view by the writer, and discussed at intervals in many published papers until 1886, when he arrived at what he has elsewhere put forth as, in his opinion, a simple and natural solution. This is found in the conclusion that the volume, not only of gases and vapours, but of all

species, whether gaseous, liquid, or solid, is constant, and that the integral weight—being the so-called equivalent or molecular weight—varies directly as the density, for which he proposes as the unit that of hydrogen at the standard temperature and pressure of 0° and 760 m.m.

In all cases of polymerisation and depolymerisation of gases and vapour, or, in other words, of intrinsic condensation and intrinsic expansion at ordinary pressure, the law of volumes, so far as known, holds good; that is to say, these changes are subordinate to a simple ratio of volumes. This same law, it is here maintained, applies equally to the production of dense vapours of liquids under increased pressure at temperatures above their critical points. Such dense vapours are polymers, which, on reduction of temperature, pass into liquid or solid polymers; the law of condensation by volumes being, by the present hypothesis, assumed to be a universal one. The relations here indicated have been elsewhere considered at length, when, after discussing the law of volumes in ordinary cases of condensation or polymerisation, it was said: "All analogy leads us to extend this law to the still greater condensations observed in the dense vapours into which liquid species above their critical points are resolvable, and to the farther condensation of these vapours into liquid and solid forms—to assume, in fact, that the law of combination by volume, like that of combination by weight (with which, so far as experience shows, it is indissolubly linked), is universal."* If this assumption, which appears to be in accordance with all the facts known, be admitted, the great problem proposed, namely the fixing of the coefficients of condensation for liquid and solid species, though a complex one, is solved.

6. As a preliminary to a further treatment of this problem it here becomes important to note the relations between what (1) we have designated respectively as the "chemical species" and the "mineral species." This will, moreover, serve to explain the language used in 1853, and cited above in speaking of crystalline species, as to "those chemical changes which commence only with the destruction of crystalline individuality." We may, perhaps, best approach the subject by conceiving the characters of a given species to be imposed upon matter by a force which is the form of that species, and which makes it what it is. The permanence of what we recognise as elementary species, in opposition to the notion of their transmutability, is the foundation of our chemical science, and from this it follows that secondary forms are imposed upon these, and present an ascending series often passing through two or more chemical forms before receiving the mineral form, which may be in turn subordinated to some biotic form.

7. These relations may be illustrated by well-known chemical facts: acetic and formic aldehyds and their sulphur and chlorine derivatives present many instructive cases of polymerism available for our purpose. Thus acetaldehyd, itself a very light and volatile liquid, is readily transformed into a denser and less volatile species, paraldehyd, which becomes a crystalline solid at 0° , melting at 10° , and having a vapour-density equal to $3(\text{C}_2\text{H}_4\text{O})$, or three times that of the normal aldehyd, into which, however, it is easily changed. The same aldehyd also gives a less fusible crystalline polymer, metaldehyd, integral weight of which, from the facility with which it reverts without melting to the normal vaporous aldehyd is unknown. Again, formaldehyd is a gas soluble in water, from which by heat it is in part expelled and in part changed into a white, volatile, crystalline solid, insoluble in water, alcohol, or ether, melting at 152° , but passing at a lower temperature into a gas having the density of the normal formaldehyd. A similar change is

also effected when it is heated with water under pressure to a temperature above 100° , the normal aldehyd being taken into solution. This insoluble body, which is sometimes called methylene-oxide, and yields another and a less fusible modification, has been regarded as $3(\text{CH}_2\text{O})$, but its integral weight is uncertain. When a solution of formaldehyd is digested with milk of lime it is changed into a sugar which has been named formose, represented by the general formula of the glucoses, $\text{C}_6\text{H}_{12}\text{O}_6 = 6(\text{CH}_2\text{O})$. Indeed, by modifying the conditions of experiment many species of sugar, alike non-fermentescible and fermentescible, are obtained from formic aldehyd. From one of the latter, which has been designated acrose, and is a form of levulose, it has been found possible to produce anhydrous crystalline dextrose, and thus from the formic aldehyd itself to effect the synthesis of dextrose.*

8. Other striking examples alike of isomerism and of polymerism are seen in many hydrocarbons, as in the terpenes in acetylene and amylene; while the higher olefines are all polymers and possible homologues of the as yet unknown methylene CH_2 . In the case of the terpenes proper we have a large number of distinct liquid and solid species differing alike in boiling point, in optical characteristics, and in various chemical relations, but having a common vapour-density corresponding to $\text{C}_{10}\text{H}_{16}$. These include (1) pinenes, which are liquids boiling at 156° – 160° and having a specific gravity of about 0.876 at 0° ; (2) citrenes; (3) sylvestrene; (4) terpine; all liquids boiling from 170° to 176° and with specific gravities very near that of the pinenes; while the (5) camphenes are solid crystalline species. The various pinenes and citrenes are in great part broken up by heat into pentine, C_5H_8 , which is again convertible into terpine. The various terpenes are, moreover, easily polymerised, yielding denser and less volatile liquids, including sesquiterpenes, $\text{C}_{15}\text{H}_{24}$, and still higher polymers boiling at 300° and upwards. Acetylene, C_2H_2 , under proper conditions of temperature, gives rise to a number of polymers, of which it suffices to mention benzene, $3(\text{C}_2\text{H}_2)$, cinnamene, $4(\text{C}_2\text{H}_2)$, itself a liquid passing into a solid modification), and retene, $9(\text{C}_2\text{H}_2)$, a crystalline solid. Of the higher olefines, at least three are known as solids at ordinary temperatures, namely, octadecylene, $18(\text{CH}_2)$, cerotene, $27(\text{CH}_2)$, and melene, $30(\text{CH}_2)$, having melting-points of from 18° to 62° and specific gravities of 0.79, 0.86, and 0.89, respectively, water being 1.00. The integral or so-called molecular weight of these various hydrocarbons is known by the density of their vapours, as in the similar cases of the chlorides of carbon, silicon, aluminium, and iron, and of the volatile oxides like those of carbon, arsenic, sulphur, selenium, ruthenium, and osmium.

9. By far the greater number of species, however, are either fixed at high temperatures or undergo heterogeneous decomposition thereby, and may be divided into two categories. First, those which are soluble in water or some other liquid, from which they can be recovered unaltered by change of temperature or by evaporation of the solvent. Such are the sugars and a vast number of non-volatile hydrocarbonaceous species, a great many chlorides, sulphates, phosphates, carbonates, and other salts, as also the elementary solid species, sulphur, phosphorus, and iodine. For these various bodies water, alcohol, ether, benzene, acetic acid, carbon disulphide, and other solvents are familiarly employed. In the second category is included the great number of species which are altogether insoluble, or else are either decomposed or enter into more or less stable combinations with their solvents. Such are the native silicates, oxides, carbonates, and sulphides among compounds, and the various metals among elementary species.

10. For these two categories of bodies it is obvious that the question of their integral or molecular weight must be approached by a wholly different process from that applied to volatile bodies. Much attention has of late been given

to the cryoscopic method of Raoult (with its modifications), which is applied for fixing this value for soluble non-volatile species, and depends upon the reduction of the temperature of congelation of the solvent which takes place after the solution therein of a known proportion of the solid species to be examined; the dissolving liquids chiefly used hitherto being water, acetic acid, and benzene. The results obtained are approximative, and, moreover, are extremely instructive as illustrations of the subject now under consideration. Thus, Tollens and Mayer have deduced thereby for formaldehyd (obtained in aqueous solution by effecting the transformation of the insoluble formic paraldehyd by heating it in a sealed tube with water to near 140°) the numbers 34 and 35, the calculated integral or molecular weight being $30(=\text{CH}_2\text{O})$. This solution, heated in a water-bath, regenerates the insoluble polymer, but evaporated over sulphuric acid gives a soft soluble solid which, by Raoult's method, is found to correspond to $2(\text{CH}_2\text{O})$. By applying this same method to dextrose, these observers found the number 188.7, the received formula for this and the other true glucoses being $\text{C}_6\text{H}_{12}\text{O}_6(=180)$; while arabinose and its isomer xylose, represented by $\text{C}_5\text{H}_{10}\text{O}_5(=150)$, give the numbers 155.1 and 154.1. For cane sugar and for lactose, which, with many other sugars, belong to the diglucosic type, designated as saccharose and represented by—

they found, by the method of Raoult, numbers which sustain this formula. For the sugar named raffinose, which occurs with saccharose in certain syrups, three formulæ, with C_6 , C_{12} , and C_{18} respectively, have been proposed. The latter, making it a triglucosic sugar, is $\text{C}_{18}\text{H}_{34}\text{O}_{16.5}\text{H}_2\text{O}(=594)$, and experiments by the cryoscopic method gave numbers from 544 to 644, thus sustaining the triglucosic character, and showing at the same time that the range of error due to the necessary imperfections of the process is not inconsiderable.

11. The recent application of this method to various uncrystalline amyloid bodies has given further results of great interest. The studies by many investigators of the hydrolysis of starch had already led to the conclusion that its constitution is far more complex than is indicated by the ancient formula $\text{C}_6\text{H}_{10}\text{O}_5$. The first action of cold dilute acids thereon changes it into the so-called soluble starch, which by hydrolysis is slowly converted into amyloextrine, with the production of a portion of dextrose. The action of diastase, in like manner, by successive stages in hydrolysis, gives rise to maltose and other forms of dextrine. By Raoult's method maltodextrine gives numbers closely approximating—

and amyloextrine,

inulin having a composition intermediate between the two. Raoult's method could not be applied to starch paste, but with soluble starch the depression in temperature produced, though slight, corresponded in a number of experiments to integral weights varying from 20,000 to 30,000. Messrs. Brown and Morris, to whom we owe these late investigations, are led to assign to soluble starch the formula $5(\text{C}_{12}\text{H}_{20}\text{O}_{10})_{20}(=32,400)$, thus multiplying the old empirical formula $\text{C}_6\text{H}_{10}\text{O}_5$ by 200. By the author's hypothesis, however, as re-stated in §5 of the present paper, the highest integral weights compatible with the observed specific gravities of starch and other amyloid bodies are approximately 32,000, and it therefore seems probable that the so-called soluble starch, which is apparently the first product of the depolymerisation of true starch, should be represented by some simple fraction, perhaps one-half the above, leading to an integral weight for soluble starch of 16,200. The above formula of Brown and Morris, equal to $200(\text{C}_6\text{H}_{10}\text{O}_5)$, will then represent starch itself, with an integral weight of 32,360 ($\text{O}=15.96$) and a theoretical specific gravity of 1.509. The recent examina-

* Fischer, *Ber. d. chem. Ges.*, xxiii., 372, cited in *Am. Chem. Journ.*, xii., 357–364.

tion by Sebanéeff of glycogen by Raoult's method leads to the formula $(C_6H_{10}O_5)_{10} (= 1620)$.

12. It will now be sufficiently evident that the values got by Raoult's method are not the integral or so-called molecular weights of the solid species themselves, or what we have designated *mineral species*, but of the *chemical species* which result from the depolymerisation of these, and which pass into solution. These values, moreover, bear no obvious relations to the specific gravities of these solid species, as appears when we compare sugars like xylose, dextrose, saccharose, and raffinose with each other, and with the dextrines and soluble starch; bodies which with such widely different integral weights in solution have almost identical specific gravities in the solid state. It is, in the language of the atomistic school, "the molecular mass" of the dissolved substance which we determine by Raoult's method, and not that of the solid or liquid mineral species, from the depolymerisation of which, in the process of solution, is derived the chemical species; the molecular or, in other words, the integral weight of which ($H=1$) may vary widely in bodies nearly allied, as in hydrocarbons of identical centesimal constitution, different sugars, and certain amyloid substances. The total mineral condensation in such cases being essentially the same, the question is whether the depolymerisation or homogeneous disintegration which takes place in vapourisation or in solution shall resolve the mineral species into a greater or less number of chemical species.

Chemical species probably never assume liquid or solid forms. They are either vapours or gases, which by intrinsic condensation (polymerisation) pass into liquids or solids, or else, if their integral weight is too great to permit their existence in a gaseous condition at ordinary temperatures, unite with water, forming liquid hydrates, from which they separate, after a longer or shorter time, in solid or, more rarely, in liquid hydrated or anhydrous species. The appearance of such solid or liquid bodies in the midst of an aqueous solution marks the passage of the dissolved *chemical species* by polymerisation into a *mineral species*: a process often favoured by mechanical agencies or by change of temperature.

13. The significance of these relations is made more apparent by the writer's theory of solution, according to which there are formed in the process of aqueous solution definite compounds of the dissolved matters with water, accompanied with all the phenomena of chemical union; the further addition of water thereto giving rise either to new chemical arrangements of the substances present, or to simple admixtures of one definite solution or liquid species with another of unlike density. Examples of such admixtures of aqueous solutions are seen in the case of phenol and water, which when heated mix in all proportions, but on cooling separate into two layers, the lower a solution of phenol in water, and the upper a solution of water in phenol. Aniline and many other bodies present similar reactions with water below $100^{\circ}C$, and like results are got through the agency of pressure at still higher temperatures. Thus salicylic acid heated with water in a sealed tube above 100° gives a solution which separates suddenly, on cooling to 91° , into two layers, each of which, according to Alexéef,* grows turbid independently as cooling goes on. Similar separations of liquids have been noticed by Hannay and Hogarth in the case of alcoholic solutions of calcic chloride and ferric chloride, under pressure. Moreover, the spontaneous separation, long suspected, of many saline solutions into layers of unlike density through the influence of gravity, has been confirmed by the studies of Bodländer and the more recent ones of Traube and Neuberg. The conversion of denser solutions into solid hydrous species is in many cases but a question of temperature. Liquidity is only an accident of solution. Not only is all solution chemical union, but "all chemical union is nothing else than

solution. The resulting species are, as it were, dissolved in each other, for solution is mutual." All precipitation and all crystallisation from solution thus involve chemical change, and all chemical species may theoretically exist in soluble states, from which they pass into polymeric mineral species, often insoluble.*

14. A given chemical species, whether elementary or complex in constitution, may in some cases pass through two or more higher *chemical forms*, by successive condensations, until at last it assumes a *mineral form* as a liquid or a solid species, which in the latter case may either be colloidal, or may take on a crystalline shape; the whole process, from the simplest chemical form, constituting an ascending series, in which the older and simpler forms are not lost but latent. It is to the converse of this process, or, in other words, to the depolymerisation by solution of solid mineral forms, that reference was had when, in 1853, the writer insisted upon "those chemical changes which commence only with the destruction of crystalline individuality," as quoted above in §4; or, in other words, to the breaking up of *mineral species* by solution into *chemical species*.

15. The mineral form itself is, however, in many cases subject to other changes, since the solid species may undergo alterations in density, in hardness, in fusibility and in crystalline shape without passing by a process of fusion or solution. Thus, for example, of the many allotropic phases of solid sulphur we may designate three as the plastic amorphous or colloidal, the clinorhombic and the orthorhombic. Of these, the first two pass spontaneously after a time into the denser and more stable orthorhombic state, an alteration which, as Spring has shown, is accelerated by pressure. A still more striking case is found in tin, the gray brittle form of which, with a density of 5.8 by gentle heat, concussion, or momentary pressure, passes into the white malleable species with the density 7.3, and may again by considerable reduction of temperature revert to the lighter brittle species. So the orthorhombic calcium carbonate, aragonite, is, at a low red heat, transformed into the lighter rhombohedral form, calcite. Ice, moreover, at 0° passes by pressure into liquid water, with a considerable increase of density (as in the case of tin); the transformations of the two species being readily repeated by slight variations of temperature or of pressure. It would be easy to multiply instances of such changes of mineral form.

16. In the case of insoluble non-volatile solids like tin and calcium carbonate we are precluded from the use alike of the vapour-density and the cryoscopic method as means of fixing the integral weight of the chemical species which by its polymerisation gives rise to the mineral species in question. We may add that even were the conditions such as to permit the application of either of these methods the presence of possible admixtures of different polymers might give rise to difficulties in their application, especially in cases where it is known that such polymers may have been simultaneously formed. Thus, for example, among the many polymers generated by the intrinsic condensation of acetylene, three, namely retene $(C_2H_2)_9$, cinnamene $(C_2H_2)_4$,—or rather its solid allotrope, metacinnamene—and benzene $(C_2H_2)_3$, are all solids at temperatures above 0° . An admixture of two or more of these might well have a fusing-point which would tend to confound it with some intermediate species. Again, among the higher olefines, $(CH_2)_n$, three of which have been mentioned above (§8), α -tridecylene ($n=18$), melts at 18° and has a density of 0.79; cerotene ($n=27$) melts at 58° and has a density of 0.86; while melene

* These views, set forth in 1853, and more fully in 1855, in "Thoughts on Solution and the Chemical Process," *Am. J. Sci.* (II.), xix., 100—103, and *Chemical Gazette* for 1855, p. 92, are reinforced in the "New Basis for Chemistry," pp. 98—99, and in "The Theory of Solution," *Brit. Assoc. Adv. Science*, Sec. B, 1888; *Chem. News*, lviii., 151. See also "Mineral Physiology, &c.," pp. 167—169. Similar views have since 1886 been put forward by Mendeléef.

($n=30$) melts at 62° and has a density of 0.89. Mixtures of any two of these would give rise to uncertainties like those which we have imagined in the case of the solid polymers of acetylene. In both these examples, it is true, separation of the intermingled hydrocarbons might be effected by differences in the solubility and the volatility of the polymeric species; but in other cases we have to deal with bodies alike non-volatile and insoluble, the problem becomes far more difficult. It is evident that, while in the case of gases and vapours the density varies directly as the integral weight of the chemical species, no such rule holds good in solids and liquids. This is well illustrated in the case of the three solid olefines just named, having, with small variations of density, integral weights for the chemical species which are to each other as 18 : 27 : 30, and also in that of the glucosic, diglucosic, and triglucosic sugars, having for the chemical species integral weights nearly as 1 : 2 : 3, yet with specific gravities for the solid or mineral species which are almost identical.

17. Among native mineral species there are not wanting instances of such mixtures, a good example being seen in the disulphide of iron, which constitutes alike the orthorhombic species marcasite, and the isometric species pyrite. Multiplied observations of specimens of the latter species by various skilled naturalists show that its specific gravity may vary from 4.80 to 5.00 and even 5.15 and 5.20 for well-defined pyritohedral crystals. On the other hand, marcasite itself may vary in specific gravity from 4.75 to about 5.00 (4.987), with a hardness on the scale of Mohs of 6.0–6.5; while the denser isometric species attains 6.5–7.0. The latter strikes fire strongly with steel, giving a faint sulphurous odour; marcasite, on the contrary, feebly, giving a strong odour. Differences in colour and texture also distinguish the denser from the lighter sulphide. A. A. Julien, who has lately examined this question with great care, concludes that we have in these minerals of intermediate density an intermingling of two disulphides of unlike degrees of condensation. Each of these species would thus be dimorphous, and might include admixtures of the other.* It is difficult to conceive any other explanation of these facts, which are precisely what we should expect in the case of admixtures of polymeric bodies like the hydrocarbons noted above. It will be found that an admixture of three parts of a disulphide of iron, sp. gr. 5.18, and two parts of one of sp. gr. 4.75, would give a mean sp. gr. of 5.00, which is that assigned by many observers to pyrite, and very near the maximum specific gravity of marcasite.

Similar differences in density are met with among the orthorhombic and isometric arsenides of cobalt, nickel, and iron, represented by the general formula MA_2 , as shown in safflorite and smaltite, verified by the recent studies of MacCay. Another example of the kind, uncomplicated by the question of dimorphism, is seen in sodium chloride. Several careful observers concur in giving for specimens of this substance at ordinary temperatures a specific gravity of about 2.25 (2.20, 2.23, 2.26); and others, apparently equally worthy of confidence, have found about 2.00 (2.01, 2.03, 2.06, 2.08), while the greater number of observations range from 2.14 to 2.20. These wide variations in density in such a familiar species are the more remarkable for the reason that the chlorides of potassium and ammonium present no such notable variations. A similar condition of things is apparent in crystals of zircon, and many other cases might be cited showing that we have, as in the case of the iron disulphides, variable admixtures of two mineral species with the same centesimal composition but of unlike condensation.

18. It will now be apparent that we have to deal with processes of condensation belonging alike to chemical species and to mineral species. Thus, for example, with acetylene, pentene, and their polymers, we have in each case chemical species having a common centesimal com-

position with widely different coefficients of chemical condensation, as is apparent when we compare their vapour-densities; which, moreover, present no simple or apparent relations to their specific gravities in the liquid or solid state. We may recall in this connection the already cited case of formaldehyd, of which the equivalent weight is fixed by its vapour-density as well as by Raoult's method, with those of xylose, glucose, and the related sugars and amyloid bodies; species for which the chemical condensation presents a very wide range. In these cases we are enabled by vapour-density, by the cryoscopic method, or else by direct chemical analysis, to determine the minimum value of the chemical integer, and in this latter way we are led to assign in many cases very elevated numbers, as seen in such compounds as the cobaltamine salts and the polytungstates, the simplest admissible formulæ of which give integral weights of thousands or tens of thousands.

(To be continued).

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, December 4th, 1890.

Dr. W. J. RUSSELL, F.R.S., President, in the Chair.

CERTIFICATES were read for the first time in favour of Messrs. Charles Henry Corbett, Barnard Castle; Hendrick Thomas Donovan, Crumpton Street, Bridgetown, Barbadoes; Henry Charles Jenkins, Lorne Villa, Iveson Road, Hampstead; William Morley Martin, Cardrew, Redruth; Arnold Whitaker Oxford, 8, Henrietta Street, Cavendish Square, W.; Frederick William De Velling, High Street, Heckmondwike, Yorkshire; Herbert D. Shaw, Castle Mount, Sandal, nr. Wakefield; R. Stockdale, The Grammar School, Leeds; Kenelm Edward Symes, Magdalen House, Bridport, Dorset.

The following were elected Fellows of the Society:—Messrs. Gustavus Anthony Abrines; John Thomas Brierley; William J. Butcher; William Waters Butler; Frank Brownswold; M. Kelway Bamber; Ernest Bents; W. E. B. Blenkinsop; Thomas Arthur Cheetham; Arthur William Crosskey; Arthur William Cooke; William L. Dudley; Thomas S. Goodwin; Alfred Henry Green; William Mahowe Heller; John Richard Jackson; Joseph Lunt; Harry C. Myers; William Mackeay; Thomas Smith Murray; William Reginald Ormandy; James Alexander Pond; Thomas Platts; G. H. Robertson; Ernest Henry Sainter; Thomas Steel; John Joseph Sudborough; Charles Thomas Sprayne; Francis Henry Tate; George Henry Wadsworth; Sidney Wood; George Young.

The following papers were read:—

95. "The Action of Heat on Ethylic β -Amidocrotonate." Part I. By J. NORMAN COLLIE, University College, London.

Some years ago, whilst working with ethylic β -amidocrotonate, the author noticed that during its purification by distillation under reduced pressure a crystalline compound of the formula—

was always produced in small quantities, and remained behind in the fractionating flask. This condensation product was found to be the ethylic salt of an acid $C_8H_7NO_3$, which from its properties was considered to be the monocarboxylic acid of a hydroxylutidine. Owing to the small quantities obtained, the investigation was carried no further. Since then, having had to work with large amounts of ethylic β -amidocrotonate, a further supply of the condensation compound has been obtained, and a

* A. A. Julien, *N. Y. Acad. Sci.*, 1886, 1887, vol. iii., No. 12, iv., Nos. 3, 5, 6, 7.

more exact study of its derivatives has been possible. The author now finds that the acid is *not* a hydroxyl derivative of lutidine, but *lutidomonicarboxylic acid*, for on heating it yields carbon dioxide and lutidone or *αα*-dimethylpyridone. This partial decomposition by heat of ethylic *β*-amidocrotonate is therefore very similar to that which ethylic acetoacetate undergoes in its conversion into dehydracetic acid during distillation:—

Feist in his interesting paper on dehydracetic acid (*Annalen*, cclvii., 253) has shown that it is easily converted into dimethylpyronecarboxylic acid, the oxygen analogue of dimethylpyridonecarboxylic acid:—

Ethylic lutidonemonocarboxylate does not decompose when boiled with caustic soda, but is merely hydrolysed and converted into the sodium salt of the acid; with phenylhydrazine and hydroxylamine it also does not form any compounds, and thus differs from dehydracetic acid. With bromine it forms a monobrominated derivative, $C_{12}H_{12}NO_3Br$, and with pentachloride of phosphorus the compound $C_{10}H_{12}NO_2Cl$. The acid obtained from the sodium salt melts at $247^\circ C.$, decomposing at the same time into carbon dioxide and a compound which agrees in every respect with the *αα*-dimethylpyridone, C_7H_9NO , obtained by Haitinger from dehydracetic acid, and also by Conrad and Geutzeit by heating lutidonedicarboxylic acid. This lutidone when heated with zinc-dust yields, according to Haitinger, *αα*-dimethylpyridine boiling at $148-151^\circ C.$, whilst the *αα*-dimethylpyridine obtained from other sources boils at $142-143^\circ C.$ Conrad and Geutzeit also obtained a lutidine from this lutidone, but do not give its boiling point. The author has been able to obtain a lutidine by four different methods:—

- (1). By distillation of the potassium salt of lutidonecarboxylic acid with excess of solid caustic potash.
- (2). By the prolonged action of nascent hydrogen (from tin and hydrochloric acid) on the chlorolutidine obtained by treating the lutidone with pentachloride of phosphorus.
- (3). By heating the chlorolutidine with zinc-dust in an atmosphere of hydrogen.
- (4). By heating the chlorolutidine obtained from dehydracetic acid by Haitinger's method with zinc-dust.

All these four methods gave a lutidine boiling at $144-145^\circ C.$, and yielding a platinum salt melting at $210-212^\circ C.$, the melting-point found by Epstein and Ladenburg for the chloroplatinate of *αα*-dimethylpyridine. The author has also been able to compare this lutidine with a lutidine boiling at $143-144^\circ$ obtained by Professor Ramsay from bone oil, and is led to regard it as identical therewith. By oxidation of the lutidine from ethylic *β*-amidocrotonate with potassium permanganate, a pyridinedicarboxylic acid was obtained melting at $235^\circ C.$ (corr.), which, on heating, gave pyridine, showing that it was dipicolinic or *αα*-pyridinedicarboxylic acid.

96. "The Action of Heat on Nitrosyl Chloride." By J. J. SUBBOROUGH, B.Sc. (Lond.), and G. H. MILLER.

An account is given of a series of determinations of the vapour-density of nitrosyl chloride, $NOCl$, at various temperatures. At temperatures from 15° to 693° , the values obtained so nearly coincide with the theoretical value 32.67 , that it is to be supposed that no dissociation takes place below about 700° . At higher temperatures, the compound is no longer stable, as the following numbers show:—(See Table, next column).

The results show that in comparison with nitrogen dioxide, NO_2 , which is completely decomposed below 620° , nitrosyl chloride is a highly stable compound.

Temperature.	Vapour-density.
784°	31.77
796	31.36
815	31.00
928	29.00
968	27.30
985	27.00

Nitrosyl chloride in its reactions with water behaves as the chloride of nitrous acid, and inasmuch as nitrous acid not only forms nitroso-compounds, but also hydroximes by interaction with the CH_2 group, nitrous acid would appear to have the formula $O:N\cdot OH$, and the chloride the formula $O:N\cdot Cl$. As nitric oxide and nitrosyl chloride show no tendency to polymerise, the union which takes place between NO_2 and NO at temperatures below 140° is probably established between oxygen atoms, and as only like molecules of NO_2 are concerned in the formation of nitrogen peroxide, it is unlikely that the latter as an unsymmetrical formula: the formula $O:N\cdot O\cdot N\cdot O$ would appear to satisfy the requirements of the case; this leads to the formula $O:N\cdot O$ for the dioxide, and it may be that the instability of the dioxide is due to the unsaturated condition of the oxygen.

97. "The Volumetric Estimation of Tellurium." By Dr. B. BRAUNER.

Hitherto only gravimetric methods have been adopted in estimating tellurium, and as they involve the use of weighed filters, the determination is subject to considerable error, besides occupying much time. The author describes two volumetric processes. The first is based on the reduction of solutions of tellurium dioxide by stannous chloride:—

The tellurium compound, together with muriatic acid, is digested with excess of stannous chloride, and the excess subsequently determined by iodine and thiosulphate.

The second method consists in adding an excess of potassium dichromate solution to the solution of tellurium dioxide in muriatic acid, the excess of dichromate being subsequently determined by means of ammonium ferrous sulphate:—

Results are quoted showing that the first method gives satisfactory results; but the second does not appear to be one of practical value.

NOTICES OF BOOKS.

Outlines of General Chemistry. By W. OSTWALD, Professor of Chemistry in the University of Leipzig. Translated, with the Author's Sanction, by JAMES WALKER, D.Sc., Ph.D. London: Macmillan and Co.

THE author of this profoundly able and interesting work has found his task rendered more difficult because "the course of study still pursued by the average chemist has laid upon him the necessity of the employment of higher mathematics." Again, he writes: "That the reader who has only an acquaintance with elementary mathematics may be brought to see the necessity of acquiring at least the rudiments of the higher analysis." If such acquirement is a "necessity," chemistry will lose many followers who are capable of doing useful work. Higher mathematics will always be a speciality of one type of minds.

The complaint of the author and the translator that the researches of Van't Hoff on the theory of solution and those of Arrhenius on electrolytic dissociation have not met with due attention in this country is well founded, and we

share the hope that the appearance of this work in an English version may cause this neglect to disappear.

Prof. Ostwald discusses in his first part the chemical laws of mass, and in the second those of energy. The former part treats, in succession, of mass, of the properties of gases, of liquids, of solutions, of solids, and of chemical systematics.

The elements he accepts as undecomposed, but not necessarily undecomposable. But he holds that if "composite, they are all composite to the same degree,"—a conclusion which is perhaps still open to doubt.

Concerning Prout's law, the author leaves unanswered the question why the atomic weights of so many elements approximate so closely to multiples of hydrogen. A similar approximation, without identity being reached, appears in the triads of Döbereiner and Lenz.

In the discussion of the periodic law, the first enunciation of the idea is ascribed to Newlands, with the remark that he "did not succeed in fully carrying it out," and that it failed to find ready recognition, as presented in a "somewhat inadequate form." Prof. Ostwald, whilst recognising that "almost every well-defined and comparable property appears as a periodic function of the atomic weight," considers that the periodic system of the elements is by no means perfect. He reminds us that "elements are frequently parted in the tables which an unprejudiced observer would consider analogous in their compounds (e.g., copper and mercury), whilst others are placed together which appear altogether dissimilar, as sodium, copper, silver, and gold." Further, Mendeleeff has called the elements with the lowest atomic weights the "typical elements." This, remarks the author, "is a name signifying just the opposite of what is really meant, for these elements are by no means typical of the groups whose first members they constitute." These criticisms cannot be pronounced other than just and weighty.

In the determination of the atomic weights, the author prefers to return to the unit of Berzelius and put, arbitrarily, $O=16$.

On the subject of structural formulæ, Prof. Ostwald expresses himself very judiciously. He considers that they stand in much the same relation to the substances they represent as do formulæ of analytical geometry to the corresponding curves and surfaces, though they do not approach the latter in certainty and completeness of expression.

The tri-dimensional formulation of atomic space-relations, as propounded first by Van't Hoff and afterwards by Wislicenus, is explained by examples. Various phenomena, hitherto incomprehensible, can thus be explained. It is to be hoped that this idea will meet with more attention than it has hitherto received, both among teachers and students.

The second part of the work, devoted to the chemical laws of energy, discusses, in succession, thermo-chemistry, photo-chemistry, electro-chemistry, and chemical dynamics.

Unlike many German books, these "Outlines" are furnished with an excellent index of subjects, and, in addition, with one of the names of authors referred to. Advanced students will find in the work before us not merely a clear oversight of the philosophy of chemistry as at present understood, but a guide to subjects for future research. It would be at once interesting and instructive to compare Ostwald's Outlines with Daubeny's Atomic Theory, or any other theoretical work of the first half of the century.

An Impurity in White Wine Vinegars.—A. Held.—In a sample sold as white wine vinegar, the author finds a considerable quantity of amylic alcohol. The vinegar in question contained no potassium bitartrate, and was merely the product of the acetic fermentation of an alcohol containing much amylic alcohol.—*Journal de Pharm. et de Chimie.*

CORRESPONDENCE.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—I am greatly surprised at the letter of Messrs. Bloxam and Blount in your issue of the 12th inst., and I may say that if the Council of the Society adopt their suggestion of advertising, twenty-five friends as well as myself will at once resign our memberships. Let it be understood that we are non-trading members.

Just fancy a distinguished and learned society like the Chemical Society of London advertising itself as suggested by Messrs. Bloxam and Blount!—I am, &c.,

A CONTRIBUTOR TO THE
Journal of the Chemical Society.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—I did not sign the circular from Messrs. Lloyd and Teed, whose object was, no doubt, the supposed welfare of the Society. The means proposed seem inquisitorial, and might suggest that the letter C in F.C.S. should stand for "Censorial." I do not see the need for so great a change. We are not called upon to apportion the exact weight which the public should attach to the letters F.C.S. Why not let well alone? If any are using the Fellowship for trade purposes, would not a remonstrance be best, drawing the delinquent's attention to the declaration against it which he signed on admission?—I am, &c.,

F.C.S.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—There appears to be a necessity for a re-statement of the main facts upon which the present situation must be resolved. These are:—

(1.) The Society imposes upon candidates for the Fellowship a certain standard of qualification—whether social or scientific. Unless, therefore, the present form of election be abandoned, the Fellowship must continue so far to constitute a "qualification;" and for any Fellow to maintain the opposite is an obvious stultification.

(2.) The constitution of the Society is democratic in principle, though the actual management of its affairs is by tacit consent autocratic, as indeed it should be.

In other words, it is in the power of the majority of the Fellows to determine any course of action within the limits of the constitution of the Society, by electing an executive representative of its views, and pledged to give effect to its will.

I venture to think that some of your correspondents on this subject are disposed to ignore these prominent factors of the situation.—I am, &c.,

A FELLOW.

THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—Messrs. Bloxam and Blount's difficulties seem to me not difficult to answer.

First, the Society has never encouraged the alleged view as to the qualifying value of the Fellowship, which, if it exists, has been conferred on it by the public. The Society is not responsible for this, and has done its best

to discourage it by freely admitting all interested in the science, as its charter requires.

Second, the charter is absolutely silent as to a qualification, and expressly withholds the power to make any bye-law "in opposition to the general scope, true intent, and meaning of this our charter." It is manifest that nothing short of an amendment of the charter will get over this.

Third, many of us think that the present system is sufficient, and that the exaggerated view, if it exists, will gradually fade as the true function of the Institute of Chemistry comes into greater prominence. But admitting all the alleged evils, surely wild blackballing is not the way to mend them; for, as Messrs. Bloxam and Blount themselves point out, either all or no candidates must be admitted; no doubt reading "all" as equivalent to all persons of good character, and "no" as none without an examination; for they surely do not intend to assert that a chance meeting of the Chemical Society could ever become an efficient qualifying body.

Mr. Livingstone has misunderstood my letter in your issue of December 5th, as the grounds of my assumptions were there given and require no explanation.—I am, &c.,

R. J. FRISWELL.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxl., No. 22, December 1, 1890.

Compressibility of Mixtures of Air and of Carbon Dioxide.—M. Ulysse Lala.—The compressibility of mixtures of dry air and of carbon dioxide when the quantity of the latter does not exceed 22 per cent is comprised between those of air and carbon dioxide. The compressibility of higher mixtures is greater than that of carbon dioxide.

A New Process for Distinguishing Arsenical and Antimonial Spots.—G. Denigès.—H. Rose pointed out long ago that arsenic acid behaves like phosphoric acid with a nitric solution of ammonium molybdate. This reaction has been utilised for the detection or determination of arsenic acid or arseniates; but it does not seem to have been applied in toxicology for distinguishing arsenical spots from those of antimony. The production of crystals of ammonium arsenio-molybdate is very easy, and this substance is distinguished by its fine yellow colour, its insolubility in nitric acid, and especially by its microscopic appearance in the form of stars with triangular branches, generally six in number, and arranged in rectangular planes according to the axes of a cube. These crystals appear very distinctly under the polarising microscope when the analyser and the polariser are turned to extinction. It must be said that ammonium phosphomolybdate presents quite identical appearance and properties; but as no trace of phosphoric products can exist in the arsenical or antimonial spots furnished by the apparatus of Marsh, it is legitimate to infer the presence of arsenic whenever we obtain yellow crystals presenting the characters described above. The suspected spots, collected in a small porcelain capsule, are mixed with a few drops of pure nitric acid; they dissolve instantly, whether they consist of antimony or arsenic. Heat is applied for a few moments to complete the oxidation, and there are added four or five drops of ammonium molybdate in a nitric solution. There is soon formed, even if there are only traces of arsenic (from 1-50 to 1-100 of a milligramme), a yellow precipitate which on examination

with the microscope shows the forms above described. Antimony gives nothing analogous. The reaction just pointed out seems the most sensitive and the most characteristic. It is easy to produce and is applicable to the determination of very small quantities of arsenic, as the author purposes to explain in a further communication. The molybdic reagent employed is prepared as follows:—Dissolve at a gentle heat 10 grms. commercial ammonium molybdate (hexammonium heptamolybdate), and 25 grms. ammonium nitrate in 100 c.c. water. Let cool, and add gradually, while stirring, 100 c.c. pure nitric acid of specific gravity 1.20. Heat on the water-bath for ten minutes, let cool, and leave it for 48 hours. At the end of this time filter through paper washed with dilute nitric acid and keep in stoppered bottles.

Bulletin de la Société Chimique de Paris.
Series 3, Vol. iv., Nos. 4 and 5.

On the Formation and the Combustion Heats of Various Nitrogenous Principles Derived from Albumenoid Matters.—MM. Berthelot and André.—The total combustion heat of the nitrogenous principles, urea and leucine excepted, exceeds that which would be calculated on the hypothesis that hydrogen separated in the state of water does not evolve any heat, and that the carbon generates as much as if it were free.

Formation-Heat of Certain Amides.—MM. Berthelot and Fogh.—The formation of anilides from the solid acid and the gaseous base evolves more heat than that of the corresponding amides; a circumstance correlated to a greater stability against the decomposing action of water.

Combustion-Heat of the Chief Nitrogenous Principles Contained in Living Beings and its Part in the Production of Animal Heat.—MM. Berthelot and André.—The authors give their results in the form of a table.

The Reduction of Alkaline Sulphates by Hydrogen and by Carbon.—M. Berthelot.—Not adapted for useful abridgment.

Thermic Researches on the Allotropic Conditions of Arsenic.—MM. Berthelot and Engel.—The two varieties of arsenic evolve almost identical quantities of heat whilst forming one and the same compound. Their relations are similar to those existing between graphite and diamond.

On the Formation-Heat and the Reactions of Hydroxylamine or Oxyammonia.—MM. Berthelot and André.—A thermo-chemical study of hydroxylamine nitrate. The conversion of ammonia into hydroxylamine, whether free or dissolved, is not an oxidation.

New Researches on the Relative Stability of Salts, both Isolated and in Presence of Water. Salts of Aniline.—M. Berthelot.—The formation-heat of salts referred to the solid state may be taken as the measure of their relative stability.

On the Isomeric Inosites and on their Transformation-Heat.—M. Berthelot.—The two symmetric inosites in a state of solution do not manifest any sign of combination any more than do the two symmetric tartaric acids. But the combination takes place as soon as they are separated from their solutions.

Researches on Certain Saccharine Principles.—MM. Berthelot and Matignon.—The true inactive nosite appears to contain a reserve of energy superior to that of the other isomers which it is apt to produce; whilst the neutral inosite, the molecule of which is double, corresponds to the greatest loss of energy.

The Oxidation of the Sulphur of Organic Compounds.—MM. Berthelot, André, and Matignon.—The authors burn the sulphuretted organic compound in the "calorimetric bomb" in an atmosphere of oxygen com-

pressed at 25 atmospheres and in presence of 10 centimetres of water.

Combustion-Heat of Certain Sulphur Compounds.—MM. Berthelot and Matignon.—The compounds in question are thiophene, taurine, and carbon disulphide.

Analysis of an Argentocupric Mineral.—Prof. E. Jacquemin.—This mineral, from Bussang, in the Vosges, and known locally as "green stones," contains, according to the samples examined, 210–225 grms. silver per ton—a quantity which admits of working, especially as the copper alone, which varies from 35 to 45 kilos. per ton, is remunerative.

Preparation of Certain Ethers by Fermentation.—Georges Jacquemin.—From a fermentation effected in the absence of air, the author obtained a large proportion of butyric ether and of ethylic ether mixed with higher alcohols.

The Preparation and Properties of Aricine.—H. Moissan and E. Landrin.—The bark operated upon contained neither quinine nor cinchonine. Aricine has a composition expressed by the formula $C_{46}H_{26}N_2O_8$. It forms fine transparent crystals, which, on prolonged exposure to the sun, turn slightly yellow. It is insoluble in water, soluble in alcohol at common temperatures, but more soluble at a boiling-heat. At 15° ether dissolves 30 grms. per litre. It melts at 188–189°.

New Preparation of Phosphorus Oxyfluoride.—Henri Moissan.—The authors cause phosphorus oxychloride to act upon anhydrous zinc fluoride (not ignited) in a metal vessel. The product obtained is a gaseous body absorbable in water, which decomposes it, and fuming in the air.

On the Critical Temperature.—M. Philippe and A. Guye.—From the tables given the authors conclude that the critical temperature is approximately equal to twice the boiling temperature *in vacuo* (20 m.m.). It is approximately equal to 4.55 times the temperature of ebullition under the atmospheric pressure.

On Fluorene Hydrides.—P. A. Guye.—The author has obtained a decahydride and an octohydride of fluorene and an octohydride of phenanthrene.

Vol. iv., Nos. 6 and 7.

Action of Mineral Acids upon the Lactic and the Butyric Ferments.—Dr. J. Effront.—The action of the mineral acids upon the lactic ferment is the same as that of the lactic acid formed in the course of fermentation; they enfeeble or entirely kill the ferments. Hydrofluoric acid acts much more energetically than the hydrochloric and the sulphuric. In the butyric fermentation the results are analogous.

Action of Isopropyl Iodide upon Aqueous Ammonia in Equi-molecular Proportion at the Ambient Temperature.—H. Malbot.—Under such conditions isopropyl iodide is converted almost entirely into mono-isopropylamine hydriodate.

The Filtration of Wort of Green Malt and Maize, through a Chamberland Filter.—The Chamberland filter holds back dextrine, albumen, and mineral matters, to a considerable proportion.

The Composition of Kaolinic Porcelains.—Georges Vogt.—This memoir will be inserted at some length.

A SIMPLE ELECTRICAL APPARATUS FOR DETERMINING THE FLASHING POINT OF MINERAL OILS.

By H. N. WARREN, Research Analyst.

THIS simple yet effective apparatus may be readily constructed from an ordinary tin canister as shown by the accompanying diagram. A represents either a copper or tinned iron cylinder, supported on tripod legs, and capable of holding about a litre of water. B is a wide-mouthed test-tube into which are fused two platinum wires connected respectively to a good induction coil capable of producing about a half inch spark. In using the apparatus the steam-pipe *r*, which is maintained in its place by inserting it through a perforated cork, is first removed and water introduced into the boiler, the tubular being replaced.

Into the tube B is placed about an ounce of the oil under question, and a light applied to the canister; the contact breaker of the induction coil should be now so regulated as to allow of a spark being passed across the tube B when desired, by merely touching the hammer.

When the apparatus has reached a temperature of about 100° F., a spark may be conveniently applied. If the effect of the explosion is somewhat violent, the light should be removed and a spark passed every few seconds until it ceases to afford any further detonation. When this point is reached it is regarded as the flashing point of the oil, and is at once indicated by the reading of the thermometer, G, which should remain inserted in the water contained in the apparatus during the testing operation. For accurate results care must be taken that any explosive residue that may remain in the tube after the passing of a former spark be removed by injecting a small quantity

of air from the mouth by means of the syphon, &c; otherwise on the admittance of a further spark a partially exhausted atmosphere may be unintentionally re-examined at a lower temperature. With due precautions the apparatus affords accurate results, and a large number of samples may be tested at a brief notice.

Oxygen in excess of Cl	0'0932
	6'0982

Having determined the component parts of the water residue in grains per gallon, it becomes necessary to unite these in chemical union, as near as possible, as they exist in the water.

The general rule may be stated as follows:—The chlorine is combined with the sodium, if still in excess, then with the potassium, magnesium, and finally calcium. The sulphuric acid to the alkalies, provided there is not enough chlorine to saturate them, then to the calcium, and finally to the magnesium.

The carbonic acid is united with the calcium and magnesium after the other combinations are made. There are exceptions to this rule, mineral waters and many artesian well waters forming notable examples.

Carrying out the above, the following is obtained:—

	Grms. per litre.	Grains per gallon.
NaCl	0'0091	0'5306
Na ₂ SO ₄	0'0033	0'1923
K ₂ SO ₄	0'0009	0'0524
CaSO ₄	0'0311	1'8136
CaCO ₃	0'0118	0'6880
MgCO ₃	0'0162	0'9446
Fe ₂ O ₃ Al ₂ O ₃	0'0051	0'2973
SiO ₂	0'0082	0'4771
Organic, &c.	0'0193	1'1254
Total	0'1050	6'1213

This analysis shows that the principal scale-forming ingredient is calcium sulphate, being more than equal to the carbonates of calcium and magnesium.

The following analysis is of a water containing sulphuric acid, but the alkalies being present in sufficient amount to combine with all of it, as well as the chlorine, no sulphate of lime is present.

	Grms. per litre.	Grains per gallon.
SiO ₂	0'0038	0'2215
So ₃	0'0110	0'6414
Cl	0'0062	0'3615
K ₂ O	0'0033	0'1923
Na ₂ O	0'0185	1'0788
MgO	0'0165	0'9388
CaO	0'0466	2'7175
Al ₂ O ₃ Fe ₂ O ₃	0'0020	0'1166
Organic	0'0246	1'4345
Carbonic acid	0'0530	3'0908
	0'1851	10'7937
Oxygen in excess of Cl	0'0021	0'1224
Total	0'1830	10'6713

Combined as follows:—

NaCl	0'0154	0'8900
Na ₂ SO ₄	0'0141	0'8223
K ₂ SO ₄	0'0061	0'5557
CaCO ₃	0'0833	4'8577
MgCO ₃	0'0338	1'9710
Al ₂ O ₃ Fe ₂ O ₃	0'0020	0'1166
SiO ₂	0'0038	0'2215
Organic	0'0246	1'4345
Total	0'1831	10'6773

Where all the chlorine is not in combination with the sodium and potassium, chloride of magnesium is usually present.

This latter compound, while not scale-forming, is considered as an active corrosive agent—upon the supposition that at the temperature of 100° C., and higher, it is decomposed, and hydrochloric acid formed and liberated—consult *Journal Society of Chemical Industry*, vol. ix., p. 472; also, "Treatise on Steam Boilers," by Wilson, p. 168.

The report, given below, is of a water from a driven well in Florida. Complaint having been made that not only was the scale excessive in amount, but that corrosive action was also very marked, an analysis was made, reference to which readily explains the difficulty encountered in the boilers.

	Grms. per litre.	Grains per gallon.
NaCl	0'323	18'87
KCl	0'067	3'91
MgCl ₂	0'104	6'06
CaSO ₄	0'197	11'52
CaCO ₃	0'293	17'10
MgCO ₃	0'144	8'40
SiO ₂	0'011	0'62
Al ₂ O ₃ Fe ₂ O ₃	0'007	0'46
Organic	0'138	8'02
Total	1'284	74'86

In all of the above analyses the constituents have been stated in grains per gallon, rather than in parts per 100,000, the former being in general use by the mechanical profession as the proper method by which to express the weights of the component parts of a water.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING NOVEMBER 30TH, 1890.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;

and C. MEYMOTT TIDY, M.B., F.C.S., Barrister-at-Law,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, *Metropolis Water Act*, 1871.

London, December 6th, 1890.

SIR,—We submit herewith the results of our analyses of the 167 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from November 1st to November 30th inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 167 samples examined, the whole (excepting two samples which were recorded as "very slightly turbid") were found to be clear, bright, and well filtered.

The seasonal variation in the composition of the water supplied to the Metropolis, for the most part too slight to constitute a variation in character, has, with the coming on of winter, to be looked for and taken note of. As regards the November supply, however, the less favourable meteorological conditions prevailing during the month including occasional periods of frost, were not found to have any significant effect on the analytical results obtained. Both absolutely, and still more in relation to the season, these results were entirely satisfactory. Thus, in the case of the Thames-derived water, the mean proportion of organic carbon was found to be 0.142 part in 100,000 parts of the water, with a maximum of 0.158 in any single sample examined, as against a mean of 0.136 part, and a maximum of 0.160 part met with in the previous month's supply. Similarly, the mean amount of oxygen consumed in the oxidation of the organic matter present in a gallon of the water was found to be 0.046 grain, against 0.040 grain (printed by mistake as 0.40 grain in the previous month's report), in the previous month's supply. Moreover, the degree of freedom from colour-tint continued to be good, the ratio of brown to blue-tint of the water being as 13.1 : 20, as against a ratio of 10.4 : 20 recorded in October, and a ratio of 14.1 : 20 recorded in September last.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES.

WILLIAM ODLING.

C. MEYMOTT TIDY.

ALLOYS OF SODIUM AND LEAD.*

By W. H. GREENE and W. H. WAHL.

RECENTLY, in the course of certain investigations in which we had occasion to make use of alloys of lead and sodium, we found that the properties of such alloys did not correspond with what we had anticipated from previous publications on the subject, and we were led to an examination of the properties of lead-sodium alloys of definite composition. These alloys may easily be made by direct combination, and the products are then sensibly constant in composition, which is not the case when they are prepared by reducing lead oxide by carbon in presence of soda, or by heating litharge with sodium tartrate, as described by Vauquelin and Serullas.

The required quantity of sodium was added to lead melted in a covered crucible, and the alloy was roughly analysed by determining lead only. Our alloys contained from 3 to 31 per cent sodium. They are all brittle and crystalline; all decompose water, that containing the least sodium producing a hardly perceptible evolution of gas, while that containing 31 per cent reacts with violence. The brittleness and oxidability increase with the percentage of sodium. The richest alloy is greenish in colour and instantly blackens on exposure to air.

We made special examinations of the alloys, corresponding in composition to Na_2Pb_2 , Na_2Pb , and Na_4Pb ; the first of these contained 10 per cent sodium, the second 19.5 per cent, rather more than would be indicated by the formula, while the last contained 31.7 per cent. The densities were determined in aniline and found to be

considerably higher than would be the densities of mixtures of the same composition. Thus the 10 per cent alloy has a density of 6.91, the 19.5 per cent a density of 4.61, and the 31.7 per cent alloy a density of 3.81. The densities of corresponding mixtures would be 5.6, 3.7, and 2.7 respectively.

The theoretical and calculated percentages of Na in alloys of above assumed composition compare as follows:—

	Na_2Pb_2 .	Na_2Pb .	Na_4Pb .
P.c. Na by theory ..	10	18.18	30.8
„ found ..	10	19.5	31.7

SIMULTANEOUS DETECTION OF THE HALOID SALTS, AND IN PARTICULAR OF CHLORIDES IN PRESENCE OF BROMIDES.

By G. DENIGÈS.

A VERY easy and characteristic means of detecting chlorine or bromine in a gaseous atmosphere is to plunge into it a glass rod, previously steeped in an alkaline lye (which, in contact with the halogens, is converted into a hypochlorite or hypobromite), and to dip the moist end of this rod in a saturated solution of aniline in water, which is coloured violet or violet-red by the hypochlorites and orange-yellow by the hypobromites.

If we have a mixture of haloid salts we need, therefore, merely to set the halogens at liberty in order to detect them by the aniline method. For this purpose we generally employ sulphuric acid and an oxidising substance, most commonly manganese peroxide; among the other oxidising agents the chromates liberate only iodine and bromine without sensibly affecting the chlorides. Permanganate quickly sets all the halogens at liberty.

On the basis of these facts, the author has devised the following method for the easy and expeditious detection of chlorides in presence of bromides, and in a more general manner for the simultaneous recognition of all the haloid salts.

For this purpose a c.c. of the liquid to be examined is put into a test-tube, and there are added from 20 to 30 drops of concentrated sulphuric acid. If a gas escapes (carbonic, sulphurous, &c.) the mixture is boiled to expel it, and there are added 20—30 drops of a solution (saturated in the cold) of yellow potassium chromate (about 50 grms. of the salt to 100 c.c. of water); into the first half of the tube there is plunged a slip of starch paper moistened with water, which, if it turns blue indicates the presence of iodine, or otherwise its absence.

In the latter case we add a few drops more of sulphuric acid, and plunge into the axis of the tube (without touching the sides) a glass rod, the rounded extremity of which has been moistened with soap-boilers' lye (!) After a few seconds it is withdrawn, and the moistened end is brought in contact, in a glass, with a c.c. of water saturated with aniline, and stirred. If there is produced an orange precipitate the liquid contains a bromide. If there is merely a white precipitate it is due to the soda and there is no bromide.

If bromine or iodine has been found, the liquid is boiled and air is blown into the tube through a long glass tube drawn out to a point, and inserted almost to the level of the liquid, so as to clear away the vapours from the test-tube. It generally takes about ten insufflations, each preceded by a short boil for the complete expulsion of bromine and iodine. This is ascertained by adding 10 more drops of potassium chromate and boiling. There are then poured in the liquid 20 drops of a solution of permanganate at 5 per cent; the whole is stirred and as much as 1 to 2 c.c. of soda-lye is added with the stirring rod to the surface of the liquid, then into a glass containing aniline water, and stirred, when if chlorine is present we obtain a violet or reddish violet colouration after stirring

* Read at the Chemical Section of the Franklin Institute, November 18, 1890.

for a few moments. It may happen, if there remain traces of bromine, that the colouration will be at first orange, but it will rapidly pass into violet if there is a chloride in the original liquid.

The author has clearly detected the chlorine in a c.c. of a liquid containing:—

	Grm.
KI	0.02
KBr	0.01
NaCl	0.004

He has even been able to detect 1 per cent of sodium chloride in potassium bromide by operating as follows:—

He put into a tube 0.5 grm. pure potassium bromide, and 0.005 grm. sodium chloride, then 40 drops potassium chromate in solution (saturated in the cold), and 30 drops of sulphuric acid. He boiled and blew in air into the tube five or six times. He added, further, 10 drops of the potassium chromate and 10 drops of sulphuric acid. After further boilings and insufflations, he added 20 drops permanganate. The stirring rod, moistened with soda, was left for a quarter of a minute in the lower third part of the tube, and on being then plunged into aniline water it quickly gave a very distinct violet colour.

If we find iodine in the first trial we should not always search directly for bromine in the vapour, because the alkaline hypoiodates give with aniline not, indeed, an orange yellow, but a canary yellow, and a second trial is necessary to detect bromine with certainty.

To this end we put into a tube 1 c.c. of the liquid, 10 drops of ferric chloride, and as much sulphuric acid; the iodine is removed by blowing and boiling; 10 drops of sulphuric acid and 20 drops of potassium chromate are further added, and we test for bromine with aniline water, making use of the stirring rod moistened with soda.

These various reactions necessitate the complete removal of bodies which might mask or enfeeble them, i.e., iodine and bromine in the case of chlorine, and iodine in that of bromine. This is quickly effected by means of boiling and insufflation, but we must not forget that, as in most cases of the analysis of a mixture, we require here a complete separation, very rapid, indeed, and not requiring filtration or distillation, but which must be as complete as possible so as to avoid errors.

This method of analysis founded on the use of glass rods moistened with reagents deserves to be generalised on account of its certainty and facility. The author has indicated its use with isatine and sulphuric acid for the detection of the mercaptans and thiophene, of nitrous vapours by sulphuric acid and diphenylamine sulphate, of ammonia by Nessler's reagent, of sulphurous acid by soda, ferric chloride, and potassium ferricyanide, of sulphuretted hydrogen by soda and sodium nitro-prusside, &c.—*Bulletin de la Société Chimique de Paris.*

ON THE COMPOSITION OF KAOLINIC PORCELAINS.

By M. GEORGES VOGT.

THE analysis of the Chinese and Japanese porcelains has led chemists to conclude that they were composed of kaolin, felspar, and quartz; and according to these analyses it was concluded that the synthesis of Oriental porcelains could be effected by mixing 50 parts kaolin, 30 felspar, and 20 quartz. Upon these data the European porcelain manufacture has been established. If we consider merely the centesimal composition of the various porcelain pastes as deduced from the elementary analysis, this view may seem correct, but if we study them more closely by the procedures of proximate analysis, we are led to perceive that another mineral than those mentioned enters into their composition.

The author has had the opportunity of examining

specimens of the raw materials used in China for the manufacture of porcelain, collected with the utmost care by the late M. Scherzer, Consul at Canton. From the total analysis of the two minerals, yeou-ko and pe-tun, we might be led to consider them as analogous to the pegmatite of Limousin. But on treating pegmatite with sulphuric acid we obtain only 3.3 per cent of soluble matter in place of 34.15 and 40.63 as found in the Chinese minerals.

But if we compare the centesimal composition of the soluble matter of yeou-ko and pe-tun (disregarding in the former the 2.04 of calcium carbonate, and 1.01 silica, which are directly soluble) with that of white mica, there appears such a close similarity that we may pronounce the soluble part found in the Chinese rocks identical in composition with white mica. The mica contained in yeou-ko and pe-tun is in very minute particles, invisible with the naked eye and even with the lens. But a microscopic examination with polarised light detects its presence and confirms the result of the analysis. Hence it appears that the minerals which form Chinese porcelain are distinguished from pegmatite by the presence of a large quantity of mica. The paste used in China in the manufacture of porcelain known as *hoa-che* is an almost pure natural mixture of hydrated aluminium silicate, and white mica in a very fine state of division. The mica found in these Chinese materials must not be confounded with the tablets of ferruginous mica, the presence of which is feared in the preparation of porcelain pastes in Europe.

The mica is first broken up in a disintegrator, then ground with water under porcelain mills, and then levigated in an apparatus with flowing water, so that only the finest portions are collected. These portions are then dried down to a thick consistence. Mica thus prepared possesses a plasticity almost equal to that of kaolin. It can be kneaded, moulded, and it dries without warping or cracking. Under such conditions the introduction of mica into a paste does not in any manner interfere with the ordinary manufacture of the porcelain. In the furnace the mica melts much less easily than felspar, and keeps its form at very high temperatures (1400°). The porcelain paste used in the Imperial manufactory of China is composed of—

Kaolin	23.4
Mica	23.4
Soda-felspar	25.0
Quartz	28.2

On the contrary, the new paste employed at Sèvres consists of—

Kaolin	35.6
Soda and potash felspars	38.0
Quartz	26.4

Total 100.0

The author has endeavoured to reproduce exactly the Chinese porcelain, but found some difficulty in obtaining in France minerals as rich in mica as those of China. He has since found at Montebas (Creuse), a mineral containing 23 per cent of mica, and a kaolin from St. Yrieix containing 20 per cent. The French mica alone is too ferruginous to yield a good paste. A paste composed of—

Kaolin	20
Mica	45
Quartz	40

yielded merely a stone-ware of fine quality. To obtain a beautiful and very transparent porcelain, a certain quantity of felspar must be added, the mixture being—

Kaolin (pure)	25
Mica	25
Orthose	25
Quartz	20

A paste containing 17 per cent of mica yielded by the following mixture—

Kaolin, containing 20 per cent of mica ..	35
Montebraz mineral (23 per cent of mica) ..	57
Orthose	20

yielded a fine porcelain of great whiteness. These porcelains, although baked at 1450°, can be covered with alkaline glazes in the furnace and with enamels in the muffle.—*Bulletin de la Société Chimique de Paris.*

THE DRY ASSAY OF TIN ORES.*

PART II.

By HEINRICH O. HOFFMANN,
Assistant Professor of Mining and Metallurgy.

(Concluded from p. 302).

VI. Preparation of the Ore for the Assay.

It will be seen from the foregoing that the influence of the associated minerals on the result of the assay is very considerable. It becomes, therefore, necessary to have as pure a black tin as possible for the dry assay. When it is remembered that tin ores contain only from 0.75 to 3 per cent of cassiterite, their preparation for the assay is seen to be a very important part of the work.

The separation of the cassiterite from the gangue is accomplished by crushing and washing. The resulting concentrates are then purified by means which vary according to circumstances. From the great difference in specific gravity between the cassiterite (6.4 to 7.1) and the non-metallic associated minerals (not over 4.1), it would appear at first sight that the separation ought to be very easy, but this for various reasons is far from being the case. Special precautions are needed if the loss of black tin is to be reduced to a minimum. The metalliferous minerals have too great a specific gravity (e.g., arsenopyrite 6 to 6.4) to be removed by washing; roasting and acids have to be used. The columbite (tantallite), whose specific gravity varies from 5.89 to 6.12, remains finally with the black tin, as it is not attacked by ordinary acids at all.

The implements used in assay laboratories for pulverising larger quantities of ore are a small hand-crusher and a pulverising plate. The ore is usually crushed, sampled down, and then pulverised on the rubbing-plate or in a mortar. Experience has proved that the common method of grinding the whole sample to a uniform size is not suited to the tin ores of the Black Hills. The main reason for this is the preponderance of mica. Anyone who has tried to pulverise mica, even if previously heated, will appreciate the difficulty. Happily, very little cassiterite occurs in the mica proper, which if ground for a short time only on the rubbing-plate will not show any black tin or other mineral. The pulverisation must be carried on with the subsequent washing in view. The first rule in concentration is, that a good preliminary sizing should precede the separation by specific gravity. The second is, that the ore should be coarse, to prevent loss in washing. The latter point is strongly emphasized in the present case by the fact that the brittle cassiterite will be ground to a slime, while other minerals in the ore are only converted into sands. The writer's practice has been to screen while the ore is being pulverised, crushing and screening alternately with a graduated series of sieves, Nos. 20, 40, 60, and 80. The ore is crushed until all the minerals, with the exception of the mica, are fine enough to pass a 20-mesh sieve; the mica is then examined for any minerals adhering to it, and these are removed by grinding, and screened. The different screenings are now washed separately in the gold pad, and the tailings panned over. The concentrates obtained by the separate washings are put together, dried,

and passed through a 60-mesh sieve, and the washing is repeated, the result being pure concentrates and tailings. These are panned over if any cassiterite appears.

The writer has done all his washings of tin ore in the gold pan; but any other apparatus, be it the vanning shovel used in Cornwall, or the "Sichertrog" of the Saxon or Bohemian miner, will, with the necessary practice, give the same result. In panning, it is found very difficult to separate the cassiterite from the garnet without losing much tin, although there is a great difference in their specific gravities, viz., 6.4 to 7.1 and 4.1. It is almost impossible to effect a complete separation, as can be seen from the analysis of the average sample, where the insoluble residue, 9.39 per cent, is principally garnet. This is on account of the different way in which the minerals break. Dana† says that both cassiterite and garnet have an uneven, subconchoidal fracture, and that both are brittle; they also differ little in hardness (6 to 7 vs. 6.5 to 7.5). But the cassiterite crushes into splinters, and the garnet into a granular form. It is probably this difference that causes the difficulty in separating the two minerals; the preponderating particles of cassiterite form an irregular angular network, and prevent the heavy garnet from being carried off by the water with the other minerals that have a lower specific gravity. If garnets are present in any large quantities it will be necessary to adopt other means to remove them. Dana‡ says that all garnets, except ouvarovite, are decomposed with hydrochloric acid after ignition. That this may be complete, the mineral has to be ground very fine. It will be remembered that the black tin used for the experiments was roasted, chilled, and treated with nitro-hydrochloric acid, and the garnets were not entirely removed. If the garnet is decomposed, the removal of the gelatinous silica, either by washing or by hydrofluoric acid, is simple.

The black tin obtained by washing still retains sulphides and arsenides. Berthier§ recommended boiling with nitro-hydrochloric acid, and burning off any sulphur that might have separated. Plattner¶ objects to this, as the sulphur would not all be eliminated. He reverses the process, roasting first and then treating with nitro-hydrochloric acid. Following Plattner, the black tin is roasted on a dish in a muffle, and, to assist the decomposition of the garnet, chilled in cold water after roasting; it is then boiled in a porcelain dish with nitro-hydrochloric acid, which will also remove particles of metallic iron coming from the implements used in grinding; when all the iron is dissolved, the solution is poured off, and any light particles washed away. If necessary, the concentrates can be transferred to a platinum dish and treated with hydrofluoric acid. This, however, will rarely be required.

The roasting seems to have a favourable effect on the cassiterite by making it more friable and more readily reducible. The unroasted cassiterite of the Black Hills is subtranslucent, brown to black, and very hard to pulverise; the roasted mineral is opaque, of a more or less reddish brown, and easily pulverised. The change that takes place in the reducibility of the ore is shown by the following experiments:—

TABLE XXVIII.

No. of assay.	Name of mine.	Per cent of tin from raw ore.	Per cent of tin from roasted ore.
168.	Occidental	48.90	49.00
169.	Glendale	65.30	65.60
170.	First Find	65.30	65.80
171.	Similias	75.00	75.00

The results show that in some cases (No. 171) no difference exists between raw and roasted concentrates, while in others it may amount to 0.5 per cent.

§ "Traité des Essais," 1847, vol. ii., pp. 486, 487.

¶ "Blowpipe Analysis," edited by Richter, and translated by Cornwall, New York, 1885, p. 466.

If the preliminary treatment of the tin ore is carried out in the manner described there will be a minimum of loss in black tin.

VII. Conclusion.

From this examination of the different methods of assaying tin ores in the dry way, it becomes apparent that, if ordinary precautions are taken, the necessary treatment, including the preliminary preparation of the ore, is a comparatively simple matter; neither is the influence of the associated minerals so great, at least with the cyanide assay, as is generally supposed. Lastly, the results obtained show that the dry assay of purified black tin gives more accurate results than that of any other base metal, if the few correct methods, none of them requiring special skill, are followed and ordinary care is given to the work.

THE COEFFICIENT OF MINERAL CONDENSATION IN CHEMISTRY.*

By T. STERRY HUNT.

(Concluded from p. 306).

19. THE history of the development of this modern conception in chemistry is one of such importance as to demand a somewhat extended study. The earliest statement, so far as the writer is aware, of the application of the doctrine of complex formulae, of high equivalent weights, and of homologous relations (already recognised among hydrocarbonaceous bodies in the domain of organic chemistry), to mineral, or inorganic, chemistry will be found in a paper by him in 1853. Therein it was contended that isomorphous solid species, at least, "have the same equivalent volume, so that their equivalent weights (as in the case of vapours) are directly as their densities; and the equivalents of mineral species are as much more elevated than those of the carbon series as their specific gravities are higher." Referring to the latter, "the hydrocarbonaceous, or so-called organic, species," and to the law of progressive or homologous series therein first pointed out by James Schiel, of St. Louis, and soon after adopted by Charles Gerhardt, it was said that, it may be expected that mineral species will exhibit the same general relations as those of the carbon series, and the principle of homology be greatly extended in its application. The history of mineral species affords many instances of isomorphous silicates, whose formulae differ by $n(\text{O}_2\text{M}_2)$, as the tourmalines, and the silicates of alumina and of magnesia.

It was then further declared that the native mineral carbonates or carbon-spars must be represented as polycarbonates having not less than from "twelve to eighteen equivalents of base replaceable so as to give rise to a great number of species"; among which the relations of their densities were said to "indicate the existence of several homologous genera which are isomorphous." In subsequent papers, in 1853 and 1854, attempts were made to show that in these polycarbonates, $n(\text{CMO}_3)$, the different values of n might be not less than 22, 25, 30, 36, and 40. Similar elevated formulae were also given in 1853 for various polysilicates, as in the cases of augite, amphibole, and wollastonite, and of the feldspars, albite, anorthite, and orthoclase. In this connection the complex silicates containing chlorides, carbonates, and sulphates were considered and compared to basic salts.†

* From the *American Chemical Journal* for November, 1890, vol. xii., No. 8.

† "The Theory of Chemical Changes and Equivalent Volumes," *Am. J. Sci.*, xv., (226-234); *Phil. Mag.* (4) v., 326; and in a German translation in the *Chem. Centrbl.* of Leipzig for the same year (p. 849); also in the author's "Chem. and Geol. Essays," pp. 427-437. Further, "The Constitution and Equivalent Volume of Mineral Species," *Am. J. Sci.*, xvi., (203-218), and in abstract, in the author's "Chem. and Geol. Essays," p. 435, &c. Also, "Illustrations of Chemical Homology," *Proc. Am. Assn. Adv. Sci.*, 1854, pp. (237-247); also, in abstract, *Am. J. Sci.* for September of the same

The variations in the ratios of silica and alumina in nearly related species, and the apparent partial replacement therein of silica by the latter, then imperfectly understood, were noted in 1854 as seeming to invalidate the distinction between silica, as the negative or acidic member, and the positive or basylous member of these oxidised compounds, in which alumina was at that time still included.

20. These views of polymerism in mineral species, involving on the one hand the conception of many equivalents of replaceable base, and on the other of many equivalents of the acidic or negative element, which might be either carbonic, silicic, or boric oxide, or might include with the latter alumina, sulphates, carbonates, or fluorides, though thus enunciated in 1853, found no favour among chemists until 1860, when Adolphe Wurtz again put forth the notion of polysilicates, citing in connection therewith the metastannates of Frémy, in which the negative element consists of $5(\text{SnO}_2)$. The similar metatungstates or tetratungstates, the pyroborates, the polyphosphates of Fleitman and Henneberg, including tetraphosphates and dekaphosphates, and the not less complex phosphates of Wallroth, with $9(\text{P}_2\text{O}_5)$, soon showed that such a polymerism is not exceptional in negative or acidic oxides. The studies of other chemists, moreover, made it known that similar compounds, including different negative oxides of the same or of unlike valencies, were not less frequent; as appears in the complex phosphovanadates and arsenovanadates, in the aluminomolybdates, the ferrimolybdates, the borotungstates, the silicotungstates, the phosphotungstates, the phosphomolybdates, the stannophosphomolybdates, and salts of still greater complexity and of very high equivalent; often presenting series which illustrate in a striking manner the extension to such mineral species of the law of progressive series.

The high integral weight, the limited basicity, and the partial instability of these complex salts are well illustrated in the phosphomolybdate of ammonia formed in the ordinary method for determining phosphorus thereby. This insoluble compound, when precipitated in presence of an excess of chlorhydric or nitric acid, contains $12\text{MoO}_3 \cdot \text{PO}_4 \cdot (\text{NH}_4)_3$, besides $2\text{NO}_3 \cdot \text{H}_2\text{O}$ or $2\text{HCl} \cdot \text{H}_2\text{O}$, constituting a nitro-, or a chlorhydro-, phosphododekamolybdate; but by desiccation at 150° these volatile acids and water are expelled, leaving the phosphomolybdate with 3.78 per cent of phosphoric oxide, P_2O_5 .

21. We have thus endeavoured to trace the steps by which, from the writer's first enunciation, in 1853, of complex formulae, high integral weights, and homologous, or progressive, series in mineral species, chemists have been led up to the comprehensive generalisation which Wolcott Gibbs has embodied in the important conception of what he has called complex inorganic acids. The results of chemical analysis, while they permit us in many instances to assign small integral weights to chemical species, force us to conclude that in other instances these integral weights are very elevated, conclusions which in the one and in the other case are confirmed alike by the vapour-density and by the cryoscopic method; which latter it will be desirable to verify still further by the study of many soluble salts of apparently complex constitution.

22. The cases which we have just considered show in chemical species of related centesimal composition, as in formaldehyd, xylose, glucose, the higher sugars, the dextrines and soluble starch, integral weights rising from 30, 150, and 180 to numbers which cannot be less than thousands. These figures suggest for chemical species a range of integral weights which may conceivably rise to that of the mineral species itself. Instead of being, as in glucose and other sugars, a multiple of the chemical integer by a high number, the coefficient for the mineral

year; and noticed, with extracts, in the author's "Chem. and Geol. Essays," p. 438 et seq. The whole question is further discussed in the author's "Mineral Physiology, &c.," pp. 288-295.

species becomes a small one, as in the case of the dextrines and soluble starch, or of the cobaltamines and the polytungstates. So far as is yet known, however, there intervenes, in all cases, a greater or less polymerisation, the study of which will be found to have important thermochemical relations.

If we consider the four groups of sugars represented chemically by xylose and arabinose (C_5), glucose (C_6), saccharose (C_{12}), and raffinose (C_{18}), but having for the mineral species essentially the same specific gravity, assumed to be 1.5, we shall have for the coefficients of the mineral species, respectively, the numbers 214, 180, 94, and 54, corresponding to a common integral weight, therefore, of 32,100; xylose being $214(C_5H_{10}O_5)$, glucose $180(C_6H_{12}O_6)$, &c. In the case of the volatile polymeric hydrocarbons already mentioned (§8), α -decylene (CH_2)₁₈, cerotene (CH_2)₂₇, and melene (CH_2)₃₀, assuming the specific gravities assigned for the solids, namely, 0.79, 0.86, and 0.89, to be correct, we have respectively the coefficients for the solid mineral species of 67, 48, and 45. Melene will be $45(CH_2)_{30}$, cerotene $48(CH_2)_{27}$, and α -decylene $67(CH_2)_{18}$.

23. The ammonio-cobalt salts, from the results of chemical analysis, have necessarily high integral weights for the chemical species, and have assigned to them densities of about 1.7–1.8; the former figure corresponding to an integral weight for the mineral species of about 36,380.* The minimum chemical weight for the orthometaphosphate of luteocobalt (=2540) would demand a coefficient for the mineral species of 14, since $14 \times 2540 = 35,560$. In like manner the soluble crystalline hydrous polyphosphotungstates have for sodium salts, according to Scheibler, specific gravities of 3.84–3.98, and for a barium salt 4.3. I find no determination of specific gravity for the highly complex polyphosphovanadate (§1) to which Gibbs assigns a chemical weight of 20,058, and which, should its coefficient of polymerisation be 4, would have a specific gravity of 3.75, nearly. More or less uncertainty must, however, still exist with regard to the true chemical formulæ, and consequently to the integral weights of chemical species of such complex constitution as those now under consideration. Under the name of tungsten-bronzes have been conveniently included several anhydrous crystalline bodies, metallic in lustre, conductors of electricity and highly electro-negative, which are nevertheless oxidised compounds of tungsten and an alkali-metal. The tungsten-bronze first described by Wöhler is, in the opinion of Gibbs, probably $16WO_3 \cdot 4WO_2 \cdot 7Na_2O (=5002)$. To this has been assigned a specific gravity of 6.617; to another sodium species, 7.28; and to a potassium species, 7.60.

24. The fact that in the soluble hydrous polytungstates, hydrocarbon radicles like methyl, ethyl, and phenyl may enter, helps to break down the barrier, not yet wholly removed, which once separated the so-called organic and inorganic compounds (§2). Even the stability of insoluble silicates is not proof against similar changes, as shown in the case of artificial ultramarine. This, which is got as a blue, green, or violet crystalline powder, appears to be essentially a peculiar sodium aluminosilicate in which the oxygen is partially replaced by sulphur. By digestion with a solution of silver nitrate a yellow substance is got in which silver replaces sodium, and this with ethyl iodide yields a compound into which the alcohol radicle enters, and which by subsequent treatment with sodium chloride gives off ethyl chloride and regenerates blue ultramarine. The silver in the yellow species may also be replaced by potassium or by lithium, the last giving also a blue ultra-

marine. Similar compounds are obtained from ultramarine* the iodides of amyl, allyl, and benzyl.* It is probable that only their great insolubility prevents us from getting somewhat similar results with more highly condensed silicates, such as the felspars, micas, and tourmalines.

25. It will be clear to those who have followed the preceding argument, that in cases where neither the vapour-density nor the cryoscopic method can be evoked, that is to say in non-volatile and insoluble mineral species, we have not the means of determining the integral weight of the chemical species which by its subsequent condensation generates such mineral species; or of discovering whether this may have attained that condensation by a single step or by successive stages. Thus, by hypothesis, a solid like retene might be generated directly by the intrinsic condensation of acetylene, or from benzene; the production of the latter hydrocarbon marking an intermediate stage in the progress of homogeneous integration. What stages, if any, intervene in the passage from the soluble normal calcium carbonate to the insoluble crystalline mineral species, calcite and aragonite, we may never know, though from the existence of these two mineral species of identical centesimal composition with different degrees of condensation and of solubility in acids, corresponding to the differences observed in the various polymers of many hydrocarbons, aldehydes, &c., we may with great probability suspect the existence of intermediate and unstable stages of condensation in calcium carbonate. The same argument applies equally to the unlike forms of silicon dioxide, tridymite, and quartz, differing alike in specific gravity and in solubility; to the two forms of iron disulphide; and to other cases too many to recall.

26. We can in very many cases recognise at least two distinct stages of polymerisation in the passage of a given chemical species, either simple or compound, into a mineral species. The first stage is seen when the vapour of sulphur (S_2) passes by intrinsic condensation into the denser vapour (S_6); gaseous acetylene into the vapour of benzene, of cinnamene, or of retene; or when formaldehyde dissolved in water is changed to an aqueous solution of formose. The second stage is seen in the passage of the dense sulphur vapour, the polymerised hydrocarbon vapours, or the dissolved formose, into liquid or solid forms. For the great multitude of mineral species of which the corresponding volatile or soluble species are unknown to us, the means of marking these separate stages are wanting, and we have but two data: the specific gravity of the mineral species, water being unity, and the equivalent weight as deduced from the results of chemical analysis; d = the specific gravity and p = the equivalent weight. The latter, for compound species, may be calculated from the simplest formula which represents intelligibly the results of such analysis,—or, as we have elsewhere proposed as the basis of a wider comparison which should include all metallic oxides, salts, and haloid compounds—by the adoption for p of a still simpler and an arbitrary unit. For all such species “we assume as the unit for p a weight including that of $H=1$, of $Cl=35.5$, or of $O \div 2=8$. By thus adopting a combining weight of 8.0 for oxygen, we get a unit which gives a common term of comparison for oxides, sulphides, chlorides, fluorides, and for intermediate compounds like the oxysulphides and oxyfluorides common in native species.” For all silicates, carbonates, sulphates, phosphates, and more complex species, we find the value for p “by dividing in all cases the empirical equivalent weight by twice the number of oxygen portions ($O=16$ plus the number of chlorine or fluorine portions.”† This

* The revision by Crafts in 1888 of Regnault's determination of the weight of a litre of hydrogen in the latitude of Paris, making it 0.08988 grm. (instead of 0.08975 grm.) gives—if $O=15.06$ —for the integral weight of water 21,335 in place of 21,406. In the uncertainty which still prevails as to the precise value of oxygen as compared with hydrogen, we may yet retain for water—the unit of specific gravity for liquids and solids—the number hitherto adopted, 21,400, as a close approximation, since the difference would only involve an error of about three-thousandths of a unit in such specific gravities.

* For a summary of the results of the study of ultramarine by Neumann, Philipp, and de Forcrand, see “Watts's Dict. Chem.,” 3rd Suppl., 2069–2071.

† For a further discussion of this question see the author on Chemical Integration in *Am. J. Sci.* for August, and in *Chem. News*, lvi., 136, 142; also his volume, “A New Basis for Chemistry,” 1888, 2nd ed., pp. 225–227, and a French translation thereof by Prof. W. Spring, with additions by the author, entitled “Un Systeme Chimique Nouveau,” Paris, 1889.

method was already adopted by the author in 1886, and he has since proposed to complete it by the device of a notation as near as may be monadic, in which, by the use of various kinds of type, the valencies of the combining elements are made apparent.*

27. Since the arbitrary mean chemical unit ρ , thus assumed, represents in all cases an aliquot part of the chemical species, however simple or however complex, which by its final intrinsic condensation has generated the mineral species whose specific gravity ($=d$) is known, it follows that the equation $\rho + d = v$, giving in v the reciprocal of the coefficient of condensation, permits a ready comparison of the relative condensation in mineral species, upon which, as we have elsewhere endeavoured to show, the hardness and the chemical indifference of solids depend.

It will be remembered that ρ , which represents the equivalent weight of the chemical unit, corresponds in the last analysis to the specific gravity of that unit presumed to be gaseous,—hydrogen gas at standard temperature and pressure being unity ($H=1$),—while d represents the specific gravity of the liquid or solid mineral species, liquid water at its point of condensation at standard pressure being unity ($I=21,400$). The value deduced from this conventional ρ is readily adapted to any rational formula which may be admitted for the species in question. Thus quartz, represented as silicon dioxide, $SiO_2=60+4=15=\rho$, and this being divided by 2.65, the specific gravity of quartz, we find $v=5.66$, which for SiO_2 gives $v=22.64$. We have then the proportion—

$$22.64 : 21,400 :: 1 : 945.$$

In other words, if simple silicon dioxide passes directly into the mineral species quartz, the coefficient of condensation is approximately 945, or perhaps 950 (SiO_2). Should it be found, as is probable, that silicon dioxide in its soluble colloidal condition is a polymer of greater or less equivalent weight, represented by $(SiO_2)_{10}$ or by $(SiO_2)_{50}$, the above coefficient therefor would be divided by these numbers: the total coefficient of mineral condensation, comprising two or even more stages, being in each case the same. In the application of Raoult's method to colloidal silica, the reduction of the freezing point, according to Sabaneff, was so slight that the values all came within the limits of errors of observation,† as would also appear to be the case with soluble starch.

To take another example, calcite—

$$CCaO_3 = 100 + 6 = 106 = \rho.$$

Dividing ρ by 2.73, as the specific gravity of calcite, we find $v=6.10$ nearly, which for $CCaO_3$ gives $v=36.6$.

$$36.6 : 21,400 :: 1 : 584.$$

The condensation from $CCaO_3$ to calcite of specific gravity 2.73 is thus represented by 584 ($CCaO_3$). Here, too, as in the case of silicon dioxide, it is probable that there exists an intermediate polymer, represented by a soluble form of carbonate of lime, long since noticed by the writer.‡

28. These numbers thus arrived at for quartz and for calcite are, of course, but approximations, since the exact equivalent weights of oxygen and of silicon are still uncertain, and since, moreover, there are small variations in the specific gravity of the mineral species themselves, from which Breithaupt with much plausibility conjectured, in the case of calcite, the existence of several species, rhombohedral in form, with specific gravities

* See in the author's "Mineral Physiology and Physiography" an essay on "A Natural System of Mineralogy, with a Classification of Silicates; and later, "Notes on Valency, Basicity, Complex Acids, and Chemical Notation: CH. M. N. W. S., lxi., 267.

† *Am. J. Sci.* (III.), xl., 87.

‡ Recently-precipitated and still gelatinous calcium carbonate is soluble in water containing small quantities of calcium chloride or of magnesium sulphate, a litre at ordinary temperatures holding for many hours a gram or more of the dissolved carbonate, which, however, finally separates completely in transparent hydrated crystals, $CCaO_3 \cdot 5H_2O$. See the "History of Lime and Magnesia Salts," *Am. J. Sci.*, 1866, (2), xlii., 58, 59; also "Mineral Physiology, &c.," p. 168.

ranging from 2.652 to 2.754. At the same time we must not overlook the calcium carbonate, aragonite, harder and less soluble in acids, with a specific gravity of 2.94, showing a higher intrinsic condensation than any calcite.

We have spoken of the views advanced in this paper as based on an hypothesis. It is, however, an hypothesis founded on a belief in the universality and the invariability of the law of volumes, and one which appears to be in complete harmony with the facts of chemistry so far observed. As one of the conclusions of a lifetime devoted to the study of certain chemical problems discussed more at length in the later editions of his "New Basis for Chemistry," the writer now submits his paper to the judgment of philosophers.

PROCEEDINGS OF SOCIETIES.

PHYSICAL SOCIETY.

December 12, 1890.

Prof. W. E. AYRTON, F.R.S., President, in the chair.

SHELFORD BIDWELL, F.R.S., showed "Some Experiments with Selenium Cells."

The crystalline variety of selenium was, he said, most interesting to physicists owing to its electrical resistance being greatly diminished by light. This property was shown experimentally with different forms of cells, the construction of which were explained. The form recommended was that in which two copper wires are wound near each other round a slip of mica, and the spaces between the wires filled with selenium. The wires form the terminals of the so-called "cell," which, before being used, is annealed for several hours at a temperature above 200° C. Many such cells were made in 1880 and 1881, and their sensitiveness to light remained unimpaired during 1882. In 1885, however, several were found less sensitive, and others totally useless; only one out of thirteen retained its sensibility till September, 1890. The loss of sensitiveness, Mr. Bidwell believes due to an excessive amount of selenide of copper being formed, for although some selenide is essential to the satisfactory working of the cell, too much is fatal to its action. The selenide of one defective cell was electrolysed, red tufts of amorphous selenium appearing on the anodes. A white substance resembling moist calcium chloride was also present; this he believed to be oxide or hydroxide of selenium. Small polarisation currents had been obtained from selenium cells.

A lecture apparatus illustrating the properties of selenium cell was exhibited. It consisted of a cell connected in series with a relay and a battery. The relay was arranged so that it might either ring a bell or light an incandescent lamp. When the bell was joined up, it remained silent so long as the selenium cell was illuminated, but on screening the cell the bell rang. By using various coloured glasses as screens, the effect was shown to be due to the red and yellow rays. A similar experiment with the glow-lamp was very striking, for on turning down the gas-lamp illuminating the cell, the electric lamp lighted, and was extinguished on turning up the gas. This demonstrated the possibility of an automatic lamp-lighter which would light or put out lamps according as they are required or are superfluous. Amongst the other practical applications suggested were, announcing the accidental extinction of railway-signal lamps or ship's lights, and the protection of safes and strong-rooms.

Prof. MINCHIN said he had lately constructed cells of a different kind to those shown by Mr. Bidwell, and found that they gave an E.M.F. when exposed to light. For his purposes the long annealing, &c., were quite unnecessary,

and a complete cell could be made in ten minutes. One of his cells gave an E.M.F. of over 0.25 volt, as measured by an electrometer, by the light of a fog. Their promptness of action falls off in a day or two, but if they are kept on open circuit a week has no effect on the final E.M.F. On closed circuit, however, they deteriorate.

Prof. S. U. PICKERING said both oxides of selenium were deliquescent, and the author's conclusion as to the white substance formed by electrolysis was probably correct.

Prof. S. P. THOMPSON believed Prof. Graham Bell had tried platinum instead of copper, and found that the selenium cracked off in annealing. He also found that it was only necessary to carry on the annealing until the characteristic slate colour appeared. Mr. Bidwell's experiments, he said, showed the possibility of seeing at a distance, and had also suggested to him that the effect of screening might be utilised for driving a completely detached pendulum electrically.

Prof. FORBES said that silver sulphide when electrolysed presented appearances resembling those noticed by Mr. Bidwell in copper selenide.

In reply to questions from the President and Prof. Perry as to whether the low resistance and unsensitiveness of old cells was due to moisture, Mr. Bidwell said, drying them had no effect, but baking restored the resistance, but not their sensitiveness. Speaking of the effect of annealing cells, he said this reduced their resistance considerably. Prof. Graham Bell, he believed, gave up using platinum because the resistances of such cells were very high.

Mr. JAMES SWINBURNE read a paper on "*Alternate Current Condensers.*"

It is, he said, generally assumed that there is no difficulty in making commercial condensers for high pressure alternating currents. The first difficulty is insulation, for the dielectric must be very thin, else the volume of the condenser is too great. Some dielectrics, 0.2 m.m. thick, can be made to stand up to 8000 volts when in small pieces, but in complete condensers a much greater margin must be allowed. Another difficulty arises from absorption, and whenever this occurs the apparent capacity is greater than the calculated. Supposing the fibres of paper in a paper condenser to be conductors embedded in insulating hydrocarbon, then every time the condenser is charged the fibres have their ends at different potentials, so a current passes to equalise them and energy is lost. This current increases the capacity. One condenser made of paper boiled in ozokerite took an abnormally large current and heated rapidly. At a high temperature it gave off water, and the power wasted and current taken gradually decreased.

When a thin plate of mica is put between tin foils, it heats excessively; and the fall of potential over the air films separating the mica and foil is great enough to cause disruptive discharge to the surface of the mica. There appears to be a luminous layer of minute sparks under the foils, and there is a strong smell of ozone.

In a dielectric which heats, there may be three kinds of conduction, viz., metallic, when an ordinary conductor is embedded in an insulator; disruptive, as probably occurs in the case of mica; and electrolytic, which might occur in glass. In a transparent dielectric the conduction must be either electrolytic or disruptive, otherwise light vibrations would be damped.

The dielectric loss in a cable may be serious. Calculating from the waste in a condenser made of paper soaked in hot ozokerite, the loss in one of the Deptford mains came out 7000 Watts. Another effect observed at Deptford is a rise of pressure in the mains. There is as yet no authoritative statement as to exactly what happens, and it is generally assumed that the effect depends on the relation of capacity to self-induction and is a sort of resonator action. This would need a large self-induction, and a small change of speed would stop the effect. The following explanation is suggested. When a condenser is put on a

dynamo, the condenser current leads relatively to the electromotive force, and therefore strengthens the field magnets and increases the pressure. In order to test this, the following experiment was made for the author by Mr. W. F. BOUNE. A Gramme alternator was coupled to the low pressure coil of a transformer, and a hot-wire voltmeter put across the primary circuit. On putting a condenser on the high pressure circuit the voltmeter wire fused. The possibility of making an alternator excite itself like a series machine, by putting a condenser on it, is pointed out.

Prof. PERRY said it would seem possible to obtain energy from an alternator without exciting the magnets independently, the field being altogether due to the armature currents.

Mr. SWINBURNE remarked that this could be done by making the rotating magnets a star-shaped mass of iron.

Sir W. THOMSON thought Mr. Swinburne's estimate of the loss in the Deptford mains was rather high. He himself had calculated the power spent in charging them, and found it to be about 16 horse power, and although a considerable fraction might be lost, it would not amount to nine-sixteenths. He was surprised to hear that glass condensers heated, and inquired whether this heating was due to flashes passing between the foil and the glass.

Mr. A. P. TROTTER said Mr. Ferranti informed him that the capacity of his mains was about $\frac{1}{4}$ microfarad per mile, thus making $2\frac{1}{2}$ m.f.s. for the seven miles. The heaping up of the potential only took place when transformers were used, and not when the dynamos were connected direct. In the former case the increase of volts was proportional to the length of main used, and 8500 at Deptford gave 10,000 at London.

Mr. BLAKESLEY described a simple method of determining the loss of power in a condenser by the use of three electro-dynamometers, one of which has its coils separate. Of these coils one is put in the condenser circuit and the other in series with a non-inductive resistance, r , shunting the condenser. If a_2 be the reading of a dynamometer in the shunt circuit, and a_3 that of the divided dynamometer, the power lost is given by $r(Ca_3 - Ba_2)$, where B and C are the constants of the instruments on which a_2 and a_3 are the respective readings.

Prof. S. P. THOMPSON asked if Mr. Swinburne had found any dielectric which had no absorption. So far as he was aware pure quartz crystal was the only substance.

Prof. FORBES said Dr. Hopkinson had found a glass which showed none.

Sir W. THOMSON, referring to the same subject, said that many years ago he made some tests on glass bottles which showed no appreciable absorption. Sulphuric acid was used for the coatings, and he found them to be completely discharged by an instantaneous contact of two balls; the duration of contact would, according to some remarkable mathematical work done by Hertz in 1882, be about 0.0004 second, and even this short time sufficed to discharge them completely. On the other hand, Leyden jars with tinfoil coatings showed considerable absorption, and this he thought due to want of close contact between the foil and the glass. To test this he suggested that mercury coatings be tried.

Mr. KAPP considered the loss of power in condensers due to two causes: first, that due to the charge soaking in; and second, to imperfect elasticity of the dielectric. Speaking of the extraordinary rise of pressure on the Deptford mains, he said he had observed similar effects with other cables. In his experiments the sparking distance of a 14000 volt transformer was increased from $\frac{1}{4}$ of an inch to 1 inch by connecting the cables to its terminals. No difference was detected between the sparking distances at the two ends of the cable, nor was any rise of pressure observed when the cables were joined direct on the dynamo. In his opinion the rise was due to some kind of resonance, and would be a maximum for some particular frequency.

Mr. MORDEY mentioned a peculiar phenomenon ob-

served in the manufacture of his alternators. Each coil was tested to double the pressure of the complete dynamo, but when they were all fitted together their insulation broke down at the same volts. The difficulty had been overcome by making the separate coils to stand much higher pressures.

Prof. RÜCKER called attention to the fact that dielectrics alter in volume under electric stress, and said that if the material was imperfectly elastic, some loss would result.

The PRESIDENT said that as some doubt existed as to what Mr. Ferranti had actually observed, he would illustrate the arrangements by a diagram.

Explanation of Diagram:— T_1 and T_2 are large transformers; t_1 and t_2 are small transformers for voltmeters V_1 and V_2 ; the numbers 1, 4, 1, 25, represent their conversion ratios.

Speaking of condensers he said he had recently tried plates in water to get large capacities, but so far had not been successful.

Mr. SWINBURNE, in replying, said he had not made a perfect condenser yet, for although he had some which did not heat much, they made a great noise. He did not see how the rise of pressure observed by Mr. Ferranti and Mr. Kapp could be due to resonance. Mr. Kapp's experiment was not conclusive, for the length of spark is not an accurate measure of electromotive force. As regards Mr. Mordey's observation, he thought the action explicable on the theory of the leading condenser current acting on the field magnets. The same explanation is also applicable to the Deptford case, for when the dynamo is direct on, the condenser current is about 10 amperes, and this exerts only a small influence on the strongly magnetised magnets. When transformers are used the field magnets are weak, whilst the condenser current rises to 40 amperes.

Mr. Blakesley's method of determining losses was, he said, inapplicable, except where the currents were sine functions of the time, and consequently could not be used to determine loss due to hysteresis in iron, or in a transparent dielectric.

Mr. Swinburne's "Note on Electrolysis" was postponed till next meeting.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxi., No. 23, December 8, 1890.

On Allyl Fluoride.—H. Meslans.—The author pours drop by drop allyl iodide upon dry silver fluoride contained in a small copper flask fitted with an ascending

condenser. The flask is kept in water at 35° , and the worm is cooled to 2° or 3° . The gas traverses a tube of silver fluoride, heated to 60° , which arrests allyl iodide, and is collected over mercury. Allyl fluoride is a colourless gas with an odour of garlic and a burning taste. It is easily ignited and burns with a smoky flame, giving off vapours of hydrofluoric acid. If cooled to 1° it is liquefied at a pressure of 760 m.m. Water dissolves 24 vols. of this gas at 15° , alcohol dissolves 60 vols., and ether 100 vols. Its specific gravity taken at 16° is in the mean 2.11, theory requiring 2.10. Its composition is C_3H_5F .

On some Endothermic and Exothermic Reactions of the Organic Alkalies.—Albert Colson.—The author compares diisobutylamine with the alkaline earths. The formation of a molecule of barium oxalate evolves 5.6 cal.; that of a molecule of diisobutylamine oxalate 6.5 cal.

On Certain Derivatives of Dimethylaniline.—Chas. Lauth.—Dimethylaniline if submitted to the action of various oxidising agents forms Paris violet. If lead peroxide is used as the oxidising agent the product is tetramethylbenzidine, $C_{16}H_{20}N_2$. The nucleus, C_6H_5 , is attacked, whilst in the formation of Paris violet the group CH_3 is oxidised and yields the methanic carbon necessary for the development of this colouring matter.

Series 3, Vol. iv., No. 8.

Bleaching Bees'-Wax and Composition of White Wax.—A. and P. Buisine.—Wax is most frequently bleached by simple exposure in thin shavings to air and light, especially to the direct rays of the sun. In the dark it is not decolorised even in a current of strongly ozonised oxygen. In air-bleaching pure yellow waxes lose only from 1 to 2 per cent of their weight; the melting-point remains sensibly the same; there are formed mere traces of acids soluble in water; the free and combined acids remain within the limits fixed for yellow waxes. The quantity of carbides is decreased, and the "iodine figure" is lowered about by one half. In practice from 3 to 5 per cent of tallow is always added to yellow wax before bleaching. The chief reason for this addition is that pure air-bleached wax is too brittle. With the addition of tallow the bleaching is more rapid, and the furnished product is whiter. The oleic acid contained in the tallow assists in the combustion of the colouring matters. Oil of turpentine added in small quantity acts in the same manner as tallow. Wax may also be bleached by being kept in fusion in presence of animal charcoal, which retains all the colouring. On filtration the wax is obtained quite colourless. Certain oxidising agents, such as permanganates and dichromates in acid solutions and oxygenated water, give good results. Reducing agents, such as sulphurous acid, sulphites, hydrosulphites, &c., do not act upon the colouring matter of waxes. Chlorine removes the colour, but it is absorbed in equivalent proportions; the constitution of the wax is profoundly modified so as to render it unfit for use. The iodine figure of a pure yellow wax having been found 11.23 became after bleaching with animal charcoal 11.36; on bleaching with permanganate 5.80, and after treatment with dichromate 7.94 and in another sample 1.08.

On the Constitution of Benzo-pinacolline.—MM. Maurice Delacre.—The author contests the formula ascribed to this compound by Butlerow.

On a Characteristic Reaction of Cocaine.—A. J. Ferreira da Silva.—The author, after pointing out the objections to the physiological tests for cocaine, and the absence of a characteristic colour reaction, shows that it may be identified by the production of a certain odour. A small portion of cocaine or of one of its salts in the solid state, or the residue from the evaporation of one of its solutions in the water-bath, is treated with a few drops of fuming nitric acid, specific gravity 1.4, evaporated to dryness in the water-bath, the residue treated with one or two drops of a strong alcoholic solution of potassium. On mixing well with a glass rod, there is perceived a distinct odour like that of peppermint. This reaction is not merely characteristic but very sensitive. The author has been able to detect by this means a demidecimilligramme of cocaine.

Equilibria and Reciprocal Displacements of the Volatile Alkalies.—M. Berthelot.—Chemical statics is governed by two principles: that of maximum work, which merely takes account of the internal energies of the systems, and determines the exothermic reactions, whilst the principle of dissociation causes an intervention of the external calorific energies, and determines the endothermic reaction. The concurrence of these principles permits us to explain all chemical phenomena, and especially the reciprocal actions of acids and bases in a state of solution. If the original bodies or products experience no dissociation, and if they are in conditions favourable for the reaction, the magnitude of the heats evolved alone determines the phenomena. But if certain of the initial bodies or products are capable of dissociation, account must be taken of its existence and degree. If we have, e.g., a dissolved salt partly dissociated into free acid and base, the whole forming a system in equilibrium. Let us add another base; whatever may be

its relative force it will necessarily tend to appropriate a function of the free acid resulting from the dissociation of the antagonistic salt. Hence the primitive equilibrium will be disturbed, and a new portion of the original salt will be dissociated, regenerating some portion of acid which will be taken up in its turn by the second base. If the salt of the second base is capable of being eliminated by insolubility or volatility, we come to the application of the laws of Berthollet. If, on the contrary, it is soluble and remains in presence of the original bodies without experiencing any dissociation, it will tend to produce itself to ally in the liquids, the base whose salt is dissociated being definitely displaced by the base which forms a salt which is not dissociated. According as the second base disengages more or less heat than the first, the complete reaction may be either endothermic or exothermic. In the two cases it is equally the necessary consequence of the play of dissociation conjointly with that of the principle of maximum work; the former decomposes the salt into acid and base, and the second combines the acid as it is set at liberty with the other base. The author applies these principles to piperidine, pyridine, and aniline.

The Determination of Nitrogen as Ammonia by Means of Soda-Lime.—M. Berthelot.—The author performs such determinations in an atmosphere of hydrogen kept in the state of a slow current. The gas is previously purified by means of solutions of alkalis and salts of copper. The objects gained are that the hydrogen expels atmospheric oxygen contained in the tubes (which might burn traces of ammonia), reduces traces of manganates present in the soda-lime, and carries off the ammonia as produced, thus avoiding the slow decomposition produced at high temperatures.

The Acetylene Condensed by the Effluve.—M. Berthelot.—Acetylene thus condensed yields a very oxidisable product, which absorbs in a few weeks more than the fourth of its weight of oxygen. This product presents then the aspect of yellowish pellicles, which deposit a carbonaceous matter. If submitted to dry distillation it is abruptly decomposed, leaving abundance of carbon and evolving a large quantity of water mixed with acetic acid and acetonic liquids. Hence the condensation effected by the effluve is quite different from that effected by heat, which towards 400° to 500° yields chiefly benzene, which does not occur in the products of the condensation by the effluve.

Simultaneous Recognition of the Haloid Salts, and Especially of Chlorides, in Presence of Bromides.—G. Denigès.—(See p. 314).

MEETINGS FOR THE WEEK.

SATURDAY, 27th.—Royal Institution, 3. "Frost and Fire" (adapted to a Juvenile Auditory), Prof. Dewar, M.A., F.R.S.
FRIDAY, Jan. 2nd.—Quekett Club, 8.
Geologists' Association, 8.

OLD PLATINUM

IN ANY FORM PURCHASED FOR CASH.

Highest prices allowed by
ROBERT PRINGLE & CO., Gold and Silver
Refiners, &c., 40 and 42, Clerkenwell Rd., E.C.,
Send for Price List.
Photographic Residues reduced and purchased.

Silicates of Soda and Potash in the state of Soluble Glass, or in CONCENTRATED SOLUTION of first quality, suited for the Manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Soap Works, Widnes, Lancashire.
London Agents, COSTE and Co., 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

INDEX.

- ABEL, F. A.**, address to the British Association, 111, 127 and B. Redwood, "Accidents with Mineral Oil Lamps" (review), 48

END OF VOLUME LXII.

THE CHEMICAL NEWS

AND JOURNAL OF PHYSICAL SCIENCE

Edited by
Wm. Crookes, F.R.S.]

(WITH WHICH IS INCORPORATED THE "CHEMICAL GAZETTE")

Established
Forty-Eight Years.

Vol. 62.—No. 1608.] Copyright reserved. Friday, September 19, 1890. Registered as a Newspaper. [PRICE, 4d. POST FREE, 4½d.]

STUDENT'S NUMBER.

CONTENTS.

ARTICLES:—	PAGE
Hints to Students	139
SCHOOLS OF CHEMISTRY:—	
University of London—University of Oxford—University of Cambridge—Trinity College, Dublin—King's College—University College—Normal School of Science and Royal School of Mines—University College of Wales, Aberystwith—University College, Bristol—Royal Agricultural College, Cirencester— Bradford Technical College—The Yorkshire College, Leeds— Mason Science College, Birmingham—University College, Liverpool—Liverpool College of Chemistry—&c.	139
The Detection of Traces of Iodine in the Presence of much Chlorine, by Alexander Johnstone, F.G.S.	153
CHEMICAL NOTICES FROM FOREIGN SOURCES	153

C. PASS AND SON, BRISTOL,

ARE BUYERS OF

LEAD ASHES, SULPHATE OF LEAD,
LEAD SLAGS, ANTIMONIAL LEAD,
COPPER MATTE, TIN ASHES, &c.,
and DROSS or ORES containing
TIN, COPPER, LEAD, AND ANTIMONY.

Chemist, thorough Analyst, with much experience in tropical produce generally, desires Engagement in India or Colonies.—Address, "India," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

TO CHEMISTS, PUBLIC ANALYSTS, AND MANUFACTURERS.

Required, an Appointment by Chemist experienced in Assaying, Analysis, and Food Adulterations. Accustomed to control of men. Moderate salary.—D. P., 49, Queen Victoria Street, E.C.

Wanted, a Situation as Manager or Assistant.

Manager by a Chemist, 30 years of age, with experience in the above capacity, and who has successfully conducted experiments and worked out new processes in the manufacture of different chemical products, and also in Electro-chemistry.—Applv. S. M. S., CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Wanted, by Young Gentleman (25), Situation

Abroad as Assayer, or Clerk and Assayer, with Gold or Silver Mining Company. Holds Science and Arts Certificates; experienced, highly recommended, best references.—Apply, C. S. J., CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Now ready, 12mo., 2s. 6d.

PRACTICAL ORGANIC CHEMISTRY:
the Detection and Properties of some of the more important Organic Compounds. By SAMUEL E. RIDEAL, D.Sc. (Lond.), F.I.C., F.C.S., Fellow of University College, London.

London: H. K. LEWIS, 136, Gower Street, W.C.

SULPHUROUS ACID,

Pure and Coml. Acetic, Sulphuric, Hydrochloric, and Nitric Acids, Sulphites, Acetates, Flowers, Roil and Rock Sulphur, &c.

JOHNSON AND HOOPER

(formerly Kindersley and Johnson).

"Crown Brand." Established 1865.

STRATFORD, LONDON.

JOHN J. GRIFFIN AND SONS (LIMITED).

MAKERS OF

CHEMICAL, PHILOSOPHICAL, AND PHOTOGRAPHIC APPARATUS.

22, GARRICK STREET, COVENT GARDEN, LONDON, W.C.

CHEMICAL APPARATUS of every description for Analytical Operations, Organic Analysis, Blowpipe Analysis, Volumetric Analysis, Assaying, Metallurgical Operations, &c.

Send for Illustrated List, free on application.

ATTFIELD'S CHEMISTRY: GENERAL, MEDICAL, AND PHARMACEUTICAL. A MANUAL OF CHEMISTRY FOR MEDICAL AND PHARMACEUTICAL STUDENTS.

By JOHN ATTFIELD, F.R.S., &c.,
Professor of Practical Chemistry to the Pharmaceutical Society of Great Britain; many years Demonstrator of Chemistry at St. Bartholomew's Hospital.

THIRTEENTH EDITION. PRICE 15s.

"For all the numerous class of students who are preparing for the medical or for the pharmaceutical profession, we know of no work in the language which can be compared with the one before us."—*Chemical News*.

GURNEY & JACKSON, 1, PATERNOSTER ROW.
(Mr. VAN VOORST'S SUCCESSORS).

SECOND EDITION, REVISED AND ENLARGED.

Extra Cloth, Red Edges. 910 pp., Demy 8vo. Price 18s.

HANDBOOK OF MODERN CHEMISTRY,
INORGANIC AND ORGANIC, for the Use of Students.
By CHARLES MEYMOTT TIDY, M.B., F.C.S., Professor of Chemistry and of Medical Jurisprudence and Public Health at the London Hospital; One of the Official Analysts to the Home Office; Medical Officer of Health for Islington; Late Deputy Medical Officer of Health and Public Analyst for the City of London; Master of Surgery; Examiner at the College of Physicians, &c., &c., &c.

"Its plan is practical rather than theoretical, and its greatest merit consists in the store of facts in all departments of chemistry with which its pages are filled. Few single volumes on the science are so valuable for practical guidance. It is a capital book for those who have but one book."—*Saturday Review*.

"The book contains an immense collection of facts, and is of a practical and really valuable kind."—*Lancet*.

"The work is written with a special view to the education of students of medicine, but may be read with advantage by all chemical students."—*British Medical Journal*.

"A truly admirable text-book."—*Spectator*.

"The whole of the 910 pages which go to form the book are absolutely bristling with information. . . . The work might almost be called a "Practical Dictionary of Chemistry."—*Journal of Gas Lighting*.

LONDON:

SMITH, ELDER, and CO., 15, WATERLOO PLACE.

CHEMIKER ZEITUNG.

(THE BEST GERMAN CHEMICAL PAPER).

Edited by DR. KRAUSE. Six Shillings Half-yearly, post free.

Specimen Numbers gratis from—

London Agents: MESSRS. LUZAC & CO., Opposite the British Museum.

IRON TUBES AND FITTINGS for Gas,
Water, Steam, Liquid Ammonia, and Hydraulic Work, galvanised white enamelled inside, or coated by Dr. Angus Smith's Composition, COILS for heating superheating, distilling, and refrigerating purposes, to 500 feet long without joints. Iron and brass cocks and valves.—JOHN SPENCER, GLOBE TUBE WORKS, WEDNESBURY, and 14, GREAT ST. THOMAS APOSTLE, CANNON ST., LONDON, E.C.

MESSRS. BELL'S PUBLICATIONS.

THE CHEMISTRY OF THE COAL-TAR COLOURS. Translated from the German of DR. R. BENEDIKT, and Edited, with Additions, by E. KNECHT, Ph.D., Head Master of the Dyeing Department of the Technical College, Bradford. Second Edition, Revised and Enlarged, 6s. 6d.

"The volume contains, in a little space, a vast amount of most useful information, classified in such a manner as to show clearly and distinctly the chief characteristics of each colouring-matter, and the relationship existing between one series of compounds and another."
—*Journal of the Society of Dyers and Colourists.*

DYEING AND TISSUE-PRINTING. By W. CROOKES, F.R.S. 5s.

"Whether viewed in connection with the examination-room or the dye-house, the volume is one which deserves a word of welcome."
—*Academy.*

EXPERIMENTAL CHEMISTRY. Founded on the work of Dr. J. A. STOCKHARDT. A handbook for the Study of the Science by Simple Experiments. By C. W. HEATON, F.I.C., F.C.S., Lecturer in Chemistry in the Medical School of Charing Cross Hospital, Examiner in Chemistry to the Royal College of Physicians, &c. New Revised Edition, 5s.

THE ALKALI-MAKERS' POCKET-BOOK. Tables and Analytical Methods for Manufacturers of Sulphuric Acid, Nitric Acid, Soda, Potash, and Ammonia. By GEORGE LUNGE, Ph.D., Professor of Technical Chemistry, Zurich; and FERDINAND HURTER, Ph.D. Crown 8vo., price 7s. 6d.

CONTENTS.—General Tables.—Atomic Weights, Equivalent Weights, and Valency of Elements.—Symbols, Molecular and equivalent Weights and Percentage.—Composition of Chemical Compounds.—Factors for Calculating Gravimetric Analyses.—Solubility of Salts.—Solubility of Gases.—Specific Gravities of Solids, Liquids, Gases, and Vapours.—Specific Gravity and Percentage of Saturated Solutions.—Weight of Substances as Stored.—Linear Expansion of Substances by Heat.—Comparison of different Thermometric Scales.—Fusing and Boiling Points.—Reduction of the Volume of Gases to the Normal Temperature and Pressure.—Volumes of Water at different Temperatures.—Reduction of Water Pressure to Mercurial Pressure.—Tensions of Aqueous Vapour at different Temperatures.—Variations of Boiling-point of Water for different Pressures.—Specific Heats.—Circumference and Area of Circles, Squares, Cubes, Square and Cube Roots.—Formulas for Mensuration of Areas and Solid Contents.—Weights, Measures and Coinages of different Countries. *Special Part.*—Fuel and Furnaces.—Sulphuric Acid Manufacture.—Salt-cake and Hydrochloric Acid.—Bleaching Powder and Chlorate of Potash Manufacture.—Soda Ash Manufacture.—Sulphur Recovery.—Nitric Acid Manufacture.—Potash Manufacture.—Ammonia Manufacture.—Preparation of Standard Solutions.—Rules for Sampling.—Comparison of the Hydrometer Degrees with the Specific Gravities.—Value of Alkali per ton.

"It is a work which must of necessity find a place on the shelves of every chemist dealing with the subject."
—*The Analyst.*
"We have no hesitation in saying that this pocket-book will prove a treasure for owners, managers, works' chemists, &c., and will prevent a great many unedifying disputes."
—*The Chemical Review.*

LONDON: GEORGE BELL AND SONS,
YORK STREET, COVENT GARDEN.

THE CHEMICAL ANALYSIS OF IRON.

A Complete Account of all the Best Known Methods for the Analysis of Iron, Steel, Pig-iron, Iron-ore, Lime, Slag, Clay, Sand, Coal, Coke, and Furnace and Producer Gases. By ANDREW ALEXANDER BLAIR, Chief Chemist, United States Geological Survey, 1880. Small Royal 8vo., Price 14s.

LONDON: WHITTAKER AND CO.,
PATERNOSTER SQUARE.

IMPORTANT WORK ON ECONOMIC BOTANY.

In crown 8vo., cloth gilt, price 6s., post free.

THE USES OF PLANTS.
A MANUAL OF ECONOMIC BOTANY.

With Special References to Vegetable Products Introduced during the last Fifty years.

By G. S. BOULGER, F.L.S., F.G.S., Professor of Botany at the City of London College, Author of "Familiar Trees," &c.

This work aims at giving a concise enumeration, with a systematic Index, of the Vegetable Substances in use in England as Food, Materia Medica, Oils, Gums, Rubbers, Dyeing, Tanning, and Paper-making Materials, Fibres, Timbers, &c., both home-grown and imported, together with Short Essays on the recent progress of Vegetable Technology in its various branches.

A FEW EXTRACTS FROM PRESS NOTICES.

"It must not be supposed that this book is of interest merely to botanists. For manufacturers on the look-out for raw materials it will prove a valuable handy book of reference."
—*Chemical News.*
"Might with advantage be widely circulated amongst owners of land. . . . Great deal of information."
—*English Mechanic.*
"For compactness, accuracy, and usefulness we know of none to equal Prof. Boulger's Manual. We cordially recommend this work."
—*Science Gossip.*

"Prof. G. S. Boulger is a writer known to all students of forestry and kindred subjects, and, though many excellent contributions have come from his able pen, we do not think he has made the public acquainted with a more useful, and what will prove a more popular, book. . . . Will, without doubt, take a position as a standard work. . . . Mass of information, admirable sequence. . . . Well up to date."
—*Timber Trades Journal.*

"So much instruction has hardly ever before been crowded into a volume of equal size, and it must prove a valuable book alike for students and general readers."
—*Daily Chronicle.*

"Very useful manual of economic botany, founded on and directed by thorough scientific knowledge."
—*Scotsman.*

"Mass of carefully digested material. . . . Handy, well printed, and in every way commendable."
—*Wesley Naturalist.*

"Amount of information . . . is prodigious. We can confidently recommend this very useful book to all whom it may concern, teachers included."
—*Schoolmaster.*

"One of the best works we have seen for compactness and fulness of information."
—*Brit. and Col. Printer.*

DEPARTMENT OF SCIENCE AND ART.

ROYAL COLLEGE OF SCIENCE,
STEPHEN'S GREEN, DUBLIN.

SESSION, 1890-91.

The Royal College of Science supplies courses of instruction in the Sciences applicable to the Industrial Arts, especially those which may be classed broadly under the heads **CHEMICAL MANUFACTURES, ENGINEERING, and MINING.**

A Diploma of Associate of the College is granted at the end of the Three Years Course, the required conditions being complied with.

Four Royal Scholarships, of the value of £50 yearly each, with free admission to the Lectures and Laboratories, are attached to the College. Two are offered for competition each year to associate students not being Royal Exhibitors, on the completion of their first year's course.

The Fees payable by Non-Associate Students are—£2 for each separate Course of Lectures, £1 for half course of Experimental Physics, or £10 for all the Lecture Courses of a Faculty, for the Session.

FOR ANALYTICAL CHEMISTRY—£2 for a special course of one month, £5 for three months, £9 for six months, £12 for the entire Session.

FOR PHYSICAL LABORATORY—£1 per month (one hour a day); £2 for a special course of one month; £3 per month for six hours a day; or £6 for the Session (one hour per day).

FOR ASSAYING—£5 for three months, £9 for six months, £12 for the entire Session.

FOR ZOOLOGICAL LABORATORY—£2 for a Special Course of one month; £3 for 1st Medical or 2nd Arts Course, Royal University of Ireland; or £5 for a Special Course of three months.

FOR BOTANICAL LABORATORY—Same as Zoological Laboratory.

FOR DRAWING SCHOOL—£3 for the Session, £2 for one Term.

The Chemical and Physical Laboratories and the Drawing Schools are Open Daily for Practical Instruction.

Mathematics, Mechanics, and Mechanism	Professor H. Hennessy, F.R.S.
Descriptive Geometry, Drawing, Engineering, and Surveying	Professor Thomas F. Pigot, C.E., M.R.I.A. (Dean of Faculty for the Session).
Chemistry, Theoretical and Practical; and Metallurgy ..	Professor W. N. Hartley, F.R.S., F.C.S., F.R.S.E.
Physics, Theoretical and Practical	Professor W. T. Barrett, F.R.S.E., M.R.I.A.
Geology	
Mining and Mineralogy .. .	Professor J. P. O'Reilly, C.E., M.R.I.A.
Botany	Professor T. Johnson, B.Sc., F.L.S.
Zoology	Professor A. C. Haddon, M.A., F.Z.S., M.R.I.A.

The Courses of Chemistry, Physics, Botany, and Zoology are recognised by the Royal University of Ireland, and Certificates of Attendance are granted to medical and other students attending the Courses, and the Chemical, Practical, Botanical, and Zoological Laboratories.

Programmes may be obtained on application at the College, or by letter addressed to the Secretary, Royal College of Science, Stephen's Green, Dublin.

The first Term of the Session will commence on Monday, the 6th October, 1890.

NOTE.—Intending Associate Students will be required to pass an Entrance Examination in Elementary Mathematics and Elementary Practical Geometry, as indicated on page 5 of Programme, copies of which may had, on application, from the Secretary.

PROFESSOR J. P. O'REILLY, Secretary.

OWEN'S COLLEGE, VICTORIA UNIVERSITY, MANCHESTER.

CHEMISTRY COURSE.

Full particulars of this Course, qualifying for the Victoria University Degrees in Chemistry and the College Certificate in Applied Chemistry, will be forwarded on application.

The Session begins October 7.

H. W. HOLDER, M.A., Registrar.

QUEEN'S COLLEGE FOR LADIES,
HARLEY STREET, W.

CHEMISTRY.—Elementary and Advanced

Classes are held by H. FORSTER MORLEY, M.A. D.Sc. The Classes cover the ground of the various Public Examinations. Practical Instruction is also given in the Laboratory in all branches of the science, including Analysis, Original Research, and the Methods of Teaching Chemistry. The Fellowship of the College is open to Students of Chemistry.

For further particulars apply to the Lady Resident, 43, Harley Street, W.

GUY'S HOSPITAL MEDICAL SCHOOL.

The Winter Session commences on Wednesday, October 1st.

The Hospital contains 695 beds, of which 500 are in constant occupation. Special Classes are held for Students preparing for the Examinations of the University of London, and other Higher Examinations.

APPOINTMENTS.—All Hospital Appointments are made strictly in accordance with the merits of the Candidates, and without extra payment.

ENTRANCE SCHOLARSHIPS in September, 1890.—Two Open Scholarships in Arts, one of the value of 100 guineas open to Candidates under 20 years of age; and one of 50 guineas open to Candidates under 25 years of age. Two Open Scholarships in Science, one of the value of 125 guineas, and another of 50 guineas, open to candidates under 25 years of age.

PRIZES are awarded to Students in their various years, amounting in the aggregate to more than £300.

DENTALSCHOOL.—A Dental School is attached to the Hospital, which affords to students all the instruction required for a Licence in Dental Surgery.

COLLEGE.—The Residential College accommodates about 50 Students in addition to the Resident Staff of the Hospital. It contains a large Dining Hall and Reading Rooms for the use of the Students' Club.

For Prospectus and further information apply to the Dean, Dr PERRY, Guy's Hospital, London, S.E.

THE LONDON HOSPITAL MEDICAL COLLEGE.

The WINTER SESSION will commence on Wednesday, October 1st.

The Hospital, which is the largest general hospital in the kingdom, contains nearly 800 beds, all in constant use. There are wards for accidents, surgical and medical cases, diseases of women and children, and ophthalmic cases. Special departments for diseases of the eye, ear, throat, skin and teeth, and for cancer, tumours, diseases of the bladder, piles and fistula. Number of in-patients last year, 9105; out-patients, 109,839; accidents, 11,400.

Surgical operations daily.

APPOINTMENTS.—Resident accoucheur, house physicians, house surgeons, &c. Forty of these appointments are made annually. Numerous dressers, clinical clerks, post-mortem clerks, and maternity assistants are appointed every three months. All appointments are free. Holders of resident appointments are also provided free board.

Two Entrance Science Scholarships, value £75 and £50, and two Buxton Scholarships, value £30 and £20, will be offered for competition at the end of September to new Students. Sixteen other Scholarships and prizes are given annually.

The London Hospital is now in direct communication with all parts of the metropolis. The Metropolitan District, and other railways have stations within a minute's walk of the Hospital and College.

For further information apply, personally or by letter, to—
MUNRO SCOTT, Warden

Midle End, E.

Founded 1668.] "SYSTEMA OMNIA VINCIT." [Incorporated 1887.

SOUTH LONDON SCHOOL OF PHARMACY, LIM.,
325, KENNINGTON ROAD, S.E.

LECTURERS:

Chemistry, Physics, and Botany.
Dr. MUTER, F.R.S.E., F.I.C., F.C.S.

Materia Medica and Pharmacy.
Mr. DODD, F.C.S.

Analytical Chemistry.
Mr. DE KONINGH, F.I.C., F.C.S.

Classics, and Mathematics and Mechanics.
Mr. TOWNSEND, A.C.P., and Lond. Mat.

Assisted by an Efficient Staff of Demonstrators.

The Fees at this School are absolutely inclusive, and there are no extras of any kind. The Board of Directors spare no expense in rendering the education thoroughly efficient and in maintaining the very high percentage of success uniformly obtained by the Students for the last twenty-two years. The Dispensing Department is most commodious and perfect, and no extra charge is made for its use.

A new Technical Laboratory for practical instruction in Manufacturing Chemistry is now added to the premises.

The School being usually full, intending Students should secure their places beforehand. Entries are now being made for January 12th, 1891.

For Fees, &c., apply by letter addressed to the Secretary.

INSTITUTE OF CHEMICAL TECHNOLOGYAND
ANALYTICAL LABORATORY,
5, 8, 9, and 11, HACKINS HEY, LIVERPOOL.

Conducted by A. NORMAN TATE, F.I.C., F.C.S., &c.

Students can enter at any time, there being no special terms kept. Each Student is required to work, under careful supervision, through a lengthy preparatory Course of Practical Chemistry, and also study Theoretical Chemistry, Physics, and other subjects, a knowledge of which is required in making chemistry practically useful in technical pursuits. After concluding this Course he can work at special subjects of Chemical Technology.

For further particulars apply to Mr. NORMAN TATE, 9, Hackins Hey, Liverpool.

LONDON: HENRY FROWDE,

CLARENDON PRESS WAREHOUSE, AMEN CORNER, E.C.

IN THREE VOLUMES, PRICE £2 2s. EACH. VOL. I. NOW READY.

A DICTIONARY OF APPLIED CHEMISTRY.

By T. E. THORPE, B.Sc. (Vict.), Ph.D., F.R.S., Treas. C.S.,
Professor of Chemistry in the Normal School of Science and Royal School of Mines, South Kensington.

ASSISTED BY EMINENT CONTRIBUTORS.

Chemical News.—"Will be universally appreciated by technical and manufacturing chemists."
Journal of Society of Chemical Industry.—"The list of the names of contributors and the selection of their subjects inspires confidence at once."

Chemical Trade Journal.—"We are much pleased with the work. . . . Descriptions of processes are brought down to as recent a date as it is well-nigh possible to achieve. . . . Will form a handy book of reference for years to come."

SIR H. E. ROSCOE in *Nature*.—"It is probable that this volume will have even a larger sale than that of the corresponding 'Dictionary of Pure Chemistry,' and, as with that important work, so with this, the public may well be congratulated on possessing such a valuable book of reference so creditable to all concerned in its production. . . . An examination of the important articles written by specially-qualified contributors indicates that each subject is brought up to the level of the present state of our knowledge. . . . Is a welcome addition to our scientific books of reference, and forms an admirable companion to 'Watts' Dictionary of Theoretical Chemistry.'"

LONDON: LONGMANS, GREEN, & CO.

NEW EDITION OF WATTS' CHEMISTRY.

WATTS' DICTIONARY OF CHEMISTRY.

COIGNET & CO.,

150, FENCHURCH STREET, LONDON, E.C.

Works: St. Denis, Paris, and Heyrieux and Barabon, Lyons.

E. BOEHM AND CO.,

EXPERIMENTAL CHEMICAL AND SCIENTIFIC GLASS-BLOWERS,

53, Red Lion Street, Clerkenwell,

and 42 & 43, Little Britain, E.C.

Chemists and Druggists supplied with all kinds of Chemical Glass Goods. Schools, &c., supplied with Experimental Glass Work and Electrical Goods. Vacuum Experiments of every description carried out.

DOULTON & WATTS

HIGH STREET, LAMBETH, LONDON, S.E.

MANUFACTURERS OF

STILLS, RETORTS, CONDENSING WORMS, WOLFF'S BOTTLES
ACID PUMPS, COCKS, PERCOLATORS, AIR-TIGHT JARS.

And every description of Stoneware for Chemical Purposes,
warranted to resist the strongest acids.

PLUMBAGO CRUCIBLES AND OTHER
FIRE STANDING GOODS.

DOULTONS'
MANGANOUS

(NEW PATENT.)

CARBON
FILTER.

ADVANTAGES:—

MANGANOUS CARBON possesses very high FILTERING POWER.

NO water can remain in reservoir to become stagnant. An entire absence of corrodible material. Can be readily taken to pieces for cleansing.

SHOW ROOMS, ALBERT EMBANKMENT, LAMBETH, S.E.

Depots:—Grenville St., Birmingham; 100, Soho St., Liverpool; and 6, Rue de Paradis, Paris.

JAMES WOOLLEY, SONS, & CO.,

69, MARKET STREET, MANCHESTER.

Chemical Apparatus and Scientific Instruments,
Pure Chemicals, &c.

Price Lists on application.

Water-Glass, or Soluble Silicates of Soda
and Potash, in large or small quantities, and either solid
or in solution, at ROBERT RUMNEY'S, Ardwick Chemical
Works, Manchester.

J. S. MERRY AND CO.,
ASSAYERS AND ANALYTICAL CHEMISTS,
SWANSEA.

Silicates of Soda and Potash in the state of
Soluble Glass, or in CONCENTRATED SOLUTION of first
quality, suited for the Manufacture of Soap and other purposes,
supplied on best terms by W. GOSSAGE and Sons, Soap
Works, Widnes, Lancashire.

London Agents, COSTE and Co., 19 and 20, Water Lane, Tower
Street, E.C. who hold stock ready for delivery.

THE PETROLEUM ASSOCIATION,
85, GRACECHURCH STREET, E.C.

Secretary and Chemist—

WILLIAM FOX, F.I.C.

Established H. K. LEWIS, [1844.
BOOKSELLER, PUBLISHER, AND EXPORTER,
136, GOWER STREET, LONDON, W.C.

Supplies books in every department of literature, Chemical and Sci-
entific, included, at a discount of 25 per cent for cash payment.
Large stock of second-hand books at reduced prices. Book Clubs,
Colleges, Libraries, &c., in all parts of the world, supplied with
English and foreign literature, periodicals, publications, &c., &c.
Cases and parcels of books, &c., packed and forwarded by best routes.
Attention is given to the prompt and careful execution of miscella-
neous orders for export of every description. Surgical instruments,
microscopes, philosophical instruments, &c., supplied at maker's prices.

CHEMICAL NOTES. By Dr. HODGKINSON.

Adapted for the Use of Students attending Lectures in
Science Schools, &c.

- I. NOTES ON CHEMISTRY.—These Notes describe the
Non-Metallic Elements and their Chief Compounds and
Reactions, and give a Short Outline of the Principal
Theories. PRICE, TWO SHILLINGS.
- II. EXERCISES IN PRACTICAL CHEMISTRY.—Qualita-
tive Analysis. PRICE, TWO SHILLINGS.
- III. METALS.—An Outline of the Metallurgical Processes.
PRICE, TWO SHILLINGS.

London: GEORGE KENNING, 16, Great Queen Street, W.C.

TEXT-BOOKS on CHEMISTRY

ADAPTED FOR THE
South Kensington, the Pharmaceutical Society's, and
the London University Examinations.

INORGANIC CHEMISTRY. By Professor
T. E. THORPE, Ph.D., F.R.S.E., Yorkshire College of Science,
and Examiner to the University of London. With numerous
illustrations, copious index, and examination questions. Vol. I.,
Non-Metals, 3s.; Vol. II., Metals, 3s.

INORGANIC CHEMISTRY, Twenty Lessons
in. By WM. VALENTIN, F.C.S., Royal College of Chemistry.
With illustrations. Post 8vo., cloth, with index, 2s.

INORGANIC CHEMISTRY. By Dr. W. B.
KEMSHEAD, F.R.A.S., Dulwich College. New Edition, revised
and extended. Post 8vo., illustrated, 2s.

PRACTICAL CHEMISTRY. By J. HOWARD,
F.C.S. New Edition, with Chapter on Chemical Analysis. Post
8v., illustrated, 1s. 6d.

QUALITATIVE CHEMICAL ANALYSIS.
By F. BEILSTEIN. Folschap 8vo., cloth 1s.

WM. COLLINS, SONS, and Co. (Limited).
Bridewell Place, London, E.C., and all Booksellers.

EMPTY CASKS.

Always on hand, a quantity of good strong
Drums, Puncheons, and Hogsheads, suitable for Chemicals.

C. R. HAIG, Cooper and Cask Merchant,
